Well-defined rigid stereochemistries may be obtained for all coordination numbers, however, in one of two ways. (i) With the exception of the tetrahedron and octahedron, most polyhedra have different types of vertex, and for complexes of the type [M(unidentate A)$_x$(unidentate B)$_y$] the sorting of the different ligands into the appropriate polyhedral vertices may stabilize a preferred structure. In general, it is found that charged ligands such as halide, and more particularly the more highly charged oxide, sulfide, and nitride, occupy the sterically less crowded vertices, in contrast to uncharged ligands which occupy the remaining sites. It is also found that for complexes of the lighter elements of lower coordination numbers that contain stereochemically active nonbonding pairs of electrons, these lone pairs also occupy the sterically less hindered sites. (ii) Complexes containing chelate groups may also have rigid stereochemistries. For bidentate ligands it is useful to define the geometry of the chelate ring in terms of a 'normalized bite' b, defined as the distance between the donor atoms divided by the metal–ligand distance.

2 FIVE-COORDINATE COMPOUNDS

The starting point for five-coordination is to consider the trigonal bipyramid and the square pyramid and the relation between them.[1,2,6] A twofold axis passes through the metal atom M and the donor atom E, the other four atoms lying on a pair of vertical mirror planes (see Figure 1). The angles between this axis and the metal–ligand bonds to the pairs of atoms AC and BD are defined by ϕ_A and ϕ_B, respectively. Neither the square pyramid nor the trigonal bipyramid is the same as those defined in classical geometry, which have equal edge lengths. The square pyramid with equal edge lengths is half an octahedron with $\phi_A = \phi_B = 90.0°$, but in real molecules the more open space created by the square face relative to the triangular faces is partially closed by increasing ϕ_A and ϕ_B to $\sim 100°$. This results in the basal sites becoming more sterically hindered than the axial site. The regular trigonal bipyramid formed from equilateral triangles would have the metal–ligand bond lengths in the triangular plane approximately 30% shorter than the metal–axial ligand bonds. The triangular plane therefore expands, making all bond lengths more nearly equal, with the consequence that the equatorial sites are less sterically crowded with only two close neighbors, compared with three for the axial sites.

There is no potential energy barrier between the square pyramid at $\phi_A = \phi_B \approx 100°$ and the two slightly more stable trigonal bipyramids at $\phi_A = 90$, $\phi_B = 120°$ and $\phi_A = 120$, $\phi_B = 90°$. Movement along this 'reaction coordinate' connecting the two trigonal bipyramids is usually described as *Berry Pseudorotation*.[7] Any one of the three equatorial site of the trigonal bipyramid can become the apical site of a square pyramid and so repetition of this process scrambles all atom sites.

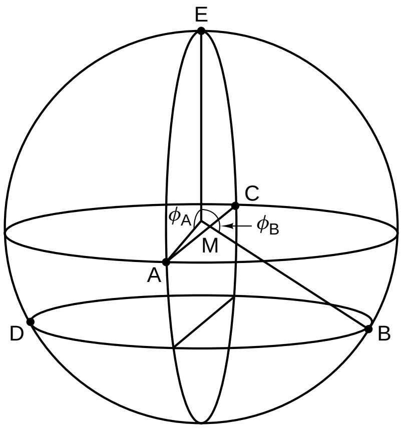

Figure 1 General stereochemistry for [M(unidentate)$_5$]

Structurally characterized molecules with five identical ligands cover the complete range from the pure trigonal bipyramid ($\phi_A = 90$, $\phi_B = 120°$) to the pure square pyramid ($\phi_A = \phi_B \approx 100°$), some simple examples being shown in Table 2. Whether a compound is near the trigonal bipyramid or near the square pyramid may often be attributed to crystal-packing forces. For example, the structure of $SbPh_5$ is near the square pyramid whereas the solvate $SbPh_5{\cdot}0.5C_6H_{12}$ is near the trigonal bipyramid. In molecules near the trigonal bipyramidal end of the range the axial bonds are about 5% longer than the equatorial bonds, whereas for molecules near the square pyramid the axial bond is about 4% shorter than the four basal bonds.

Many five-coordinate molecules exhibit very rapid intramolecular rearrangements, leading to all five ligands being equivalent over the NMR timescale.[1,2,5] For example, the ^{19}F NMR spectrum of PF_5 shows all fluorine atoms equivalent over the temperature range 60 to −197 °C. Proton NMR studies on $SbMe_5$ in carbon disulfide down to about −100 °C also show the presence of only one type of methyl group. The ^{13}C NMR spectra of [Fe(CO)$_5$] and [Fe(CNBu)$_5$]

show only a single resonance at temperatures as low as −170 and −80 °C, respectively. Both the ^{19}F NMR and ^{31}P NMR studies of [Fe(PF_3)$_5$], [Ru(PF_3)$_5$], and [Os(PF_3)$_5$] down to −160 °C in $CHClF_2$ show all ligands are equivalent.

When there is a mixture of different types of ligand, a more well-defined structure is usually observed. In general, charged ligands such as halides require more space about the central atom than do uncharged ligands and occupy the less sterically hindered axial site of a square pyramid or the trigonal planar sites of a trigonal bipyramid, examples being shown in Table 3. The dominant stereochemistry for monooxo complexes is the axially substituted square pyramid, examples including [$ReOCl_4$] and [$MOCl_4$]$^-$ (M = Cr, Mo, W) as well as the nitrido complexes [$MNCl_4$]$^-$ (M = Mo, Tc, Re, Ru, Os).[1]

For compounds containing a lone pair, this occupies one of the three trigonal sites of a trigonal bipyramid,[2] as in Rb[Bi(**:**)(SCN)$_4$] and [Te(**:**)Ph_4]. The trifluoro complexes ClF_3 and XeF_3^+ are T-shaped but can be considered as trigonal bipyramidal if the two nonbonding lone pairs are considered.[2] Likewise, linear trihalide ions such as I_3^- can be regarded as trigonal bipyramidal with three nonbonding pairs of electrons in the three equatorial sites.[2]

The edge lengths for a trigonal bipyramid, square pyramid, and intermediate structures vary from 1.73r for the edges linking the equatorial sites of a trigonal bipyramid to 1.39r for the edges linking the basal sites of a square pyramid, where r is the metal–ligand distance. The introduction of chelating ligands of fixed normalized bite influences the structure obtained, the simplest examples being of the type [M(bidentate)$_2$(unidentate)]. Complexes with bidentate ligands of small bite, as in [Fe(S_2CNR_2)$_2$X] ($b = 1.24$)[9] are close to square pyramidal, whereas complexes with a larger bite, for example [P($O_2C_6H_4$)$_2$X] ($b \approx 1.42$)[1] have stereochemistries intermediate between a square pyramid and

a trigonal bipyramid (X = halide, alkyl, etc.). Superimposed on this effect of normalized bite upon stereochemistry is that due to the unidentate ligand necessarily being different to the bidentate ligands. Thus complexes containing O^{2-} as the unidentate ligand have structures close to square pyramids at all values of the normalized bite, as in [V(MeCOCHCOMe)$_2$O] ($b = 1.38$)[10] and [V(S_2CNEt$_2$)$_2$O] ($b = 1.21$).[11] A number of compounds of the p-block elements containing two bidentate ligands can be considered as trigonal bipyramidal if a nonbonding pair of electrons occupies an equatorial site, as in [Pb(RCOCHCOR)$_2$(**:**)] and [Sn(S_2CNR$_2$)$_2$(**:**)].[1]

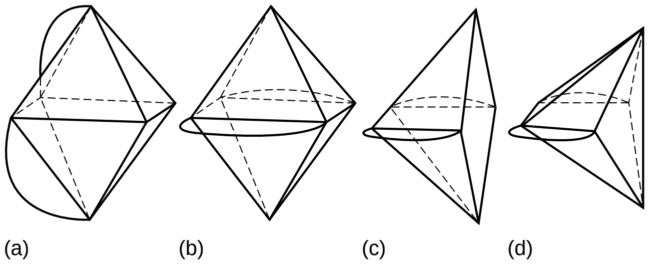

Figure 2 Stereochemistries of [M(bidentate)$_2$(unidentate)$_2$]: (a) *cis* octahedral; (b) *trans* octahedral; (c), (d) skew-trapezoidal bipyramidal

3 SIX-COORDINATE COMPOUNDS[1,2,12]

3.1 [M(unidentate)$_6$]

The octahedron is the dominant stereochemistry for complexes containing six unidentate ligands. For complexes containing two ligands different from the other four, the rigid nature of the octahedron is illustrated by the ability to separate both *cis* and *trans* isomers. When one pair of ligands is grossly different to the other four, the *trans* structure is more stable. An important example is the dioxo complexes as in the uranyl complexes [UO$_2$X$_4$]$^{2-}$.[2] Other examples of *trans*-dioxo complexes are [ReO$_2$py$_4$]$^+$, [ReO$_2$(CN)$_4$]$^{3-}$, and [MoO$_2$(CN)$_4$]$^{4-}$.[2] However, complexes containing two different unidentate ligands in addition to O^{2-} may be either *cis* or *trans*.

Compounds containing two nonbonding pairs of electrons and four unidentate ligands are invariably observed to be square planar, as in [Te^{II}(ligand)$_4$(**:**)$_2$]$^{2+}$, [I^{III}Cl$_4$(**:**)$_2$]$^-$, and [Xe^{IV}F$_4$(**:**)$_2$].[2]

A second-order Jahn–Teller effect leads to a trigonal prismatic structure being preferred for some d^0 ML$_6$ species, such as WMe$_6$. This illustrates the role of electronic effects in determining coordination geometry.

3.2 [M(bidentate)$_2$(unidentate)$_2$]

Complexes containing two bidentate and two unidentate ligands may be either *cis* or *trans* octahedral, but it is important to note that both structures show very large distortions as the size of the chelate rings is reduced; the *trans* structure turns into the skew-trapezoidal bipyramidal structure (Figure 2).

For a normalized bite of $b = 2^{1/2}$, the *cis* and *trans* structures have the same energy, but as the normalized bite is reduced the *cis* structure becomes more stable. A survey[1] of all structurally characterized compounds showed that for $b > \sim1.3$ there were an approximately equal number of *cis* and *trans* structures, but for four-membered chelate rings with $b < \sim1.2$ there was a strong preference for the *cis* structure.

Reduction in size of the chelate rings in *cis*-[M(bidentate)$_2$(unidentate)$_2$], as in [Mo(S_2CNEt$_2$)$_2$O$_2$],[13] is accompanied by a substantial rotation of the bidentate ligands about the twofold axis of the molecule, relative to the MoO$_2$ plane: $\theta_A = 15°$, $\theta_B = -60°$ (Figure 3). At the same time the bonding of the bidentate ligand becomes significantly unsymmetrical with the metal ligand bond *cis* to both unidentate ligands becoming shorter than the metal–sulfur bond to the other end of the bidentate ligand: (M–A)/(M–B) = 0.93.

The *trans* structure of [M(bidentate)$_2$(unidentate)$_2$] with five- or six-membered chelate rings and relatively large normalized bites ($b \approx 1.2–1.5$) are normally undistorted. For four-membered chelate rings with $b < \sim1.2$, however, the plane formed by the two bidentate ligands becomes a trapezoid (Figure 2). The unidentate ligands are simultaneously skewed toward (Figure 2(c)) or even past (Figure 2(d)) the long edge of the trapezoid. The bonding of the bidentate ligand becomes grossly unsymmetrical, the end nearer the unidentate ligands becoming sterically very crowded.

Important examples of this skew trapezoidal bipyramid structure are the dialkyltin complexes with four-membered

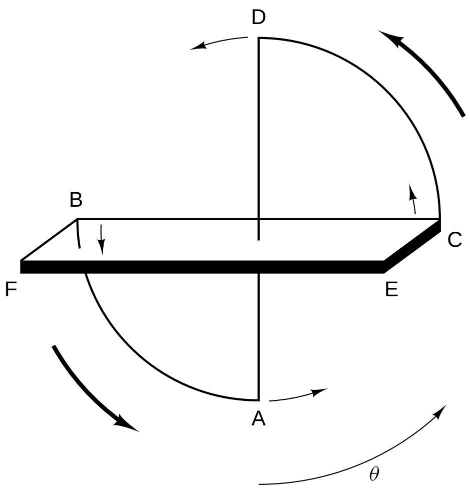

Figure 3 Distortion in *cis*-[M(bidentate)$_2$(unidentate)$_2$] as the size of the chelate ring is reduced. The bidentate ligands are rotated in an anticlockwise direction to higher θ relative to the M(unidentate)$_2$ plane

chelate rings. Structural parameters for typical examples are given in Figure 4, together with the undistorted [Sn(MeCOCHCOMe)$_2$Me$_2$] for comparison. A notable feature of these structures is the very unsymmetrical bonding of the bidentate ligands, one bond being 20–35% longer than the other. Similar skew-trapezoidal bipyramidal structures are observed for dialkylgermanium[14] and -lead[15] complexes.

Selenium(II) and tellurium(II) xanthates, dithiocarbamates, and related molecules have planar trapezoidal structures with the *trans* sites apparently occupied by lone pairs of electrons. Detailed parameters for a typical structure, [Te(S$_2$COMe)$_2$(:)$_2$],[16] are shown in Figure 5.

3.3 [M(bidentate)$_3$]

The stereochemistries of complexes of the type [M(bidentate)$_3$] occupy an important place in inorganic

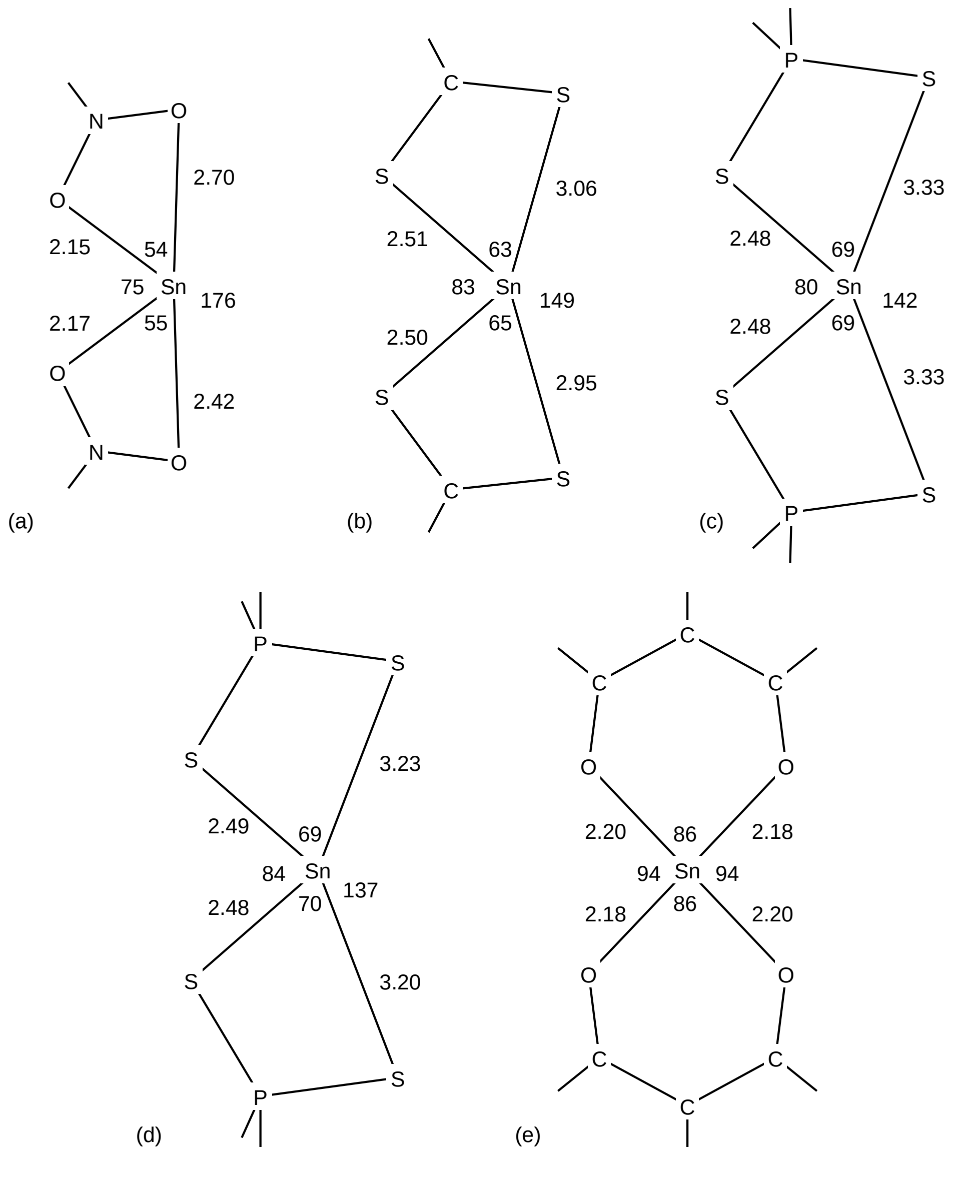

Figure 4 Geometries, in degrees and Å, of the Sn(bidentate)$_2$ plane in [Sn(bidentate)$_2$(alkyl)$_2$]. The alkyl groups above and below the plane are skewed towards the long edge of the Sn(bidentate)$_2$ trapezoid:

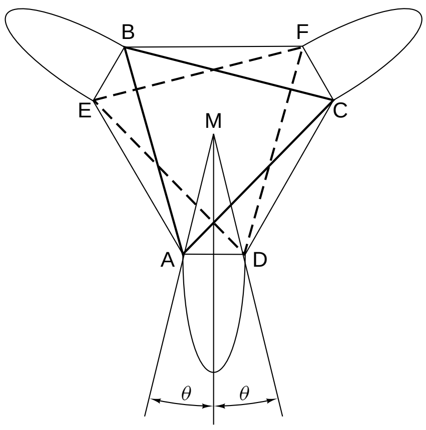

Figure 6 General stereochemistry for [M(bidentate)$_3$]

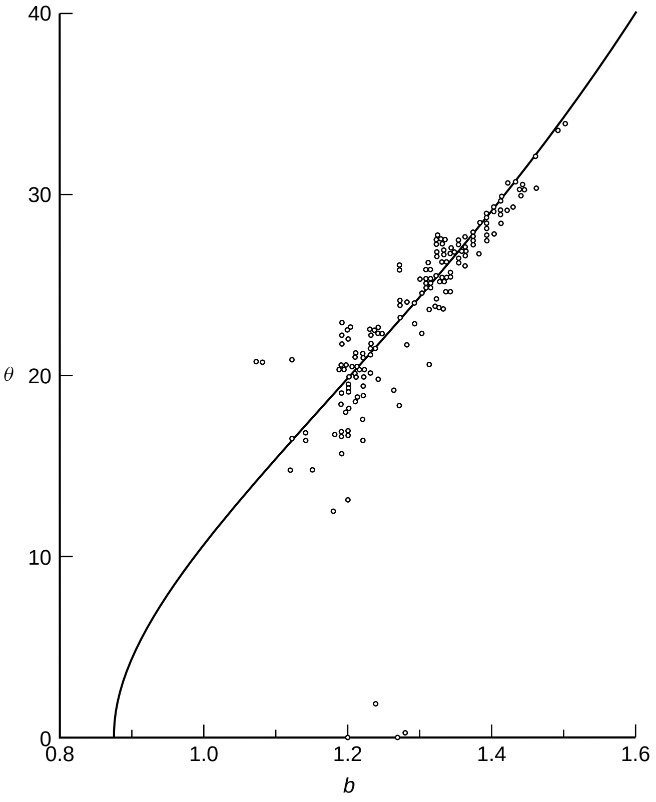

Figure 7 Angle of twist, θ (degrees), and normalized bite, b, for complexes of the type [M(bidentate)$_3$]. A theoretical curve is also shown

chemistry. The general stereochemistry is shown in Figure 6, viewed down the threefold axis. The stereochemistry is defined by the normalized bite b of the bidentate ligands and the angle of twist θ between the upper and lower triangular faces. The regular octahedron corresponds to $b = 2^{1/2}$ and $\theta = 30°$. The trigonal prism is the eclipsed arrangement with $\theta = 0$.

A theoretical dependence of θ upon b is shown by the line in Figure 7. For $b = 2^{1/2}$ the regular octahedron at $\theta = 30°$ is as expected, but as b is progressively decreased θ also progressively decreases until a trigonal prism is formed. The overwhelming majority of tris(bidentate) complexes have structures intermediate between the octahedron and trigonal prism. The structures are indicated in Figure 7.[1] (Dithiolate molecules, [M($S_2C_2R_2$)$_3$]$^{x-}$, are not included in Figure 7 as many have structures much closer to the trigonal prism than would be expected.[2]) Figure 8 displays some of the data in Figure 7, but is now restricted to complexes of the first-row transition elements from chromium to copper to avoid large variations in the size of the central atom.

To a first approximation the ligands divide into three groups. The first group is contained within the limits $b = 1.37_5$ to $b = 1.50$ and consists of those ligands that form six-membered chelate rings, such as acetylacetonate and trimethylenediamine. The second group is contained within the limits $b = 1.25$ to $b = 1.37_5$ and contains the complexes with five-membered chelate rings, such as *o*-phenanthroline and ethylenediamine. The third group is contained within $b = 1.05$ to $b = 1.25$ and contains the complexes with four-membered rings, such as nitrate and dithiocarbamates. This strikingly simple and important correlation is further illustrated in Figure 9 with three representative examples: [Co(MeCOCHCOMe)$_3$],[17] [Co($NH_2CH_2CH_2NH_2$)$_3$]$^{3+}$,[1] and [Co(NO_3)$_3$].[18]

Further subdivisions can be made according to the size of the nonmetal atoms in the chelate ring. For example, the four-membered chelate ring group may be divided into four subgroups. The subgroup containing ligands of lowest normalized bite ($b = 1.05$–1.12_5) consists of (PhN_3Ph)$^-$ and NO_3^-, where three small second-row elements complete the chelate ring. There are no known examples of the second subgroup. The third subgroup of normalized bite 1.17–1.25 contains ligands with one second-row element and two larger elements in the chelate ring, such as the dithiocarbamates and xanthates. The fourth subgroup contains the dithiophosphates with three large ring atoms, and this subgroup intrudes into the group containing the five-membered chelate rings. A comparison of the ring geometries of [Co(NO_3)$_3$],[18] [Co(S_2COEt)$_3$],[19] and [Co{S_2P(OMe)$_2$}$_3$][20] is shown in Figure 10.

Unusually large normalized bites may be achieved with five-membered chelate rings by again incorporating large

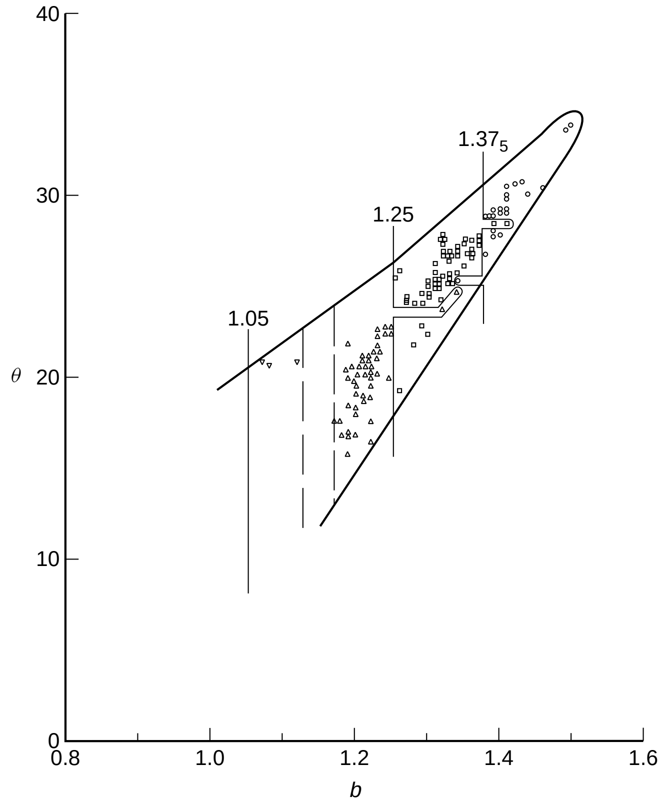

Figure 8 Angle of twist, θ (degrees), and normalized bite, b, for complexes of the type [M(bidentate)$_3$] (M = Cr, Mn, Fe, Co, Ni, Cu)

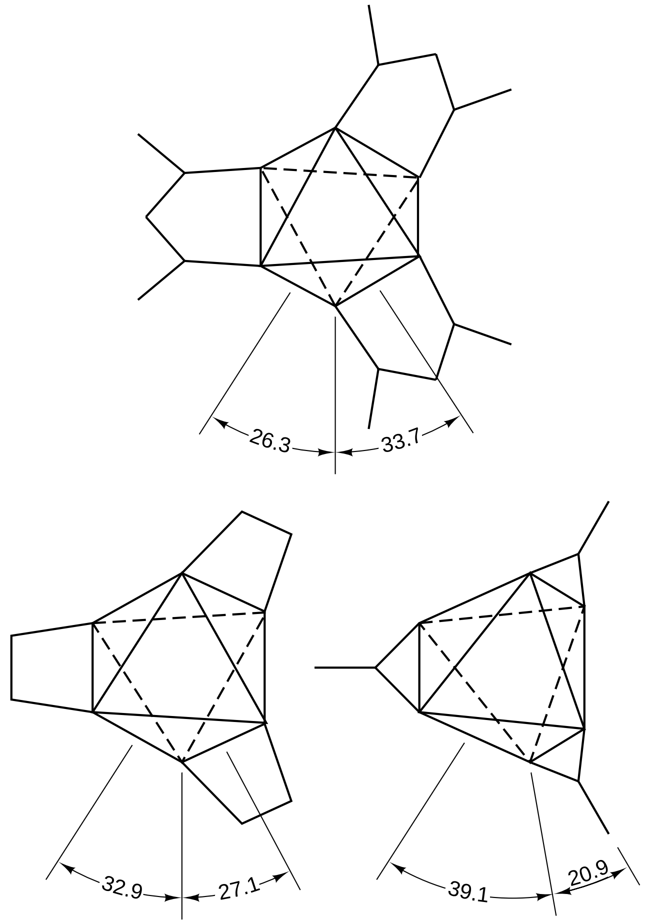

Figure 9 [Co(acac)$_3$], [Co(en)$_3$]$^{3+}$, and [Co(NO$_3$)$_3$]

atoms into the ring. The intrusion of the five-membered ring region into the six-membered ring region in Figure 8 is due to a dithiooxalate complex containing two sulfur atoms in the chelate ring, all other five-membered rings in Figure 8 containing only carbon, nitrogen, and oxygen atoms. Comparative ring geometries in $[Co(C_2O_4)_3]^{3-}$[21] and $[Co(S_2C_2O_2)_3]^{3-}$[22] are also shown in Figure 10.

The size of the metal atom is also important in determining the normalized bite, the smaller normalized bites being obtained with the larger metal atoms. Thus the lowest normalized bite for a six-membered ring containing a transition metal ion is that observed for [Sc(MeCOCHCOMe)$_3$][23] in which the normalized bite of 1.31 is similar to complexes of the other transition metals containing five-membered chelate rings. Similarly, the lowest normalized bite for a transition metal complex containing a five-membered ring is $b = 1.20$, observed for the tropolonate complex $[Sc(O_2C_7H_5)_3]$.[24]

4 SEVEN-COORDINATE COMPOUNDS

The starting point for the consideration of seven coordination is three structures with very similar stabilities: the pentagonal bipyramid, capped octahedron, and capped trigonal prism (Figure 11).[1,2,25] There are no potential energy barriers between these polyhedra and a range of structures is expected. For example, moving one of the equatorial atoms of the pentagonal bipyramid (starred in Figure 11) downward forms a capped octahedron with the starred atom as the capping atom. Further movement in the same direction forms a capped trigonal prism. The mirror plane in the plane of the page is retained.

Structurally characterized molecules with seven identical ligands are restricted mainly to some fluoro complexes $[MF_7]^{x-}$, aqua complexes $[M(H_2O)_7]^{2+}$, isonitrile complexes $[M(CNR)_7]^{2+}$, and cyanide complexes $[M(CN)_7]^{x-}$. The stereochemistries are distorted along the long 'reaction coordinate' connecting the capped trigonal prism and the pentagonal bipyramid. The X-ray data on IF_7[2] and $[TeF_7]^-$[26] are not sufficient to establish the precise stereochemistry. The NMR spectra show rapid intramolecular rearrangement. The anions in $K_2[NbF_7]$ and $K_2[TaF_7]$ are intermediate between a capped octahedron and a capped trigonal prism.[27]

In the calcium polyiodide compound $[Ca(H_2O)_7](I_{10})$ the stereochemistry appears to be intermediate between a capped octahedron and a pentagonal bipyramid, whereas

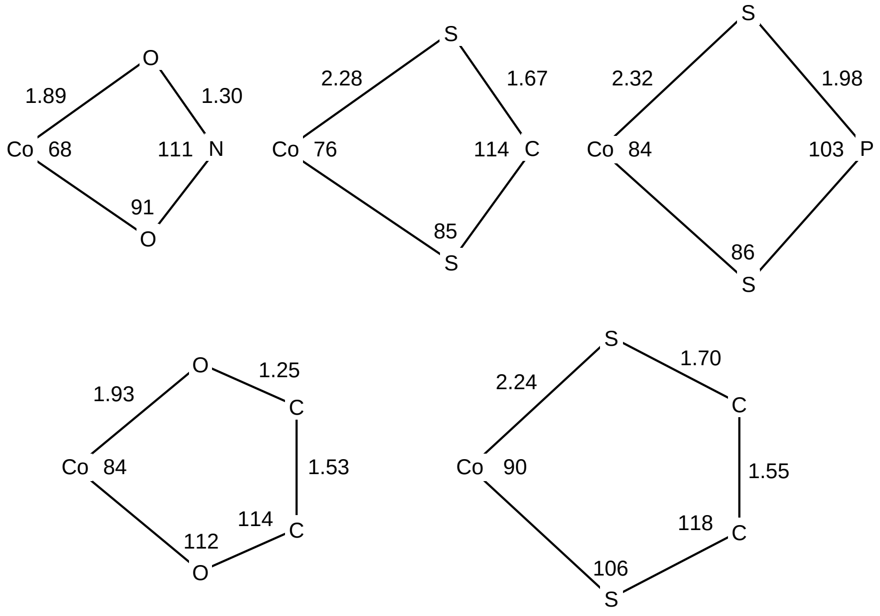

Figure 10 Ring geometries, in degrees and Å, in: $[Co(NO_3)_3]$, $[Co(S_2COEt)_3]$, $[Co\{S_2P(OMe)_2\}_3]$, $[Co(C_2O_4)_3]^{3-}$, and $[Co(S_2C_2O_2)_3]^{3-}$

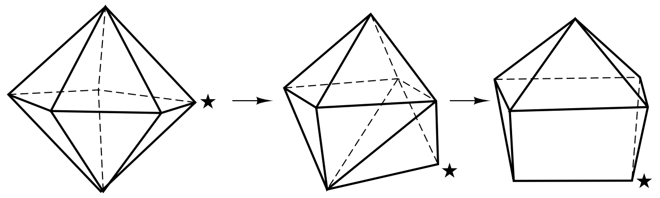

Figure 11 The pentagonal bipyramid, capped octahedron, and capped trigonal prism

$[Sr(H_2O)_7](I_{12})$ and $[Ca(H_2O)_7]_2[Cd_6Cl_{16}(H_2O)_2]\cdot H_2O$ contain capped trigonal prismatic cations.[2]

A close approximation to a capped trigonal prism is observed for $[Mo(CNBu)_7](PF_6)_2$. However, the closely related compounds $[Cr(CNBu)_7](PF_6)_2$, $[Mo(CNPh)_7](PF_6)_2$, $[Mo(CNMe)_7](BF_4)_2$, and $[W(CNBu)_7](W_6O_{19})$ lie further towards capped octahedra than capped trigonal prisms.[2] Solutions of $[Mo(CNBu)_7]^{2+}$ yield only a single ^{13}C NMR signal even down to $-135\,°C$, confirming the expected stereochemical nonrigidity.[2]

The structures of $K_4[V(CN)_7]\cdot 2H_2O$, $K_5[Mo(CN)_7]\cdot H_2O$, $Na_5[Mo(CN)_7]\cdot 10H_2O$ and $K_4[Re(CN)_7]\cdot 2H_2O$ are close to pentagonal bipyramids.[2]

As for five coordination, a mixture of unidentate ligands may lead to more well-defined stereochemistries due to the different types of polyhedral vertices available and the different spatial requirements of the different ligands. For example, the sterically least hindered sites in these structures are the axial sites of a pentagonal bipyramid as these are the only ones with no neighboring ligands having ligand–metal–ligand angles less than 90°. As expected, the O^{2-} ligand occupies this site and forces this structure in $Na_3[NbOF_6]$[28] and a range of uranyl complexes such as $[UO_2(OSMe_2)_5](ClO_4)_2$.[29] Likewise, a planar pentagonal arrangement of fluorine atoms is observed in $(Me_4N)[XeF_5(:)_2]$ with the pentagonal bipyramidal structure presumably completed by the two lone pairs of electrons.[30]

Well-defined stereochemistries may also be obtained by replacing the unidentate ligands with chelate groups which have a relatively fixed normalized bite. For example, ligands of very small normalized bite occupy one of the pentagonal edges of the pentagonal bipyramid, these being the shortest edges available among the seven-coordinate polyhedra. Examples include peroxo complexes with three-membered chelate rings, $[Ti(O_2)F_5]^{3-}$[31] and $[Cr(O_2)_2(CN)_3]^{3-}$,[32] and a number of complexes with four membered chelate rings, $[Cd(NO_3)_2py_3]$[33] and $[Hg(O_2CCF_3)_2py_3]$.[34] This dependence of structure upon size of the chelate ring is also illustrated by a group of molybdenum and tungsten carbonyl iodides.[35] A complex containing a four-membered chelating phosphine, $[W(Ph_2PCH_2PPh_2)I_2(CO)_3]$, has the pentagonal bipyramidal structure as above, whereas complexes containing larger rings, $[Mo(Ph_2PCH_2CH_2PPh_2)I_2(CO)_3]$ and $[Mo(Ph_2PCH_2CH_2CH_2PPh_2)I_2(CO)_3]$, have capped trigonal prismatic structures.

For complexes containing larger bidentate ligands which can wrap around the metal atom in a variety of stereochemistries, the structure is dependent upon both the size of the chelate ring and the nature of the unidentate ligands. A particularly well-studied group of complexes is of

the type [M(bidentate)$_3$(unidentate)].[2] Uncharged unidentate ligands form two types of structure. The first is a capped octahedron with the unidentate ligand in the capping site and the three bidentate ligands forming a three-bladed propeller as in [M(bidentate)$_3$], examples including [Tc(S_2COBu)$_3$(PPh_3)],[36] [Ho(PhCOCH_2COPh)$_3$(H_2O)],[37] and [Y(PhCOCH_2COMe)$_3$(H_2O)].[38] The second structure approximates to a capped trigonal prism and is observed for [Dy(BuCOCH_2COBu)$_3$(H_2O)], [Lu(C_3F_7COCH_2COBu)$_3$ (H_2O)], and [Yb(MeCOCH_2COMe)$_3$(H_2O)].[2] Charged unidentate ligands, on the other hand, form a structure which approximates to a pentagonal bipyramid but is distorted by the constraints of the bidentate ligands to be intermediate between a pentagonal bipyramid and a capped trigonal prism. Examples include [Nb(S_2CNEt_2)$_3$O],[39] [V(S_2CNEt_2)$_3$O],[39] (NH_4)$_3$[Nb(C_2O_4)$_3$O]·H_2O,[40] and [Zr(MeCOCH COMe)$_3$Cl].[41]

5 EIGHT-COORDINATE COMPOUNDS

The starting point for the consideration of eight coordination is the square antiprism and the triangular dodecahedron (Figure 12).[1,2,42] The square antiprism is usually slightly more stable than the dodecahedron and is more commonly observed.

The ideal square antiprism has all edge lengths equal but, because the square faces are larger than the triangular faces, the structure distorts slightly by decreasing the size of the square faces, in an analogous way to the distortion observed in square pyramidal molecules. This distortion is measured by a decrease in the angle α, the angle the eight metal–ligand bonds make with the fourfold axis, from the idealized 59.3° to about 57° (Table 4).

The dodecahedron has one set of four donor atoms necessarily different from the other set of four, labeled A and B, respectively, in Figure 12. A useful way of viewing the dodecahedron is to consider it as two interpenetrating and mutually orthogonal planar trapezoids, BAAB (Figure 12).

Table 4 Square antiprismatic [M(unidentate)$_8$] Molecules[2,43,44]

Complex	α (°)
H_4[W(CN)$_8$]·6H_2O	57.6
Na_3[W(CN)$_8$]·4H_2O	59.1

[NO(NOF)$_2$][IF$_8$]	57.6
[Sr(H_2O)$_8$](AgI$_2$)$_2$	58.2
[Cu(H_2O)$_6$]$_2$[ZrF$_8$]	57.1
Cs_4[U(NCS)$_8$]	56.7

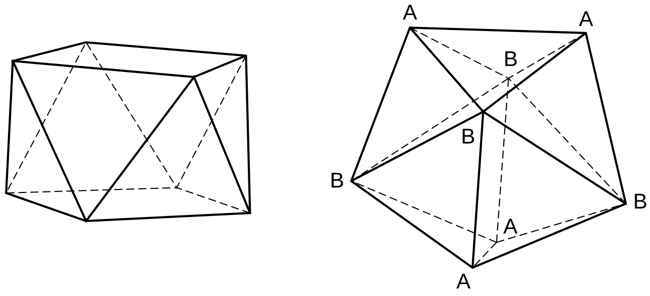

Figure 12 The square antiprism and dodecahedron

The B–B edges are approximately 25% longer than the A–A and A–B edges so that the B sites, which consequently have only three close neighbors, are sterically less crowded than the A sites. Examples of dodecahedral structures include K_4[Mo(CN)$_8$]·2H_2O,[45] (Bu_4N)$_3$[Mo(CN)$_8$],[46] [Gd(H_2O)$_8$]Cl_3·2$C_{10}H_8N_2$, and [Y(H_2O)$_8$]Cl_3·2$C_{10}H_8N_2$.[47]

The square antiprism can be converted to the dodecahedron by creasing along a diagonal of each square face so that it becomes the B–B edge of a dodecahedron. Conversely, the dodecahedron in Figure 12 is converted to a square antiprism by forming square faces from two ABAB pairs of triangular faces. There is no potential energy barrier to this interconversion and intermediate structures are also possible, as observed for (Et_3NH)$_2$(H_3O)$_2$[Mo(CN)$_8$].[48] As indicated above, the structures of [M(CN)$_8$]$^{x-}$ (x = 3, 4; M = Mo, W) may be square antiprismatic, dodecahedral, or intermediate. In solution, only a single ^{13}C NMR signal is observed for [Mo(CN)$_8$]$^{4-}$ at temperatures as low as −165 °C, consistent with very rapid intramolecular rearrangement.[49]

For complexes with a mixture of different ligands, the dodecahedron with its two different types of ligand site is generally favored. Charged ligands such as halide preferentially occupy the B sites of a dodecahedron, as observed for [UCl(DMF)$_7$]$_2$[UO$_2$Cl$_4$]$_3$,[50] [UCl$_4$(MeCN)$_4$],[51] [ThCl$_4$(OSPh$_2$)$_4$],[52] and [ThBr$_4$(THF)$_4$].[53] On the other hand, [EuCl$_2$(H_2O)$_6$]Cl[54] and [U(NCS)$_4${OP(NMe$_2$)$_3$}$_4$][55] retain the square antiprismatic structure.

A preference by charged ligands to occupy the B sites of a dodecahedron is also indicated for complexes containing two bidentate ligands, as in [WCl$_4$(Me$_2$PCH$_2$CH$_2$PMe$_2$)$_2$],[56] [ThCl$_4${OP(NMe$_2$)$_2$OP(NMe$_2$)$_2$O}$_2$],[57] and a series of diarsine complexes [MX$_4${C$_6$H$_4$(AsMe$_2$)$_2$}$_2$]$^{x+}$, where M is Ti^{IV}, Nb^{IV}, Nb^{V}, etc. and X is Cl or Br.[58–60]

The influence the size of the chelate ring has upon the stereochemistry around the metal atom is clearly shown by complexes of the type [M(bidentate)$_4$]. Bidentate ligands of small normalized bite form dodecahedral structures, in which each of the BAAB trapezoids is formed from a pair of ligands (Figure 13). There are numerous examples of this structure with three- and four-membered chelate rings such as peroxide, nitrate, acetate, xanthate, and dithiocarbamate

(Table 5). Larger rings form an intermediate structure which can be represented as a square antiprism with the bidentate ligands spanning the square edges, but which is frequently distorted due to a creasing of the square faces as has been noted above, and alternative descriptions of the structure may be preferred (Figure 13). This structure is commonly observed for six-membered chelate rings such as the acetylacetonates of the lanthanide and actinide elements (Table 5). Ligands of intermediate size, such as the five-membered chelate rings oxalate and tropolate, and four-membered chelate rings containing large atoms such as dithiophosphate, may have either of the above structures, or an intermediate structure. The largest normalized bites are obtained with a combination of six-membered rings and smaller (than lanthanides or actinides) metal atoms, as in $[Nb(BuCOCHCOBu)_4]$, which has a square antiprismatic structure in which the bidentate ligands span the triangular edges to form a four-bladed propeller (Figure 13, Table 5). As for the octahedron–trigonal prism correlation found for $[M(bidentate)_3]$, the angle of twist between the two square faces is dependent upon the size of the chelate ring; in this case $b = 1.28$ and $\theta = 24°$.

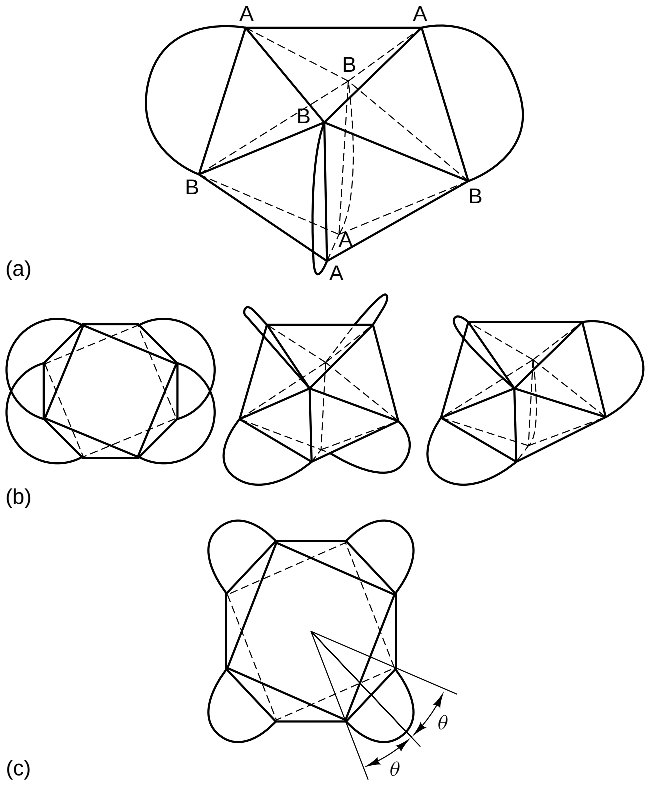

Figure 13 Stereochemistries of $[M(bidentate)_4]$. (a): the dodecahedron observed for low values of b. (b): alternative depictions of the intermediate structure observed for intermediate values of b. (c): the square antiprismatic structure observed for large values of b

Table 5 Stereochemistries and chelate ring size for examples of complexes of the type $[M(bidentate)_4]$[2,61]

Ring size	Complex	Stereochemistry
3	$K_3[Cr(O_2)_4]$	Dodecahedron
3	$[Zn(NH_3)_4][Mo(O_2)_4]$	Dodecahedron
4	$[Sn(NO_3)_4]$	Dodecahedron
4	$[Ti(NO_3)_4]$	Dodecahedron
4	$[Sn(O_2CMe)_4]$	Dodecahedron
4	$(Et_4N)[Bi(S_2COEt)_4]$	Dodecahedron
4	$[Ti(S_2CNEt_2)_4]$	Dodecahedron
4	$[Mo(S_2CNEt_2)_4]Cl$	Dodecahedron
4	$[Th(S_2PMe_2)_4]$	Dodecahedron
4	$(Ph_4P)[Pr(S_2PMe_2)_4]$	Intermediate
5	$[Hf(O_2C_7H_5)_4]\cdot DMF$	Dodecahedron
5	$Na_4[Zr(C_2O_4)_4]\cdot 3H_2O$	Distorted dodecahedron
6	$[U(PhCOCHCOPh)_4]$	Intermediate
6	$[Zr(MeCOCHCOMe)_4]$	Intermediate
6	$[Sm(NH_2CONHCONH_2)_4](NO_3)_3$	Intermediate
6	$[Nb(BuCOCHCOBu)_4]$	Square antiprism

6 NINE-COORDINATE COMPOUNDS

The two important stereochemistries for nine coordination[1,2,62] are the capped square antiprism and the slightly more stable tricapped trigonal prism (Figure 14). The tricapped trigonal prism can be converted to the capped square antiprism by converting two of the capping atoms and the two intervening prism atoms into a square. There is no potential energy barrier to this interconversion and repetition scrambles all nine atoms.

The most important structurally characterized compounds containing nine equivalent unidentate ligands are the aqua lanthanoid complexes $[Ln(H_2O)_9]^{3+}$.[2,63] In these compounds the capping atoms are more sterically hindered than the prism atoms and the metal–capping atom bond lengths are larger than the metal–prismatic atom bond lengths. As the size of the metal atom decreases, all three capping atoms are further squeezed out so that the 9-coordinate structure approaches a $(6 + 3)$-coordinate structure rather than an 8-coordinate

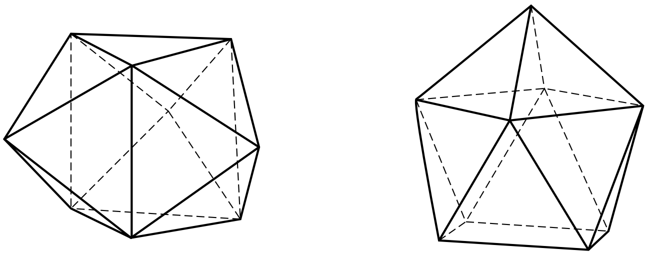

Figure 14 The tricapped trigonal prism and capped square antiprism

structure. For example:

	M–O$_{cap}$	M–O$_{prism}$	(M–O$_{cap}$)/(M–O$_{prism}$)
$[La(H_2O)_9](CF_3SO_3)_3$	2.62 Å	2.52 Å	1.04
$[Gd(H_2O)_9](CF_3SO_3)_3$	2.55	2.40	1.06
$[Lu(H_2O)_9](CF_3SO_3)_3$	2.50	2.29	1.09

The tricapped trigonal prismatic structure is retained in a series of trinitrato complexes such as $[Ln(NO_3)_3(H_2O)_3]$[2,64] in which bidentate nitrates span the capping and prism sites with retention of threefold symmetry. The angle of twist between the two triangles spanned by the three bidentate ligands is ∼46°, in good agreement with theory; compare with [M(bidentate)$_3$] and the capped octahedral [M(bidentate)$_3$(unidentate)]. Each bidentate ligand is unsymmetrically bonded as expected, (M–O$_{cap}$)/(M–O$_{prism}$) ≈ 1.05.

The most symmetrical way four equivalent bidentate ligands can be wrapped around a nine-coordinate metal atom is to form a capped square antiprism with the bidentate ligands linking the two square faces of the antiprism to form a four-bladed propeller with the unidentate ligand capping one square face. This structure is observed for $[Th(CF_3COCHCOCH_3)_4(H_2O)]$.[65] The angle of twist between the two square faces of 42° is as expected for the normalized bite of $b = 1.15$. In the capped square antiprism the four atoms forming the capped face are sterically less crowded than the four atoms forming the uncapped face, and this is reflected in the Th–O bond lengths of 2.39 and 2.46 Å, respectively.

7 TEN-COORDINATE COMPOUNDS[1,2,62]

There is, as yet, no structurally characterized compound containing ten unidentate ligands. Nevertheless, the geometry of these hypothetical compounds is a useful introduction to the stereochemistry of known ten-coordinate compounds containing chelate groups, such as [M(bidentate)$_5$].

Three structures can be envisaged for ten coordination: the bicapped square antiprism, sphenocorona, and trirhombohedron (Figure 15).

The two most important structures for [M(bidentate)$_5$] are shown in Figure 16, drawn as idealized bicapped square antiprisms. Isomer I is possible at all values of the normalized bite whereas isomer II is expected only for larger chelate rings. A number of lanthanoid and actinoid complexes with four-membered nitrate or carbonate rings, $[M^{III}(NO_3)_5]^{2-}$ and $[M^{IV}(CO_3)_5]^{6-}$, have structure I. The only monomeric molecule in which structure II is observed is $[Ba(MeCONHCOMe)_5](ClO_4)_2$ with six-membered chelate rings.

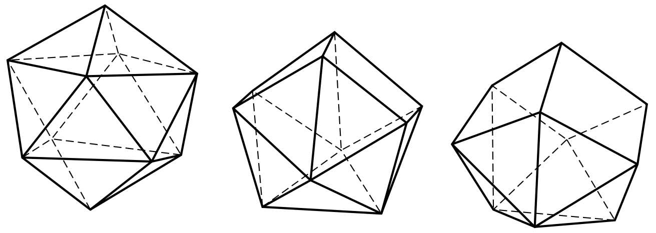

Figure 15 The bicapped square antiprism, sphenocorona, and trirhombohedron

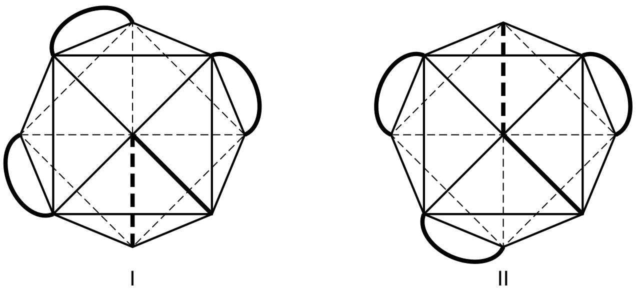

Figure 16 Bicapped square antiprismatic isomers of [M(bidentate)$_5$]

8 TWELVE-COORDINATE COMPOUNDS[1,2,62]

The tetrahedron, octahedron, and icosahedron are the three polyhedra formed from equivalent triangular faces, and these rigid, close packed structures dominate the stereochemistries for coordination numbers four, six, and twelve, respectively.

As for ten coordination, there are no twelve-coordinate complexes containing only unidentate ligands. The most common twelve-coordinate molecules are of the type [M(bidentate)$_6$]. Three structural isomers may be formed by wrapping six bidentate ligands along the edges of an icosahedron (Figure 17). Isomer III is less stable than the other two and is not observed. Isomer I is observed for a number of hexanitrato complexes, for example $[La(NO_3)_6]^{3-}$ and $[Th(NO_3)_6]^{2-}$. Isomer II has been observed for the naphthyridine complex $[Pr(napy)_6]^{3+}$.

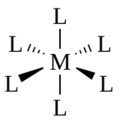
1 INTRODUCTION

This article is adapted with permission from the first two chapters of the author's book *Organometallic Chemistry of the Transition Metals*.[1c] Several other useful texts are also available on organometallic and coordination chemistry.[1] Transition metal ions can bind ligands (*see Ligand*), L to give a coordination compound, or complex (*see Coordination Complexes*) ML_n, as in the familiar aqua ions $[M(OH_2)_6]^{2+}$ (M = V, Cr, Mn, Fe, Co, or Ni) where O is considered the donor atom. Where the ligands have only N, O, or halide donor atoms, the complexes are considered to be classical coordination compounds. On the other hand, complexes with any C-donor ligands or hydrides are usually considered as being organometallic compounds. Organometallic species tend to be more covalent, and the metal is often more reduced than in other coordination compounds. Typical ligands which usually bind to metals in their lower oxidation states are CO, alkenes, and arenes, for example, $Mo(CO)_6$, $(C_6H_6)Cr(CO)_3$, or $Pt(C_2H_4)_3$. Apart from these inner-sphere complexes, outer-sphere complexes also exist, for example, in which a counterion is associated with the inner-sphere complex in an ion pair.

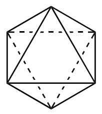
2 WERNER COMPLEXES[2]

The simplest metal–ligand bond is perhaps $L_nM{-}NH_3$, where an ammonia binds to a metal fragment. This fragment will usually have other ligands, represented here by L_n. The bond consists of the lone pairs of electrons present in free NH_3 that are donated to the metal to form the complex. The metal is a polyvalent Lewis acid capable of accepting the lone pairs of several ligands, L, which act as Lewis bases.

The most common type of complex is ML_6, which adopts an octahedral coordination geometry (**1**),[1,2] based on one of the Pythagorean regular solids. The ligands occupy the six vertices of the octahedron, which allows them to minimize their M–L bonding distances while maximizing their L$\cdots$L nonbonding distances. From the point of view of the coordination chemist, it is perhaps unfortunate that Pythagoras decided to name his solids after the number of faces ($octa$ = eight) rather than the number of vertices. After (**1**), ML_4 and ML_5 are the next most common types (*see* ***Coordination Numbers & Geometries***).



(**1**)

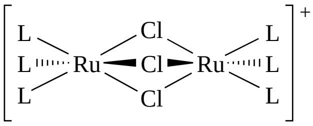


Octahedron

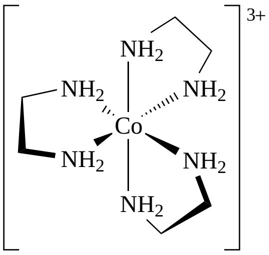
The assembly of metal and ligands that we call a complex may have a net charge, in which case it is a complex ion (e.g. $[PtCl_4]^{2-}$). Together with the counterions, we have a complex salt (e.g. $K_2[PtCl_4]$). In some cases both the cation and the anion may be complex, as in Magnus's green salt, $[Pt(NH_3)_4][PtCl_4]$. Square brackets are used to enclose the individual complex molecules or ions where necessary to avoid ambiguity. Those ligands with more than one lone pair can donate one to each of two or more metal ions to give polynuclear complexes, such as the orange crystalline compound (**2**) ($L = PR_3$). The bridging group is represented in formulae by using the Greek letter μ, as in $[Ru_2(\mu\text{-}Cl)_3(PR_3)_6]^+$. Note how (**2**) can be considered as two octahedral fragments sharing the face that contains the three chloride bridges.

Other ligands can have more than one donor atom; an example is ethylenediamine ($NH_2CH_2CH_2NH_2$, often abbreviated as en). Such ligands most commonly donate both lone pairs to the same metal to give a ring compound known as a chelate (*see Chelating Ligands* and *Chelate Effect*). A typical example of such a complex is (**3**).

The early Russian investigator Chugaev first drew attention to the fact that chelating ligands are much less easily displaced



(**2**)



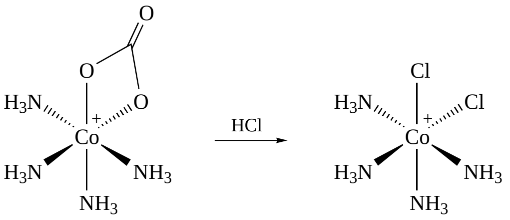
(**3**)

from a complex than are monodentate ligands of the same type. The reason is illustrated in equation (1).

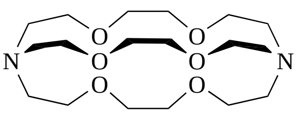
$$[M(NH_3)_6]^{n+} + 3\ en \rightleftharpoons [M(en)_3]^{n+} + 6NH_3 \quad (1)$$

Formation of the chelate releases six NH_3 molecules so that the total number of particles increases from four to seven. This creates entropy, and so favors the chelate form. Each chelate ring usually leads to an additional factor of about 10^5 in the equilibrium constant for reactions like equation (1). Equilibrium constants for complex formation are usually called formation constants; the higher the value the more stable the complex.

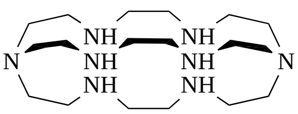
Not only does chelation make the complex more stable, but it also forces the donor atoms to take up adjacent or cis sites in the resulting complex. Equation (2) shows how displacement of a chelating carbonate ion gives the unusual *cis* dichloride product instead of the thermodynamically more stable trans dichloride. Polydentate chelating ligands with three or more donor atoms also exist. Macrocyclic ligands, such as (**4**) and (**5**), confer an additional increment in the formation constant (the macrocyclic effect); they have been given trivial names, such as 'cryptates' (**4**) and 'sepulchrates' (**5**).[1]



(2)

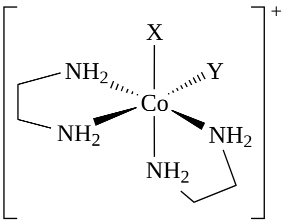


(**4**)

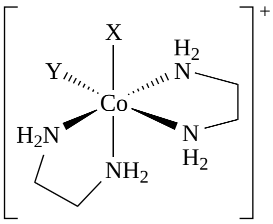


(**5**)

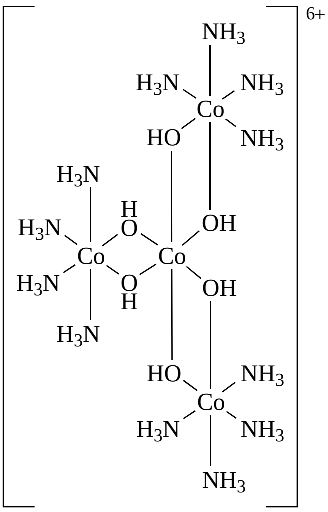
Ligands such as nitrite can have isomers (linkage isomers; see *Linkage Isomerism*), in which the metal is bound via N in one case (M–NO_2) or O (M–ONO) in the other. Complexes such as $[Co(en)_2XY]^{n+}$ can have optical isomers (**6**) and (**7**), as a result of the absence of a plane of symmetry. Some have very large optical rotations: Werner's complex (**8**), which is unusual in containing only inorganic elements, has the extraordinarily high specific rotation of 36 000°, and required 1000 recrystallizations to resolve.



(**6**)



(**7**)

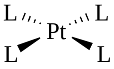


(**8**)

3 THE TRANS EFFECT

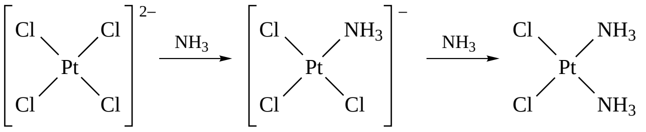
In the 1920s, Chernaev discovered that certain ligands facilitate the departure of a second ligand *trans* to the first, and their replacement or substitution by an external ligand (*see Ligand Substitution*). Ligands that are more effective at this labilization are said to have a higher *trans effect*. The effect is most marked in substitution on Pt^{II}, and the highest trans effect ligands either form unusually strong σ-bonds, such as H^-, Me^-, or $SnCl_3^-$, or unusually strong π-bonds, such as CO, C_2H_4, and thiourea ($(NH_2)_2CS$, a ligand often represented as tu). The same ligands also weaken the trans M–L bonds in the ground state, as shown by a lengthening of the M–L distances found by X-ray crystallography, or by some spectroscopic measure, such as the M–L coupling constant in the NMR, or the ν(M–L) stretching frequency in

the IR spectrum. A change in the ground-state thermodynamic properties, such as these, is usually termed the *Trans Influence* to distinguish it from the parallel effect on the properties of the transition state for the substitution reaction, which is the trans effect proper, and refers to differences in *rates* of substitution and is therefore a result of a change in the energy difference between the ground state and transition state for the reaction. A classic system in which trans effects are very marked is PtL_4^{2+}, in which Pt^{II} adopts the square-planar geometry (**9**), a square with the metal at the center.

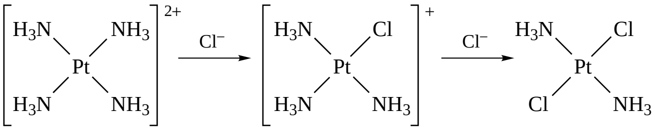


(**9**)

An important application of the trans effect is the synthesis of specific isomers of coordination compounds. Equations (3) and (4) show how the cis and trans isomers of $Pt(NH_3)_2Cl_2$ can be prepared selectively by taking advantage of the trans effect order Cl > NH_3. This example is also of practical interest because the cis isomer is an important antitumor drug, but the trans isomer is ineffective. In each case the first step of the substitution can give only one isomer. In equation (3) the cis isomer is formed in the second step because the Cl trans to Cl is more labile than the Cl trans to the lower trans effect ligand, ammonia. On the other hand, in equation (4) the first Cl to substitute labilizes the ammonia trans to itself to give the trans dichloride as final product.



(3)



(4)

4 SOFT VERSUS HARD LIGANDS

Chatt[3a] pointed out in the 1950s that most metal ions in their usual oxidation states tend to bind saturated ligands such as NH_3, H_2O, or F^-. These are now[3b] called *hard* metals by allusion to their low polarizability. On the other hand, a small group of ions, including the platinum metals, Ag^+, Hg^{2+}, and a few others, form stronger complexes with unsaturated or polarizable ligands, such as Br^-, I^-, PPh_3, or C_2H_4 (now called *soft*; see *Hard & Soft Acid–Base Theory*). Soft ligands either have donor atoms from the second or subsequent rows of the periodic table (e.g. Br^-, PPh_3, or Me_2S), or they have double or triple bonds (ethylene, acetylene, benzene). We now know that essentially all the transition metals can become soft if they are reduced to a sufficiently low valence state. The peculiarity of the small group of metals identified by Chatt is that they normally occur in low oxidation states, and so had long been known to form soft complexes. Table 1 shows some formation constants that illustrate the differences. The reason that low oxidation state metals tend to bind soft ligands is that these metals have excess electron density by virtue of their reduced state. They therefore avoid strong donor ligands, but prefer ligands with which they can form covalencies, and that have available empty orbitals into which they can donate some of their excess electron density (see Section 7). High oxidation state metals, on the other hand, are short of electron density and require good donor ligands.

5 THE CRYSTAL FIELD

An important advance in understanding the spectra, structure, and magnetism of transition metal complexes is provided by the crystal field (CF) model (*see Crystal Field Theory*). The d orbitals of the metal are assumed to be affected by the presence of the ligands, which are considered to act simply as negative charges. For a free metal ion isolated in space, the d orbitals are degenerate (have the same energy). As the ligands L approach the metal from the six octahedral directions $\pm x$, $\pm y$, and $\pm z$, the d orbitals take the form shown in Figure 1. Those d orbitals that point toward the L groups ($d_{x^2-y^2}$ and d_{z^2}) are destabilized by the negative charge of the ligands and move to higher energy. Those that point away from L (d_{xy}, d_{yz}, and d_{xz}) are less destabilized. The pair of orbitals that are most strongly destabilized are often identified by their symmetry label, e_g, or simply as d_σ, because they point along the M–L σ-bonding directions. The three more stable orbitals have the label t_{2g}, or simply d_π; these point away from the ligand directions but can form π bonds with

Table 1 Hard and soft acids and bases: some formation constants[a]

	Ligand			
Metal ion	F^-	Cl^-	Br^-	I^-
H^+	3	−7	−9	−9.5
Zn^{2+}	0.7	−0.2	−0.6	−1.3
Cu^{2+}	1.2	0.05	−0.03	–
Hg^{2+}	1.03	6.74	8.94	12.87

[a]The values are the negative logarithms of the equilibrium constant for $[M{\cdot}aq]^{n+} + L = [ML{\cdot}aq]^{(n-1)+}$, and show how H^+ and Zn^{2+} are hard acids, forming stronger complexes with F^- than with Cl^-, Br^-, or I^-. Cu^{2+} is a borderline case, and Hg^{2+} is a very soft acid, forming much stronger complexes with the more polarizable halide ions.

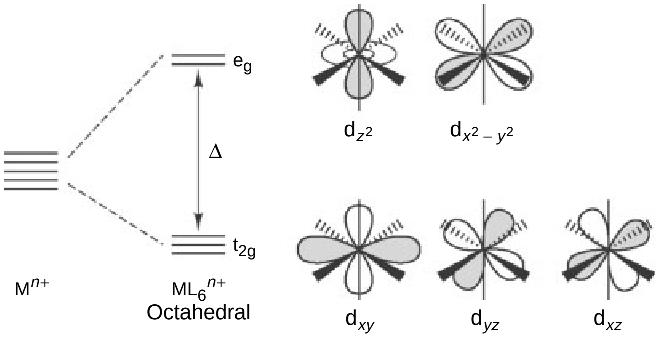


Figure 1 The effect on the d orbitals of bringing up six ligands along the $\pm x$, $\pm y$, and $\pm z$ directions. In this figure, shading represents the symmetry (not the occupation) of the d orbitals; shaded parts have the same sign of Ψ

the ligands. The magnitude of the energy difference between the d_σ and d_π set, usually called the CF splitting, and labeled Δ (or sometimes 10*Dq*) depends on the value of the effective negative charge and therefore on the nature of the ligands.

The metal ion Werner studied, Co^{3+}, has a strong preference for the octahedral geometry because it has a d^6 configuration. Six electrons just fill the three low-lying d_π orbitals of the CF diagram, and leave the d_σ empty. This is a particularly stable arrangement and other d^6 metals (Mo^0, Re^I, Fe^{II}, Ir^{III}, and Pt^{IV}) also show a very strong preference for the octahedral geometry. In spite of the high tendency to spin pair the electrons in the d^6 configuration (to give the low-spin form $t_{2g}^6e_g^0$; *see High-spin & Low-spin Compounds*), if the crystal field splitting is small enough, then the electrons may rearrange to give the high-spin form $t_{2g}^4e_g^2$. The high-spin form has all the spins aligned, as prescribed for the free ion by Hund's rule and shown in Figure 2. The high-spin form is favored because fewer electrons are paired up in the same orbitals and so electron–electron repulsions are reduced. On the other hand, if Δ becomes large enough, then the energy gained by dropping from the e_g to the t_{2g} level will be big enough to drive the electrons into pairing up in spite of e–e repulsions. The spin state of the complex can usually be determined by measuring the magnetic moment of the complex. This is done by placing a sample of the complex in a magnetic field gradient. In the low-spin form of a d^6 ion the molecule is diamagnetic (*see Diamagnetism*), that is to say it is very weakly repelled by the field. This behavior is exactly the same as is found for the vast majority of organic compounds, which are also spin paired. On the other hand, the high-spin form is paramagnetic (*see Paramagnetism*), in which case it is attracted into the field. The complex does not itself form a permanent magnet as does a piece of iron or nickel (this property is called *Ferromagnetism*), because the spins are not aligned in the crystal in the absence of an external field, but they do respond to the external field by lining up together when placed in an external magnetic field in order to measure the magnetic moment.

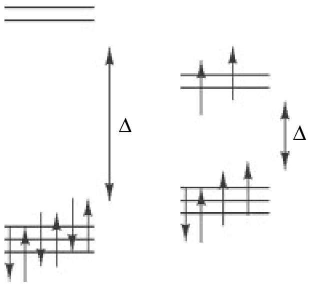

Figure 2 In a d^6 metal ion, both low- and high-spin complexes are possible, depending on the value of Δ. A high Δ leads to the low-spin form

The great majority of organometallic complexes are diamagnetic, because Δ is usually large in these complexes, favoring electron configurations that completely fill the low-lying levels. Paramagnetic organometallic species are becoming more common, however. This is always the case for molecules like $V(CO)_6$ that have an uneven number of electrons. For molecules with an even number of electrons, a high-spin configuration is more likely for the first-row metals, where Δ tends to be smaller than in the later rows. Paramagnetic centers are present in many metalloenzymes that involve organometallic intermediates, such as hydrogenase and CO dehydrogenase.

Sometimes the low- and high-spin forms of a metal complex have almost exactly the same energy. Each state can now be populated, and the relative populations of the two states vary with temperature; this happens for $Fe(S_2CNEt_2)_3$, for example. When two metals are present in the same complex, each having one unpaired electron, they may show singlet (↑↓) or triplet (↑↑) behavior. This depend on the strength of the coupling between the spins; once again, spin equilibria can occur.[4] It is now recognized that spin state crossings may occur in the course of chemical reactions of metal complexes, leading to unexpected pathways and abnormal kinetics. Even diamagnetic species can react via paramagnetic spin states.

In an octahedral d^7 ion, we are obliged to place one electron in the higher-energy d_σ level to give the configuration $t_{2g}^6e_g^1$, and this will normally make the complex paramagnetic (Figure 3). The net stabilization, often termed the crystal field stabilization energy or CFSE, of such a system will also be less than for d^6 (low spin), where we can put all the electrons into the more stable t_{2g} level. This is reflected in the chemistry of d^7 ions (e.g. Co^{II}), which, as long as they remain octahedral, are more reactive than their d^6 analogues. For example, they undergo ligand dissociation much more readily. The reason is that the d_σ levels are really M–L σ-antibonding in character, as we see later. Werner was able to study his chemistry with Co^{III} because the ligands tend to stay put. This is why Co^{III} and other d^6 ions are often referred to as coordinatively inert (*see Coordinatively Inert & Labile Complexes*); d^3 ions like Cr^{III} are also coordinatively inert because the t_{2g} level is now exactly half filled, another favorable situation. On

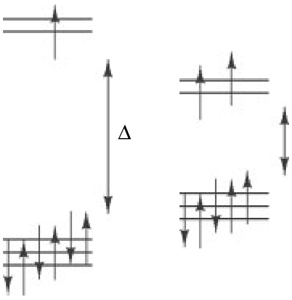

Figure 3 A d^7 ion is paramagnetic even in the low-spin form

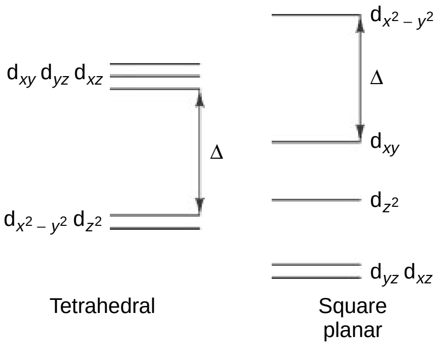

Figure 4 Crystal field splitting patterns for the common coordination geometries: tetrahedral and square planar. For the square-planar arrangement, the z-axis is conventionally taken to be perpendicular to the square plane

the other hand, Co^{II} and other non-d^6 and -d^3 ions can be coordinatively labile.

The colors of transition metal ions often arise from the absorption of light that corresponds to the d_π to d_σ energy gap, Δ. The spectrum of the complex can then give a direct measure of this gap, and therefore of the CF strength. So-called high-field ligands (*see Ligand Field Theory*) such as thiourea, CO, and C_2H_4 give rise to a large value of Δ. Low-field ligands such as H_2O or NH_3 can give such a low Δ that the spin pairing is lost and even the d^6 configuration can become paramagnetic (Figure 2, right). This rarely occurs for organometallic ligands, since they tend to induce a large Δ splitting, and are therefore high-field ligands. Other important CF splitting patterns are shown in Figure 4. For the same ligand set the tetrahedral splitting parameter is smaller than that for the octahedral geometry by a factor of 2/3, because we now have only four ligands, not six, and so the chance of having a high-spin species is larger. The ordering of the levels is also reversed, three going up and only two down in energy. This is because the d_{xy}, d_{yz}, and d_{xz} orbitals now point toward, and the $d_{x^2-y^2}$ and d_{z^2} orbitals away from the ligands. d^{10} ions (e.g. Zn^{II}, Pt^0, Cu^I) are often tetrahedral. The square-planar splitting pattern is also shown. This geometry tends to be adopted by d^8 ions such as Au^{III}, Ni^{II}, Pd^{II}, or Pt^{II}, and Rh^I or Ir^I, in which case the complex is diamagnetic; it is also common for paramagnetic d^9 ions, for example Cu^{II}.

5.1 Electron Transfer

A very important feature of Werner complexes is the ease with which they can undergo electron transfer (ET) reactions[5] in which they are reduced or oxidized by one or more electrons. This can completely change the properties of the complex. A classic case is Co^{III}, which as a d^6 metal is coordinatively inert but on reduction the coordinatively labile d^7 Co^{II} state is formed. The work of Taube[5a] showed how certain electron-transfer reactions occur between two separate complexes (outer-sphere reactions), while others take place through a bridging ligand (inner-sphere type). This was most elegantly shown by experiments in which the bridging group was transferred from one coordinatively inert metal, which becomes labile in the redox process to a second metal, initially labile but which becomes inert in the redox process. The rate of outer-sphere ET reactions is often well predicted by Marcus-Hush theory,[6] which relates k_{12}, the rate of reaction between A_{red} and B_{ox}, to the equilibrium constant for the reaction (K_{12}) and the rates for the degenerate exchanges between A_{red} and A_{ox} (k_{11}) and between B_{red} and B_{ox} (k_{22}). The form of the equation which is most often used is shown in equation (5).

$$k_{12} = [k_{11}k_{22}K_{12}]^{1/2} \tag{5}$$

This is very similar in principle to a free energy relationship, such as the Hammett equation in organic chemistry. Normally the reaction rate goes up as the driving force goes up. Under certain special circumstances the rate reaches a maximum and begins to fall at very high driving force; the existence of this 'Marcus inverted region[7]' has been confirmed in several systems. This is fully covered in the article (*see* ***Electron Transfer in Coordination Compounds***) as well as in all standard textbooks of inorganic chemistry. ET can also occur in electrochemical processes (*see* ***Electrochemistry: Applications in Inorganic Chemistry***) and in photochemical processes (*see* ***Photochemistry of Transition Metal Complexes***).

6 THE LIGAND FIELD

The CF picture gives a useful understanding of coordination chemistry and one that is widely used for qualitative discussions. A more sophisticated version of this approach, LF theory (*see* ***Ligand Field Theory & Spectra***), which is really a conventional molecular orbital (or MO) picture, can be used for more accurate electronic structure calculations. In the CF model (Figure 5) we consider the s, the three p, and the five d orbitals of the valence shell of the isolated ion as well

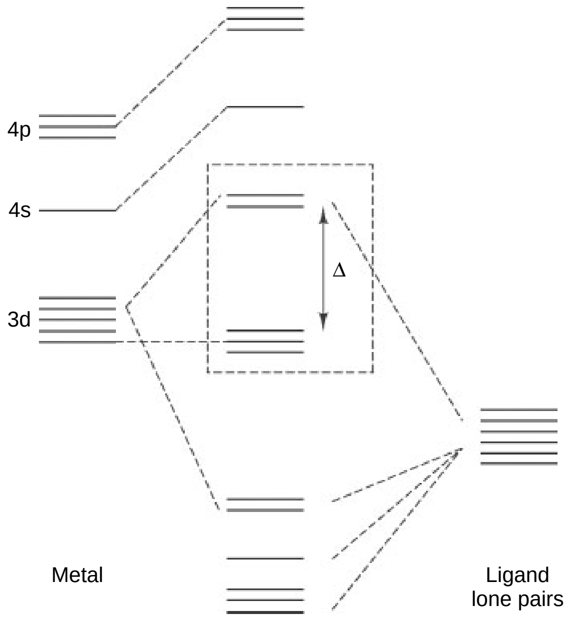

Figure 5 The molecular orbital or ligand field picture of metal–ligand bonding in an ML_6 complex. Compare this picture with Figure 1 to see how the octahedral crystal field splitting pattern (in the box) is still present in the MO model

as the six lone-pair orbitals of a set of pure σ donor ligands in an octahedron around the metal. Six of the metal orbitals, the s, the three p, and the two d_σ, which we will call the dsp_σ set, find symmetry matches in the six ligand orbitals. In combining the six metal orbitals with the six ligand orbitals, we make a bonding set of six (the M–L σ bonds) which are stabilized, and an antibonding set of six (the M–L σ^* levels) which are destabilized when the six L groups approach to bonding distance. The remaining three d orbitals, the d_π set, do not find a match among the ligand orbitals and remain nonbonding. In a d^6 ion we have six electrons from Co^{3+} and 12 electrons from the ligands, giving 18 in all. This means that all the levels up to and including the d_π set are filled, and the M–L σ^* levels remain unfilled. Note that we can identify the familiar CF splitting pattern in the d_π and two of the M–L σ^* levels. The Δ splitting will increase as the strength of the M–L σ bonds increase. The bond strength is the analog of the effective charge in the CF model. In the LF picture, high-field ligands are ones that form strong σ bonds. We can now see that a d_σ orbital is better described in the CF picture as an M–L σ-antibonding orbital, d_{σ^*}.

The L lone pairs start out in free L as pure ligand electrons but become bonding electron pairs shared between L and M when the M–L σ bonds are formed; these are the six lowest orbitals in Figure 5 and are always completely filled (12 electrons). Each M–L σ-bonding MO is formed by the combination of the ligand lone pair, L(σ), with M(d_σ) and has both metal and ligand character, but L(σ) predominates. Any MO will more closely resemble the parent atomic orbital (AO) which lies closest in energy to it, and L(σ) almost always lies below M(d_σ) and therefore closer to the M–L σ-bonding orbitals. This means that electrons which were purely L lone pairs in the free ligand gain some metal character in the complex; in other words the L(σ) lone pairs are partially transferred to the metal. As L becomes more basic, the energy of the L(σ) orbital increases, and the extent of ET will increase.

7 BACK BONDING

Ligands like NH_3 are good σ-donors but are not significant π-acceptors. CO, in contrast, is an example of a good π-acceptor, sometimes also called a π-acid ligand. Such ligands are of very great importance in organometallic chemistry. They tend to be very high-field ligands and form strong M–L bonds. All have empty orbitals of the correct symmetry to overlap with a filled d_π orbital of the metal. In the case of CO, this acceptor orbital is the CO π^*. Figure 6 shows how overlap takes place to form the M–C π-bond. It may seem paradoxical that an antibonding orbital like the π^*(CO) can form a bond, but this orbital is only antibonding with respect to C and O; it can still be bonding with respect to M and C.

We can make the LF diagram of Figure 5 appropriate for the case of $W(CO)_6$ by including the π^* levels of CO (Figure 7). The d_π set of levels still find no match with the six CO(σ) orbitals, which are lone pairs on C. They do interact strongly with the empty CO π^* levels. Since the M(d_π) set are filled in this d^6 complex, the result is that d_π electrons that were metal-centered now spend some of their time on the ligands: this means that the metal has donated some electron density to the ligands. This is called *Back Bonding* and is a key feature of M–L bonds where L is an unsaturated molecule.

As antibonding orbitals, these π^* levels are high in energy, but they are able to stabilize the d_π set as shown in Figure 7. This has two important consequences. First, the LF splitting parameter Δ rises, explaining why π-bonding ligands have such a strong LF. Secondly, back bonding allows electron density on the metal to make its way back to the ligands. This in turn allows low-valent or zerovalent metals to form complexes. Such metals are in a reduced state, and already have a high electron density (they are said to be very electron rich; *see Electron Rich Compound*). They cannot accept

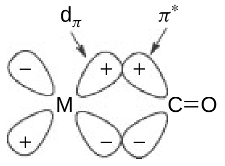

Figure 6 The overlap between a filled metal d_π orbital and an empty CO π^* orbital to give the π component of the M–CO bond. The plus and minus signs refer to the symmetry

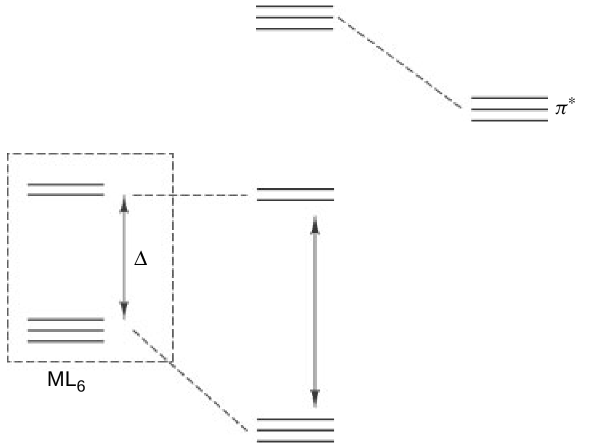

Figure 7 The effect of 'turning on' the π interaction between a π-acceptor ligand and the metal. The unoccupied, and relatively unstable, π^* orbitals of the ligand are shown on the right. Their effect is to stabilize the filled d_π orbitals of the complex and so increase Δ

further electrons from pure σ-donors; this is why $W(NH_3)_6$ is not a stable compound. By back bonding, the metal can relieve itself of some of this excess electron density. In $W(CO)_6$, back bonding is so effective that the compound is air stable and relatively unreactive; the CO groups have so stabilized the electrons that they have no tendency to be abstracted by an oxidizing agent. In $W(PMe_3)_6$ by contrast, back bonding is inefficient and the compound is very air sensitive and reactive.

Spectroscopic and theoretical studies show that for CO this π back donation is usually comparable to or greater than the CO-to-metal electron donation that constitutes the σ-bond. One of the most direct arguments is structural. The M=C bond in metal carbonyls is usually substantially shorter than an M–C single bond. This is easiest to test when both types of bond are present in the same complex, such as $CpMo(CO)_3Me$, where M–C is 2.38 Å, and M=CO is 1.99 Å. We have to remember that a putative M–CO single bond would be shorter than 2.38 Å by about 0.07 Å, to allow for the higher s-character (and therefore shorter bond length) of the sp hybrid on CO compared to the sp^3 hybrid of the methyl group. The remaining shortening of 0.32 Å is still substantial.

If CO were bound to the metal by its carbon lone pair, nonbonding with respect to CO, then the ν(CO) frequency in the complex would be very little different from that in free CO. BH_3, which is as pure a σ-acceptor as will bind to CO, shows a slight shift of ν(CO) to higher energy: free CO, 2149 cm^{-1}; H_3B–CO, 2178 cm^{-1}. Metal complexes, in contrast, show ν(CO) coordination shifts of hundreds of wave numbers to lower energy, consistent with the weakening of the C=O bond that would be expected if the π^* orbital were being filled by back donation (e.g. $Cr(CO)_6$, $\nu(CO) = 2000\ cm^{-1}$). Not only is there a coordination shift, but the shift is larger in cases where we would expect stronger back donation and vice versa. A net positive charge raises ν(CO), and a net negative charge lowers it (e.g. $V(CO)_6{}^-$, 1860 cm^{-1}; $Mn(CO)_6{}^+$, 2090 cm^{-1}). The effect of replacing three π-acceptor COs by the three pure σ-donor nitrogens of the dien ligand ($H_2NCH_2CH_2NHCH_2CH_2\ NH_2$) is almost as great as changing the net charge by one unit (e.g. $Cr(dien)(CO)_3$, 1880 cm^{-1}). This makes ν(CO) a good indicator of how electron rich a metal is, and it often correlates well with other ways of estimating electron-rich character, such as the ease of removing an electron.[4]

Series of compounds such as $V(CO)_6{}^-$, $Cr(CO)_6$, and $Mn(CO)_6{}^+$ are said to be *Isoelectronic* complexes because they have the same number of electrons distributed in very similar structures. Isoelectronic ligands are CO and NO^+ or CO and CN^-, for example. Strictly speaking, CO and CS are not isoelectronic, but as the difference between O and S lies in the number of core levels (the valence shell being the same), the term isoelectronic is often extended to cover such pairs. A comparison of isoelectronic complexes or ligands can be useful in making analogies and understanding trends.[8]

The dipole moments of a variety of coordination compounds show that the bond dipole moments of the M–L bonds of most σ-donor ligands are about 4 D, with the donor atom positive. In contrast, metal carbonyls show an M–C bond moment which is essentially zero because the M → L back donation compensates for L → M direct donation plus the enhanced polarization of CO on binding. Formation of the M–CO bond weakens the C–O bond relative to free CO because a π^* orbital on CO is now partly filled by back donation. This will still lead to a stable complex as long as the energy gained from the M–C bond exceeds the loss in C–O. Bond weakening within L on binding to a metal is a common feature in many M–L systems.

7.1 Frontier Orbitals

The picture sketched above for CO holds with slight modifications for a whole series of π-acceptor (or soft) ligands, such as alkenes, alkynes, arenes, carbenes, carbynes, NO, N_2, and PF_3. Each of these ligands has a filled orbital that acts as a σ -donor and an empty orbital that acts as a π-acceptor. These orbitals are almost always the highest occupied (*HOMO*) and lowest unoccupied molecular orbitals (*LUMO*) of L, respectively. The HOMO of L is a donor to the LUMO of the metal, which is normally d_σ. The LUMO of the ligand accepts back donation from a filled d_π orbital of the metal. The HOMO and LUMO of each fragment are the so-called *Frontier Orbitals,* and it is nearly always the case that these dominate the bonding. The HOMO of each fragment, M and L, is usually closest in energy to the LUMO of the partner fragment than to any other vacant orbital of the partner. Strong bonding is therefore expected if the *HOMO−LUMO Gap* of both partners is small. A small HOMO−LUMO gap usually makes a ligand soft, because it is a good π-acceptor.

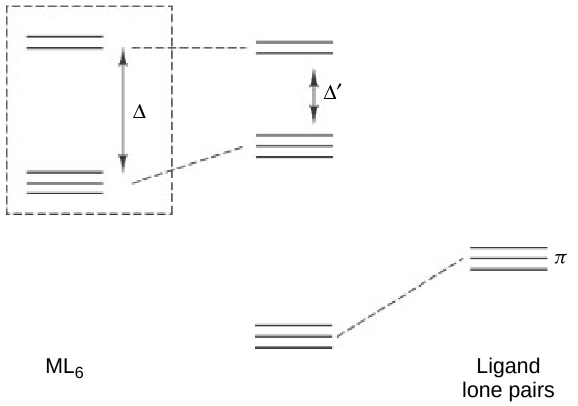

Figure 8 The effect of 'turning on' the π interaction between a π-donor ligand and the metal. The occupied, and relatively stable, lone pair (π) orbitals of the ligand are shown on the right. Their effect is to destabilize the filled d_π orbitals of the complex and so decrease Δ

7.2 π-Donor Ligands

Ligands such as OR^-, F^-, and Cl^- are π-donors as a result of the lone pairs that are left after one lone pair has formed the M–L σ-bond. Instead of stabilizing the d_π electrons in a d^6 complex as does a π-acceptor, these electrons are now destabilized by what is effectively a repulsion between two filled orbitals. This lowers Δ, as shown in Figure 8, and leads to a weaker M–L bond than in the π-acceptor case. Lone pairs on electronegative atoms, such as Cl and O, are much more stable than the $M(d_\pi)$ level and this is why they are lower in Figure 8 than are the π^* orbitals in Figure 7. A d^0 complex, in contrast, readily binds π-donor ligands, as in $Ti(OMe)_4$ or $[TiF_6]^{2-}$ because the empty d_π orbitals are now available for π-bonding.

8 ELECTRONEUTRALITY

In 1948, Pauling[9] proposed the powerful *Electroneutrality* principle. This says that the atoms in molecules arrange themselves so that their net charges fall within rather narrow limits, from about $+1$ to -1 overall. In fact, the range for any given element is likely to be narrower than this, and will tend toward a preferred charge, which will differ according to the electronegativity of the element concerned. The nonmetals, such as C, N, or O, will tend to be closer to -1, and the metals such as Li, Mg, and Fe, will tend to be closer to $+1$. This implies that as far as electroneutrality arguments go, an element will bond best to other elements which have complementary preferred charges. In this way, each can satisfy the other. An electropositive element will prefer an electronegative one, for example, NaCl, TiO_2, and elements with an intermediate electronegativity will tend to prefer each other, for example, HgS, Au metal. An isolated Co^{3+} ion is not an electroneutral species, as it has an excessively high positive charge. In its compounds it will therefore seek good electron donors as ligands, such as O^{2-} in Co_2O_3, or NH_3 in the amine complexes. On the other hand, an isolated W^0 atom is too electron rich for its electronegativity, so it will prefer net electron attracting ligands such as CO.

There is a deeper reason why the d orbitals of transition metals are only available for back donation in electron-rich complexes. Co^{III}, for example, has a filled d_π level, but it does not bind CO because it is too low in energy and therefore not sufficiently basic. The reason is that the s, p, and d orbitals respond differently to a change in the charge on the metal. If the metal is in a high oxidation state, like Co^{III}, then there are three electron 'holes' in the valence shell compared with the neutral atom. This means that the valence shell of the ion is positive with respect to the situation in the atom. Since d orbitals tend to have their maximum electron density far away from the nucleus (because they have two planar nodes), p orbitals reach their maximum somewhat closer to the nucleus (one planar node), and s orbitals reach their maximum at the nucleus (no planar nodes), the orbitals will be less sensitive to the 3+ change in the net charge that took place on going from Co^0 to Co^{III}, in the order $d > p > s$. In other words, the d orbitals will be much more strongly stabilized than the others on going from the atom to the ion. This is why the atomic electron configuration for the transition metals involves s orbital occupation, for example, Co is d^7s^2, but the configuration of the ion is d^6, not d^4s^2. On the other hand, the more electron rich (i.e. the more reduced, or low oxidation state) the metal complex, the less positive will be the charge on the metal. This will destabilize the d orbitals and make them more available for back donation.

We also alter the orbital energies as we go from left to right in the transition series. For each step to the right, a proton is added to the nucleus. This extra positive charge stabilizes all the orbitals. The earlier metals are the more electropositive because it is easier to remove electrons from their less-stable energy levels. The sensitivity of the orbitals to this change is different from what we saw above. This time the order is $d \sim s > p$ because the s orbital, having a maximum electron density at the nucleus, is more stabilized by the extra protons that we add for each step to the right in the periodic table, than are the p orbitals, that have a planar node at the nucleus. The d orbitals are stabilized because of their lower principal quantum number (e.g. 3d versus 4s and 4p for Fe). The special property of the transition metals is that three types of orbital are in the valence shell, neither too stable nor too unstable to contribute significantly to the bonding. Metal carbonyls, for example, are only stable for groups 4–10 because CO requires d orbital participation to bind effectively. For the same reason, d^0 metals form carbonyls with very low stability, and in the later d^{10} metals, the d orbitals become too stable to back donate and carbonyls are rare.

Finally, as we go down a group from the first-row transition element to the second row, the outer valence electrons become more and more shielded from the nucleus by the extra shell of electrons that has been added. They are therefore more easily lost, and the heavier element tends to be the more basic and more electronegative, and forms more stable high oxidation state complexes. This trend also extends to the third row, but as the f electrons that were added to build up the lanthanide elements are not as effective as s, p, or even d electrons in shielding the valence electrons from the nucleus, there is a smaller change on going from the second- to the third-row element than was the case for moving from the first row to the second. Compare, for example, Cr^{VI} in Na_2CrO_4 and Mn^{VII} in $KMnO_4$, which are unstable and make good oxidizing agents, with their stable analogues in the second and third rows, Na_2MoO_4, Na_2WO_4, and $KReO_4$. Similarly, the increase in covalent radii is larger on going from the first to the second row than it is on going from the second to the third. This is termed the 'Lanthanide Contraction'; it arises because the f-block elements occur between the second and third rows of the transition metals. These add 14 additional protons to the nucleus, while adding 14 f-electrons that poorly shield the additional nuclear charge, thus increasing the stability of the electrons in later elements.

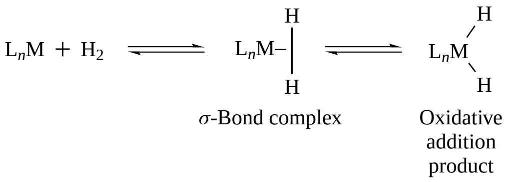
Another aspect of electroneutrality is that ionic compounds with excessively high positive or negative charges are not normally formed. The great majority of compounds are neutral, net charges of ± 1 are not uncommon, but net ionic charges of ± 2 or greater are increasingly rare unless there is some special reason to expect them, such as the presence of several metals to share the ionic charge.

9 TYPES OF LIGANDS

Most ligands form the M–L σ-bond by using a lone pair, that is, a pair of electrons which are nonbonding in the free ligand. For ligands which have them, lone pairs are often the HOMO and the most basic electrons in the molecule. Classical Werner coordination complexes always involve lone-pair donor ligands. There are two other types of ligand found in organometallic compounds, of which C_2H_4 and H_2 are typical examples.

Ethylene is an example of a molecule that has no lone pairs, yet it binds strongly to low-valent metals. In this case the HOMO is the C=C π-bond and it is these electrons that form the M–L σ-bond, as shown in Figure 9(a). The arrow marked '1' represents the π-bonding electron pair of ethylene being donated to the metal. There is also a back bonding component (marked '2') where the π^* orbital of ethylene plays the role of acceptor. Since the C=C π-bond lies above and below the molecular plane, the metal has to bind out of the plane where the electrons are. This type of binding is sometimes represented as (η^2-C_2H_4), where η represents the hapticity of the ligand, defined as the number of atoms in the ligand bonded to the metal.

Molecular hydrogen has neither a lone pair nor a π-bond, yet it also binds as an intact molecule to metals in such complexes as the Kubas[10] complex, $[W(\eta^2\text{-}H_2)(CO)_3L_2]$. The only available electron pair is the H–H σ-bond and this becomes the donor ('3' in Figure 9(b)). Back donation in this case ('4' in Figure 9(b)) is accepted by the $H_2\sigma^*$ orbital. The metal binds side-on to H_2 to maximize σ- and π-overlap (equation 6). Related *σ-Complexes*[11] are formed with C–H, Si–H, B–H, and M–H bonds. In general, the basicity of electron pairs decreases in the order: lone pairs > π-bonding pairs > σ-bonding pairs, because taking part in a bond stabilizes electrons. The usual order of binding ability is therefore: lone-pair donor > π-bond donor > σ-bond donor.



(6)

For lone-pair donors the M–L π-bond can have two electrons (2e) and be attractive, as we saw for CO (Figures 6 and 7) or 4e and be repulsive, as is the case for F^- (Figure 8). For the more weakly binding σ- and π-bond donors, the M–L π-bond is nearly always attractive because if it were not, L would not bind strongly enough to form an isolable complex. In the π-bond a $M(d_\pi)$ electron pair is donated to an empty antibonding orbital of the ligand, usually a π^* for π-bond donors and a σ^* for σ-bond donors (Figure 9). In the case of a π-bond donor like ethylene, this back bonding weakens the C=C π-bond but does not break it because C_2H_4 is still held together by strong C–C and C–H σ-bonds which are not involved in M–L bond formation. The C=C distance of 1.32 Å in free ethylene is only lengthened to 1.35–1.5 Å in the complex.

For σ-bond donors such as H_2, forming the M–L σ-bond partially depletes the H–H σ-bond because electrons that were fully engaged in keeping the two H atoms together in free H_2 are now also delocalized over the metal (hence the name 2-electron–3-center bond for this type of interaction). Back bonding into the H–H σ^* causes additional weakening of

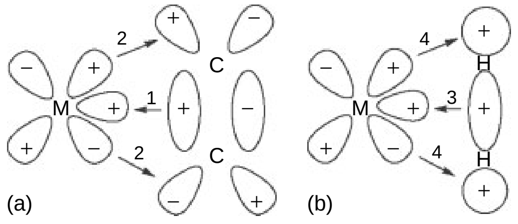


Figure 9 The bonding of a typical π-ligand, ethylene

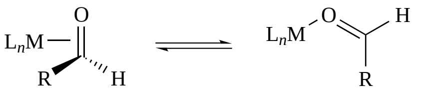
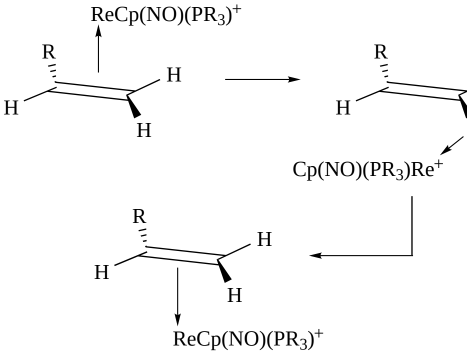
the H–H σ-bond. Free H_2 has an H–H distance of 0.74 Å, but the H–H distances in H_2 complexes go all the way from 0.82 to 1.5 Å. Eventually the H–H bond breaks and a dihydride is formed (equation 6); this is called the *Oxidative Addition*. Formation of a σ-bond complex can be thought of as an incomplete oxidative addition. Table 2 classifies common ligands by the nature of the M–L σ- and π-bonds.

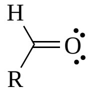
Some ligands have several types of electron pair available for bonding. For example, aldehydes (**10**) have the C=O π-bond and lone pairs on the oxygen. When they act as π-bond donors, aldehydes bind side-on (**11**) like ethylene; when they act as lone-pair donors, they bind end-on (**12**). Sometimes an equilibrium is found (equation 7) but strongly π-donor metals favor (**11**) and strong σ-acceptors favor (**12**). Alkenes have both a C=C π-bond and C–H σ-bonds. Gladysz[12] has shown how metals can move from one face of a C=C bond to the other via intermediate binding to the C–H bond (equation 8).



(**11**) (**12**) (7)

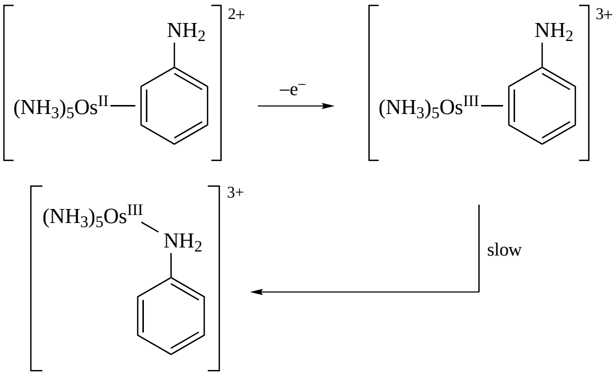


(8)



(**10**)

The $\{(NH_3)_5Os^{II}\}^{2+}$ fragment in equation (9) is a strong π-donor because NH_3 is strongly σ-donor but not a π-acceptor ligand, and it prefers to bind to one C=C bond of aniline. Oxidation to Os^{III} causes a sharp fall-off in π-donor power because the extra positive charge stabilizes the d orbitals, and the complex rearranges to the N-bound aniline form.[13] This illustrates how the electronic character of a metal can be altered by choosing the ligand set and oxidation state.



(9)

Table 2 Types of ligands

Type	Examples
Lone-pair donors	NH_3, H_2O, PPh_3, CO, Cl^-, CH_3^-, H^-
π-Bond donors	η^2-C_2H_4, η^6-C_6H_6, η^4-C_4H_6
σ-Bond donors	η^2-H_2, η^2-R_3C–H, η^2-R_3Si–H

10 THE EIGHTEEN ELECTRON RULE AND ITS LIMITATIONS

The 18e rule[14] is a way to help decide whether a given d-block transition metal organometallic complex is likely to be stable. In carbon chemistry, CH_5 with a pentavalent carbon is not stable, but CH_4 with its octet is stable. Carbon therefore follows an 8e rule which corresponds to carbon using its s and three p orbitals to form four filled bonding orbitals and four unfilled antibonding orbitals. On the covalent model we can consider that of the eight bonding electrons, four come from carbon and one each comes from the four H substituents. We can therefore think of each H atom as being a 1e ligand to carbon. The same applies to a transition metal but the target electron count is now 18.

We can also assign an oxidation state to a metal in a complex much as we can assign a formal oxidation state to carbon in an organic molecule by artificially dissecting it into ions. In doing this, each electron pair in any bond is assigned to the most electronegative of the two atoms or groups that constitute the bond. For methane, this dissection gives $C^{4-} + 4H^+$, carbon being the more electronegative element. This makes methane an 8e compound with an oxidation state of C^{-IV}. The net electron count is invariant whether we adopt the covalent (4e{C atom} + 4 × 1e{4H atoms} = 8e), or ionic models (8e{C^{4-}ion} + 4 × 0e{$4H^+$ions} = 8e). In the 18e rule, which applies to many low-valent transition metal complexes, the metal now uses nine orbitals: one s and three p orbitals, as before, but now also five d orbitals. Only a limited number of combinations of metal and ligand will be able to attain the 18e count. Figure 5 shows that 18e will fill the MO diagram of the complex ML_6 up to the d_π level, and leave the d_σ orbitals empty. The resulting configuration is analogous to the closed shell present in the group 18 elements and is therefore called the *noble gas configuration*. Each AO on the metal that remains nonbonding will clearly give rise to one MO in the complex; each AO that interacts with a ligand orbital will give rise to one bonding MO, which will be filled

in the complex, and one antibonding MO, that will normally be empty. Our nine metal orbitals will therefore give rise to nine low-lying orbitals in the complex and to fill these we will need 18 electrons.

Table 3 shows how the first-row carbonyls mostly follow the 18e rule. Each metal contributes the same number of electrons as its group number, and each CO contributes 2e for its lone pair. π Back bonding makes no difference to the electron count for the metal. In the free atom it had one AO for each pair of d_π electrons it uses for back bonding; in the complex it still has one filled MO, but now delocalized over metal and ligands.

In cases where we start with an odd number of electrons on the metal, we can never reach an even number, 18, by adding 2e ligands like CO. In such cases, M–M bonds are often formed; for example, $Mn_2(CO)_{10}$ achieves 18e because two 17e $Mn(CO)_5$ units combine. For the 17e fragment $Co(CO)_4$, dimerization also takes place via a metal–metal bond, but a pair of COs also move into bridging positions. It makes no difference to the electron count whether a CO bridges or not, because the bridging CO is a 1e ligand to each metal, so an M–M bond is still required to attain 18e. The even-electron metals are able to achieve 18e without M–M bond formation, and in each case they do so by binding the appropriate number of COs; the odd-electron metals need to form M–M bonds.

In Table 4 we see some of the common ligands and their electron counts on the ionic and covalent models. In the former, we dissect an M–X bond into M^+ and X^- and in the latter model into M• and X• radicals. The symbol L is commonly used to signify a neutral ligand, which can be lone-pair donors (such as CO or NH_3), π-bond donors (such as C_2H_4), or σ-bond donors (such as H_2), which are all 2e ligands on both models. The symbol X refers to ligands such as H, Cl, or Me, which are 1e X ligands on the covalent model and 2e X^- ligands on the ionic model. In the covalent model we regard them as 1e $X^\bullet$ radicals bonding to the neutral metal atom; in the ionic model we regard them as 2e X^- anions bonding to the M^+ cation. Green has developed a useful extension of this nomenclature by which more complicated ligands can be classified. For example, benzene (**13**) can be considered as a combination of three C=C ligands, and therefore as L_3. The allyl group can be considered as a combination of an alkyl and a C=C group. The two canonical forms (**14**) and (**15**) show how we can consider allyl groups in which all three carbons are bound to the metal as LX ligands. This can also be represented in the delocalized form as (**16**). In such a case the hapticity of the ligand, the number of ligand atoms bound to the metal, is 3 and so (**17**), referred to as bis-π-allylnickel in the older literature, is now known as bis-η^3-allylnickel, or $[Ni(\eta^3\text{-}C_3H_5)_2]$. Occasionally the letter h is used instead of η and sometimes η is used without a superscript as a synonym for the older form, π. The electron count of the η^3 form of the allyl group is 3e on the covalent model and 4e on the ionic model, as suggested by the LX label. The advantage of the LX label is that those who follow the covalent model will translate LX as meaning a 3e ligand, and the devotees of the ionic model will translate LX as meaning a 4e ligand.

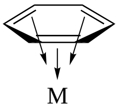
Table 3 The first-row carbonyls

$V(CO)_6$	17e; $V(CO)_6{}^-$ also stable
$Cr(CO)_6$	
$(CO)_5Mn\text{–}Mn(CO)_5$	The M–M bond contributes 1e to each metal; all the CO groups are terminal
$Fe(CO)_5$	
$(CO)_3Co(\mu\text{-}CO)_2Co(CO)_3$	A μ-CO contributes 1e to each metal and there is also an M–M bond
$Ni(CO)_4$	

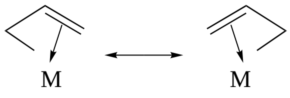
Table 4 Common ligands and their electron counts

Ligand	Type	Covalent model	Ionic model
Me, Cl, Ph, Cl, η^1-allyl, NO (bent)[a]	X	1e	2e
Lone-pair donors: CO, NH_3	L	2e	2e
π-Bond donors: C_2H_4	L	2e	2e
σ-Bond donors: (H_2)	L	2e	2e
η^3-Allyl, η^3-acetate	LX	3e	4e
NO (linear)[a]	LX	3e	2e
η^4-Butadiene	L_2[b]	4e	4e
η^5-Cp	L_2X	5e	6e
η^6-Benzene	L_3	6e	6e

[a]Linear NO is considered as NO^+ on the ionic model. [b]The alternative LX_2 structure sometimes adopted gives the same electron count.



(**13**)



(**14**) (**15**)

(**16**)

(**17**)

(**18**)

There is also a second way (**18**) that the allyl group can bind: this is the η^1-allyl or σ-allyl form. In this bonding mode the allyl behaves as an X-type ligand, like a methyl group, and is therefore a 1e ligand on the covalent model and a 2e ligand on the ionic model. Some examples of electron counting, such as (**21–23**), are shown in Figure 10. Note the dissection into atoms and radicals in the covalent model and into ions in the ionic model.

Bridging ligands are very common in coordination chemistry and their presence is symbolized by the prefix μ. Bridging ligands are usually counted as follows. First, we will look at bridging halide. This carries a lone pair, which is donated to the second metal in forming the bridge. An L_nMCl

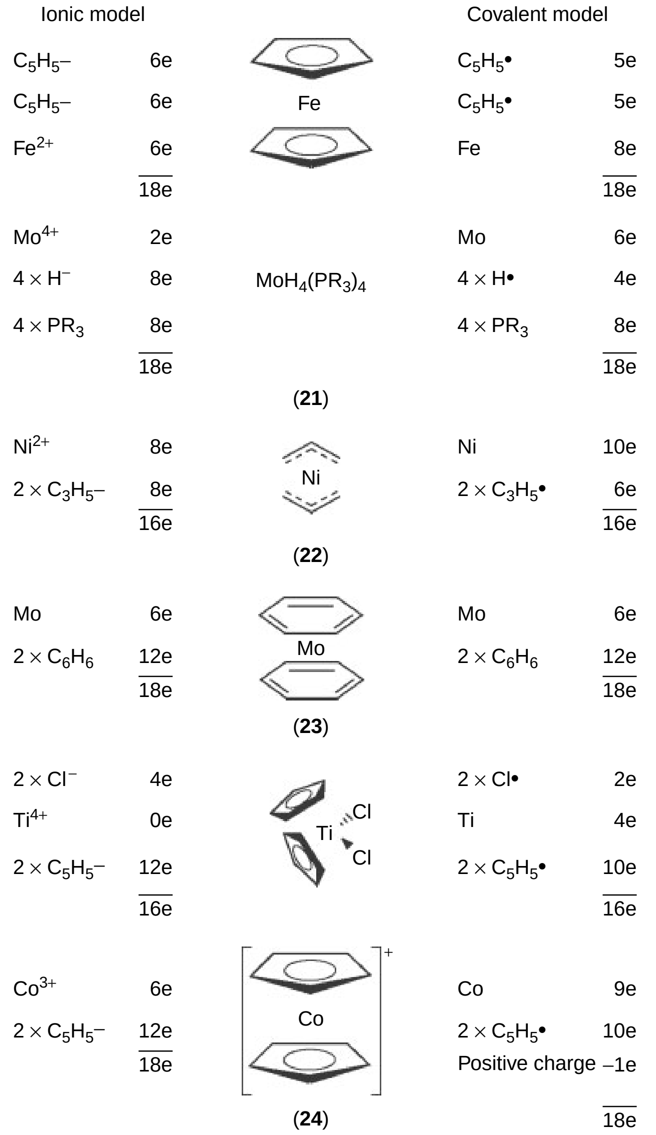


Figure 10 Electron counting on the covalent and ionic models. For (**24**), note the adjustment to account for the positive ionic charge on the complex as a whole; for anions, the net charge is added to the total

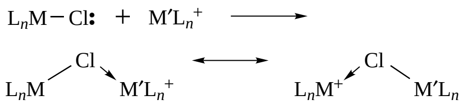
group is effectively acting as a ligand to the second metal. If $ML_n = M'L_n$ then the two bonds to Cl are indistinguishable by resonance between (**19**) and (**20**) (equation 10).



(10)

(**19**) (**20**)

As shown in (**25**) and (**26**), M–X signifies a normal covalent bond but L → M is used for the coordinate bond, as an indication that both electrons are regarded as originating from the ligand L. For complex ions we have to adjust for the net ionic charge in making the electron count. For example, $CoCp_2^+$ (**24** in Figure 10) is counted on the covalent model as $9 + 10 - 1 = 18$e. Electron counting can be summarized by equation (11), which shows the electron count for a generalized complex $[MX_aL_b]^{c+}$, where N is the group number of the metal (and therefore the number of electrons in the neutral M atom):

$$\text{electron count} = N + a + 2b - c \tag{11}$$

M←L M—X

(**25**) (**26**)

10.1 Limitations of the Eighteen Electron Rule

There are many cases in which the electron count for a stable complex is not 18 (e.g. $MeTiCl_3$, 8e; Me_2NbCl_3, 10e; WMe_6, 12e; $Pt(PCy_3)_2$, 14e; $[M(H_2O)_6]^{2+}$ (M = V, 15e; Cr, 16e; Mn, 17e; Fe, 18e); $CoCp_2$, 19e; $NiCp_2$, 20e). The rule works best for hydrides and carbonyls, because these are sterically small, high-field ligands. Being small, as many will generally bind as are required to achieve 18e. As high-field ligands, Δ for the complex will be large. This will mean that the d_{σ^*} orbitals, which would be filled if the metal had more than 18e, are high in energy and therefore poor acceptors. On the other hand, the d_π orbitals, which would have to give up electrons if the molecule had less than 18e, are low in energy thanks to π-bonding by CO (or, in the case of H, thanks to the very strong σ-bond and the absence of repulsive π-interactions with any lone pairs). The d_π level is therefore a good acceptor and, to be stable, a complex must have this level filled (otherwise the electrophilic metal will gain electrons by binding more CO, or the solvent or some functional group in the ligands until the 18e configuration is attained). M–M bonded compounds also tend to obey the rule.

Conversely, the rule works least well for high-valent metals with weak-field ligands. In the hexaaqua ions $M(H_2O)_6{}^{2+}$ (M = V, Cr, Mn, Fe, Co, Ni), the structure is the same whatever the electron count of the metal and so must be dictated by the fact that six H_2O molecules fit well around a metal ion. H_2O has two lone pairs, one of which it uses to form a σ-bond. This leaves one remaining on the ligand, which acts as a π-donor to the metal and so lowers Δ; H_2O is therefore a weak-field ligand. If Δ is small, then the tendency to adopt the 18e configuration is also small because it is easy to add electrons to the low-lying d_{σ^*}, or to remove them from the high-lying d_π.

An important class of complexes follow a 16e, rather than an 18e, rule, because one of the nine orbitals is very high-lying and is usually empty. This can happen for the d^8 metals of groups 8–11 (Table 5). Group 8 shows the least, and group 11 the highest, tendency to become 16e. When these metals are 16e, they normally adopt the square-planar geometry, which makes the $d_{x^2-y^2}$ orbital very high in energy. To go to an 18e species the metal has to rehybridize to

Table 5 The d^9 metals which can adopt a 16e configuration

Group	8^a	9^b	10	11
	Fe^0	Co^I	Ni^{II}	$Cu^{III c}$
	Ru^0	Rh^I	Pd^{II}	–
	Os^0	Ir^I	Pt^{II}	Au^{III}

[a]These metals prefer 18e to 16e. [b]The 16e configuration is more often seen, but 18e complexes are common. [c]A rare oxidation state.

give a trigonal bipyramidal geometry, so as to direct the empty orbital toward the incoming fifth ligand and lower its energy. Some examples of 16e complexes of this sort are $RhClL_3$, $IrCl(CO)L_2$, $PdCl_2L_2$, $[PtCl_4]^{2-}$, and $[AuMe_4]^-$ (L = t-phosphine).

The smaller metal clusters, such as $Os_3(CO)_{12}$, often obey the 18e rule for each metal, but for clusters of six metals or more there are deviations, for which special cluster counting rules have been devised.[1c] The rule is not useful for main group elements (e.g. $ZnMe_2$, 14e; $MeHg(bipy)^+$, 16e; $[I(py)_2]^+$, 20e; $[SbF_6]^-$, 22e; IF_7, 24e). The lanthanides and actinides have seven f orbitals to fill before they even start on the d orbitals, and so they are essentially never able to bind a sufficient number of ligands to raise the electron count to the $s^2p^6d^{10}f^{14}$ or 32e configuration of the appropriate noble gas (e.g. $U(cot)_2$, 22e; Cp_2LuMe, 28e). This means that the stoichiometry of the complex tends to be decided by steric saturation of the space around the metal. Paramagnetic complexes (e.g. $V(CO)_6$, 17e; Cp_2Fe^+, 17e; Cp_2Ni, 20e) do not generally obey the 18e rule. Some of these have reactions in which they attain an 18e configuration, for example, the 19e CpFe(η^6-arene) is a powerful 1e donor.[10]

Electron counting in metal clusters uses Wade's rule (*see Ligand Field Theory*).

11 OXIDATION STATE

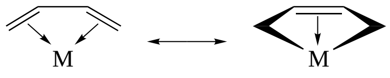
The oxidation state of a metal in a complex is simply the charge that the metal would have on the ionic model. In practice, all we have to do for a neutral complex is to count the number of X ligands. For example, Cp_2Fe has two L_2X ligands and so can be represented as MX_2L_4; this means that the oxidation state (OS) is 2+, so Cp_2Fe is said to be Fe^{II}. For a complex ion we need also to take account of the net charge, as shown for $[MX_aL_b]^{c+}$ in equation (11). For example, Cp_2Fe^+ is Fe^{III} and $[W(CO)_5]^{2-}$ is W^{-II}. Once we have the oxidation state, we can immediately obtain the corresponding d^n configuration. This is simply the number of d electrons that would be present in the free metal ion which corresponds to the oxidation state we have assigned. For Cp_2Fe^+ the OS is Fe^{III}, which corresponds to the Fe^{3+} ion. The iron atom, being in group 8, has 8e, and so the ion has 8 − 3 = 5e. Cp_2Fe^+ is therefore said to be a d^5 complex. Equations (12) and (13) give the value of n in a general form. The significance of the d^n configuration is that it tells us how to fill up the CF diagrams we saw in Section 4. For example, the odd number for Cp_2Fe^+ implies paramagnetism because in a mononuclear complex we cannot pair five electrons, whatever the d orbital splitting.

$$\mathrm{OS} = c + a \tag{12}$$

$$n = N - (c + a) = N - c - a \tag{13}$$

11.1 Ambiguous Oxidation States

There are many situations in which the formal oxidation state is ambiguous and cannot be specified. Any organometallic fragment that has several resonance forms that contribute to a comparable extent to the real structure can be affected. For example, this is the case for the resonance forms (**27**) and (**28**) in butadiene complexes. One structure is L_2 (or π_2), the other LX_2 (or $\pi\sigma_2$). The binding of butadiene as (**27**) leaves the oxidation state of the metal unchanged, but as (**28**) it becomes more positive by two units. On the covalent model, each gives exactly the same electron count: 4e. On the ionic model, the count changes by 2e (**27**, 4e; **28**, 6e) but this is compensated by a 2e 'oxidation' of the metal. In the case of W(butadiene)$_3$, we can attribute any even oxidation state between W^0 and W^{VI} to the molecule by counting one or more of the ligands as LX_2, rather than L_2. To avoid misunderstandings it is therefore necessary to specify the resonance form to which the formal oxidation state applies. For neutral ligands like butadiene the neutral L_2 form is generally used because this is the stable form of the ligand in the free state. Yet crystal structural studies show that the ligand can in reality more closely resemble (**28**) rather than (**27**). Clearly, we can place no reliance on the formal oxidation state to tell us about the real charge on the metal in W(butadiene)$_3$. In spite of its ambiguities, the oxidation state convention is almost universally used in classifying organometallic complexes.



(**27**) (**28**)

One very useful generalization is that the oxidation state of a complex can never be higher than the group number of the transition metal involved. Ti can have no higher oxidation state than Ti^{IV}, for example. This is because Ti has only four valence electrons with which to form bonds and $TiMe_6$ cannot exist.

12 COORDINATION NUMBER

The coordination number (CN) of a complex is easily defined in cases in which the ligands are all monodentate;

it is simply the number of ligands present (e.g. $[PtCl_4]^{2-}$, CN = 4; $W(CO)_6$, CN = 6). A useful generalization is that the coordination number cannot exceed nine for the transition metals. This is because the metal only has nine valence orbitals, and each ligand will need its own orbital. In most cases the CN will be less than nine, and some of the nine orbitals will either be lone pairs on the metal or engaged in back bonding.

$$\text{Coordination number: CN} = a + b \leq 9 \quad (14)$$

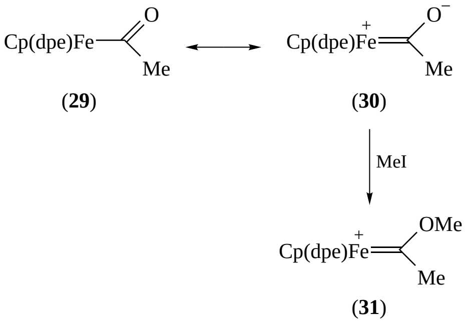
$$\text{Electron count:} N + a + 2b - c = 18 \quad (15)$$

$$\text{Oxidation state:} \quad \text{OS} = a + c \leq N \quad (16)$$

Each coordination number has one or more coordination geometries associated with it. The most common are: CN = 4, tetrahedral and square planar; CN = 5, trigonal bipyramidal and square pyramidal; CN = 6, octahedral. The article (*see* ***Coordination Numbers & Geometries***) should be consulted for other examples. In order to reach the maximum coordination number for d-block metals of nine, we need relatively small ligands, for example $[ReH_9]^{2-}$. Coordination numbers lower than four tend to be found with bulky ligands, which cannot bind in greater number without prohibitive steric interference between the ligands, for example $Pt(PCy_3)_2$.

Unfortunately, the definition of coordination number is less clear-cut for organometallic species, such as Cp_2Fe. Is this molecule two-coordinate (there are two ligands), or six-coordinate (there are six electron pairs involved in metal–ligand bonding), or ten-coordinate (the 10 C atoms are all within bonding distance of the metal)? Most often it is the second definition that is used, which is equivalent to adding up the number of L's and X's from all the ligands.

Equations (14–17) summarize the different counting rules as applied to our generalized d-block transition metal complex $[MX_aL_b]^{c+}$, where N is the Group number, and n is the d^n configuration.



(29) (30) (17)

(31) (18)

13 EFFECTS OF COMPLEXATION

Much of the interest and importance of coordination chemistry comes from the fact that the chemical character of many ligands is profoundly modified on binding to the metal. For the typical range of metal fragments L_nM, there is a smooth gradation of properties from strongly σ-acceptor to strongly π-basic. A typical unsaturated ligand Q will be depleted of charge and made more electrophilic by a σ-acceptor L_nM fragment, and be made to accept electrons and therefore become more nucleophilic for a π-basic L_nM fragment. As an example, water is made more acidic by 4–6 pK units on binding to a divalent metal ion. As another example, free benzene is very resistant to attack by nucleophiles, but reacts readily with electrophiles. In the complex $(C_6H_6)Cr(CO)_3$, in contrast, the $Cr(CO)_3$ fragment is a good acceptor, by virtue of its three CO ligands, and so depletes the electron density on the aromatic ring. This makes it susceptible to nucleophilic attack, but resistant to electrophilic attack. A factor that increases the electrophilic character of the ligands is a net positive charge on the complex, e.g. $[Ru(\eta^6\text{-}C_6H_6)_2]^{2+}$. On the other hand, both Cp groups and phosphines are strong donors, and so the acetyl group in (**29**) in equation (18) is very largely in the carbene form shown in (**30**). It is subject to electrophilic attack to give (**31**).

There is a third important situation that we need to consider. If the metal fragment is somewhere in the middle of the range of electronic properties mentioned above, and is both a σ-acceptor and a π-donor, then it might be thought that the unsaturated ligand would differ little in its chemical character from the situation in the free state. In fact, the ligand can still be strongly activated by polarization (*see Polarizability*). This is because the σ-donation from the ligand to the metal usually depletes the electron density of one atom or set of atoms in the ligand, but π-back donation from the metal raises the electron density on a different set of atoms. For example, in the case of molecular nitrogen N_2, σ-donation to the metal comes from a lone pair on the nitrogen directly bonded to the metal. The back bonding from the metal goes into a π^* orbital which is delocalized over both nitrogens. This means that the nitrogen directly bound to the metal tends to become positively charged, and the terminal nitrogen negatively charged on binding (see (**32**)).

$$M{-}N^{\delta+}{=}N^{\delta-}$$

(**32**)

This polarization activates the coordinated N_2 toward chemical reactions, such as protonation at the terminal nitrogen and nucleophilic attack at the vicinal nitrogen; the free ligand is, of course, notably unreactive. If a ligand is normally reactive toward, say, nucleophiles, we can deactivate it by binding to a nucleophilic metal. The metal can then be thought of as acting as a protecting group. A ligand that is inert toward nucleophilic attack can be activated by binding to an electrophilic metal.

13.1 Free ≠ Bound

The bound form of a given ligand is usually very different in properties compared to the same ligand in the free state. A knowledge of the behavior of carbenes, dienes, and so on, can be misleading in trying to understand the chemistry of their complexes. For example, one of the most notable features of diene chemistry is their reaction with dienophiles in the Diels–Alder reaction. Dienes coordinated in the η^4-fashion do not give this reaction. In a sense, we might consider that the complex is already a Diels–Alder adduct, with the metal as the dienophile.

Not only are the properties of ligands altered by binding, so are the properties of the metal ions. For example, Co^{III} is very strongly oxidizing in a simple compound such as the acetate. We know from Werner's work that most of this oxidizing power can be quenched by binding ammonia to the Co^{III} ion. The $Co(NH_3)_6{}^{3+}$ ion lacks the severe electron deficiency of the acetate as a result of the presence of six strong σ-donor ligands. Molybdenum atoms are strongly reducing, yet $Mo(CO)_6$ is an air-stable compound with only modest reducing properties.

Finally, it is important to remember that donor and acceptor are relative terms. If we take a complex L_nM–H, in which the hydride ligand bears no strong positive or negative charge, then we can consider the complex as arising from $L_nM^+ + H^-$, $L_nM\cdot + H\cdot$, or $L_nM^- + H^+$. We would have to regard H^- as a strong donor to L_nM^+, H^+ as a strong acceptor from L_nM^-, and H• as being neither with respect to $L_nM\cdot$. Normally the ionic model is assumed and the first type of dissection is implied.

14 EFFECTS OF CHANGING METAL

Changing the metal has an important effect on the properties of the resulting complexes. So great are the differences that it is not unusual for a single research group to confine itself to one part of the periodic table. As we move from left to right, the electronegativity of the elements increases substantially. This means that the orbitals in which the electrons are located start out relatively high in energy and fall steadily as we go to the right. Table 6 shows the Pauling electronegativities of the transition elements. The early transition metals are electropositive and so readily lose all their valence electrons. These elements are therefore often found in the highest permissible oxidation state, for example, d^0 Zr^{IV} and Ta^V. Lower oxidation states, such as d^2 Zr^{II} and Ta^{III}, are very easily oxidized, because the two d electrons are in an orbital of relatively high energy, and therefore easily lost. These systems can be very air sensitive. Not only are they easily lost to an oxidizing agent, they also have a strong tendency to be lost to the π^* orbitals of an unsaturated ligand in back donation. This makes d^2 early metal ions very π-basic and able to bind π-ligands strongly with the effects we saw earlier. Ligands like CO, C_6H_6, and C_2H_4, which require back bonding for stability, will tend to bind only weakly, if at all, to d^0 metals.

Table 6 The Pauling electronegativities of the transition elements[a]

Sc	Ti	V	Cr	Mn	Fe	Co	Ni	Cu
1.3	1.5	1.6	1.6	1.6	1.8	1.9	1.9	1.9
Y	Zr	Nb	Mo	Tc	Ru	Rh	Pd	Ag
1.2	1.3	1.6	2.1	1.9	2.2	2.3	2.2	1.9
La	Hf	Ta	W	Re	Os	Ir	Pt	Au
1.1	1.3	1.5	2.3	1.9	2.2	2.2	2.3	2.5

[a]Lanthanides and actinides: 1.1–1.3. The electronegativities of important ligand atoms are: H, 2.2; C, 2.5; N, 3.0; O, 3.4; F, 4; Si, 1.9; P, 2.2; S, 2.6; Cl, 3.1; Br, 2.9; I, 2.6. Effective electronegativities of all elements are altered by their substituents; for example, the electronegativities estimated for an alkyl C, a vinyl C, and a propynyl C are 2.5, 2.75, and 3.3, respectively.

Late metals, in contrast, are relatively electronegative, so they tend to retain their valence electrons. The low oxidation states, such as d^8 Pd^{II}, tend to be stable, and the higher ones, such as d^6 Pd^{IV}, often find ways to return to Pd^{II}, that is, are oxidizing. Back donation is not so marked as with the early metals and so any unsaturated ligand attached to the weak π-donor Pd^{II} accumulates a positive charge. This makes the ligand subject to attack by nucleophiles, Nu^-, and is the basis for important applications in organic synthesis.

A net anionic charge on a complex, for example, $[Mo(CO)_5]^{2-}$, or the presence of donor ligands, for example, PR_3 or Cp, tends to enhance the π-basicity of the metal. Conversely, a net positive charge or the presence of π-acceptor ligands, such as NO or CO, will tend to diminish the π-basicity of the metal. The size of the effects produced can be estimated from the ν(CO) frequency changes in a series of CO complexes as shown in Table 7. The effect of net charge is surprisingly large.

First-row metals have lower M–L bond strengths and CF splittings compared with their second- and third-row analogues. They are more likely to undergo 1e redox changes rather than the 2e changes often associated with the second and third rows. Finally, the first-row metals do not attain high oxidation states so easily as the second and especially the third row. Mn^V, Mn^{VI}, and Mn^{VII} (e.g. $MnO_4{}^-$) are rare and usually highly oxidizing; Re^V and Re^{VII} are not unusual and the complexes are not strongly oxidizing.

15 OTHER PROPERTIES OF COORDINATION COMPOUNDS

Other aspects of coordination and organometallic chemistry, such as ET and catalysis, are dealt with under these headings.

Table 7 Effects of changing metal, net charge, and ligands on the π-basicity of a metal, as measured by the ν(CO) values in the IR spectrum

Changing metal

1 INTRODUCTION

Copper is a ubiquitous transition metal that is involved in a number of metabolic pathways including those involving dioxygen processing.[1–5] One of the best characterized and most extensively studied biological motifs for copper is the coupled dinuclear copper center, which is found in enzymes such as hemocyanin (Hc),[1,2] tyrosinase (Tyr)[1,2] and catechol oxidase (Co) (*see* ***Copper Proteins with Dinuclear Active Sites***).[6] Hc is a dioxygen carrier protein in mollusks and anthropods, whereas Tyr and Co perform oxidation reactions. Tyr *ortho*-hydroxylates phenols to give *ortho*-catechols, while Co performs the oxidation of *ortho*-catechols to *ortho*-quinones. X-ray crystal structures have been solved for both Hc and Co in various states of oxidation and activity. In Hc's fully reduced form (redHc), the active site is characterized by an unbridged Cu_2^I moiety with a $Cu^I\cdots Cu^I$ separation of ∼4.5 Å.[7] Each copper(I) cation is coordinated by three imidazole ligands from histidine (His) protein residues, forming a pseudo-trigonal coordination geometry about copper (Figure 1). Upon exposure to dioxygen (forming oxyHc), the two Cu^I centers bind and reduce O_2, producing a μ-η^2:η^2-peroxo (bridging side-on) ligand, that is, a $Cu_2^{II}(O_2{}^{2-})$ core. The Cu···Cu distance shortens to ∼3.5 Å (Figure 1). In Hc, the reversible binding and reduction of dioxygen to peroxide is responsible for its blood O_2-transporting activity. Although no crystal structure has been elucidated for Tyr and no oxyCo X-ray structure is available,[6] the nearly identical spectroscopic properties of oxyHc, oxyTyr, and oxyCo suggest similar active-site structures.[1,2] This implies that the $Cu_2^{II}(O_2{}^{2-})$ core is not only a competent oxidant (in Co), but an oxygenating agent (monooxygenase) in Tyr.

The oxy form of these O_2-binding dinuclear copper centers is characterized by a number of distinct spectroscopic signatures. The electronic absorption spectrum contains two intense charge transfer bands in the visible region, at ∼350 nm ($\varepsilon \sim 20\,000\ M^{-1}\ cm^{-1}$) and ∼570 nm ($\varepsilon \sim 1000\ M^{-1}\ cm^{-1}$).[8] Strong magnetic coupling ($-2J > 600\ cm^{-1}$) between the two Cu^{II} centers is also observed, which results in a diamagnetic behavior, and hence no EPR signal. It should be pointed out that the inactive met forms of these enzymes (produced by F^-, $N_3{}^-$, and SCN^- coordination to the oxidized copper ions) also display similar characteristics. These met forms were previously the best spectroscopically characterized forms, and represented a major thrust in early synthetic modeling endeavors.[8,9] Since most of the recent modeling work in this field has been aimed at mimicking the oxy form of the enzymes, this review will focus exclusively on this aspect. In addition to these two (above) physical properties, resonance Raman (rR) studies on oxyHc have shown that the $Cu_2^{II}(O_2{}^{2-})$ core displays an exceptionally low O–O stretching frequency of ∼750 cm^{-1}, compared with a υ_{O-O} of 800–900 cm^{-1} normally displayed by transition metal peroxo complexes. In addition, rR studies have also elucidated a symmetrical binding mode for the peroxo moiety (based

on using mixed ^{18}O–^{16}O gas experiments to generate the peroxo form) many years before the structure of oxyHc was crystallographically determined.

The remainder of this review will concentrate on synthetic models for the dioxygen bound forms of these enzymes. Synthetic modeling endeavors have been of fundamental importance in elucidating structural information concerning hemocyanin peroxo coordination (prior to the elucidation of the structure for oxyHc), the mechanism of the hydroxylation of tyrosine by Tyr, and in gaining insight into Co activity. Many detailed reviews have been written on specific aspects of this field.[5,10–17] We will be giving a general overview of this field, highlighting major advances made in the past, as well as directions this field may be taking in the future. There are far too many important contributions in this field to be adequately covered in the space provided, therefore only prototypical systems are highlighted. To add coherence, we will be focusing mainly on copper–dioxygen adduct structure, formation, and reactivity.

2 STRUCTURE OF Cu^{II}_2–O_2 ADDUCTS

Early endeavors in the late 1970s into modeling Hc's ability to bind dioxygen and form a μ-peroxo-Cu^{II}_2 species met with little success.[18] Although the formation of such species was indirectly suggested, the extreme thermal sensitivity of these complexes made isolation difficult. Thus definitive evidence (e.g. vibrational, electronic absorption, and structural data) was lacking. It was only with advances in low–temperature spectroscopic techniques (e.g. better laser sources for rR studies, CCD detectors for rR and crystallographic studies, and improved optics for X-ray absorption studies), coupled with a better understanding of how to handle these generally thermally unstable has allowed for an explosion in the number of Cu-peroxo species has been reported. Generation of $Cu_2(O_2)$ species is usually performed at low temperatures ($<-40\,°C$) in weakly coordinating solvents such as THF and CH_2Cl_2 by exposing solutions of discrete Cu^I complexes to dioxygen.[10]

An early successful example of generation and subsequent spectroscopic study of a dioxygen adduct of a dicopper(I) complex was reported in 1984 by Karlin and coworkers, where dioxygen was shown to bind quasireversibly to the dinuclear Cu^I complex $[Cu^I_2(XYL\text{-}O)]^+$ (Figure 2a).[19–21] This complex, which contains a bridging phenoxo ligand, formed $[Cu^{II}_2(XYL\text{-}O)(O_2{}^{2-})]^+$ (**1**) upon exposure to dioxygen. It was thought that this complex would be a good mimic for Hc based on the initial formulation of the active site of oxyHc from early rR and XAS work, which suggested the protein contained a bridging oxygen ligand (such as a tyrosine, see Figure 2(b)) and may bind dioxygen in either a μ-1,1 or μ-1,2 fashion. EXAFS studies demonstrated a Cu···Cu separation

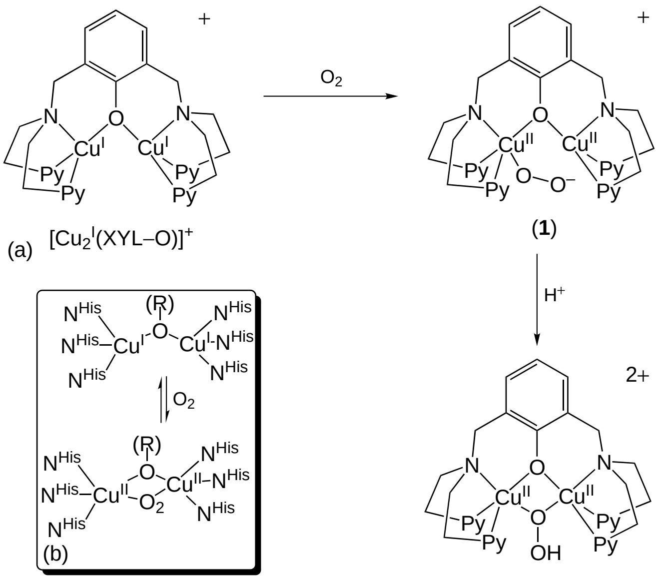

Figure 2 (a) Formation of peroxo species $[Cu^{II}_2(XYL\text{-}O)(O_2{}^{2-})]^+$ (**1**) and its protonation to a hydroperoxo complex, by O_2 reaction with $[Cu^I_2(XYL\text{-}O)]^+$. (b) An earlier description for O_2-binding in Hc

of ~3.3 Å for (**1**),[22] which was consistent with what had been reported for oxyHc. However, the ν_{O-O} stretching frequency ($803\,cm^{-1}$) and an inconsistent electronic absorption spectrum ($\lambda = 505$ nm ($\varepsilon = 6300\,M^{-1}\,cm^{-1}$), 610 nm ($2400\,M^{-1}\,cm^{-1}$)) suggested the binding mode of O_2^{2-} was not similar to that found in the enzyme. Mixed isotope rR spectroscopic studies[23] demonstrated that the peroxo ligand was in an unsymmetric coordination environment, possibly binding end-on to one copper ion (Figure 2a), and hence inconsistent with data reported for the enzymes. Upon exposure of (**1**) to a proton source, a bridging hydroperoxo species is formed (Figure 2).[24] EXAFS measurements[24] demonstrate a short Cu···Cu separation of 3.0 Å, which is consistent with a μ-1,1 binding mode of OOH, but is significantly shorter than that reported for the oxy forms of the enzymes. In addition to shedding light on possible active-site structures of oxyHc, study and characterization of these complexes also demonstrated the feasibility of preparing and manipulating dinuclear copper–dioxygen adducts.

The first crystallographically characterized peroxo-containing model for oxyHc was originally reported by Karlin, and resulted from dioxygen binding to the tetradentate Cu^I center of $[Cu^I(TMPA)]^+$, forming the purple $[\{Cu^{II}(TMPA)\}_2(O_2)]^{2+}$ complex (**2**, Figure 3); the crystal structure of (**2**) was obtained in 1988, and featured a *trans*-μ-1,2 peroxo ligand coordination.[25,26] Although the Cu^{II} centers were strongly magnetically coupled ($-2J > 600\,cm^{-1}$), the electronic absorption spectrum ($\lambda = 440$ (2000), 525 (11500), and 590 nm (7600)) and relatively high-energy ν_{O-O} stretching frequency ($834\,cm^{-1}$) were significantly different from the corresponding properties of oxyHc, strongly suggesting the peroxo binding mode was not the same.

This dioxygen binding mode (end–on) seems to be the preferred one when Cu is placed in a tetradentate ligand environment; however, recent studies have suggested this is not a steadfast rule.[10,27] Although apparently not a biologically relevant binding mode for O_2^{2-} at dinuclear copper centers, complex (**2**) (and derivatives thereof)[16] have been exceptionally important in determining the fundamental dioxygen chemistry of Cu^I complexes. A good number of *trans*-μ-1,2 peroxo complexes have since been generated.[10,28]

Aliphatically tethered dinuclear Cu^I complexes, where the metal center was bound to tri- and tetradentate ligands, were prepared by Karlin and coworkers (tridentates; Figure 4a), and demonstrated reversible O_2 binding at low temperatures.[16,29] Tolman and coworkers more recently reported on the preparation of Cu^I complexes contained in tethered TACN ligands (Figure 4b).[17] In the case of the dinuclear complexes with tridentate ligand donors for each copper ion ($[Cu^I_2(Nn)]^{2+}$ (**3**)), it was suggested by low-temperature solution EXAFS that the peroxo ligand bridged the metal centers in a side–on fashion.[22,29] The spectroscopic properties were consistent with those of oxyHc, with an intense charge transfer band in the UV/Vis region at ~350 nm ($\varepsilon \sim 20\,000\,M^{-1}\,cm^{-1}$), and rR spectroscopy showed a range for ν_{O-O} between $760-730\,cm^{-1}$.[30] The shorter tether was found to impose a structural constraint about the $Cu^{II}_2O_2^{2-}$ core and according to EXAFS data, causes a distortion or 'butterflying', so that the peroxo ligand moves out of the Cu_2O_2 plane (based on Cu···Cu separations, Figure 4c).[29,30] This butterflying causes

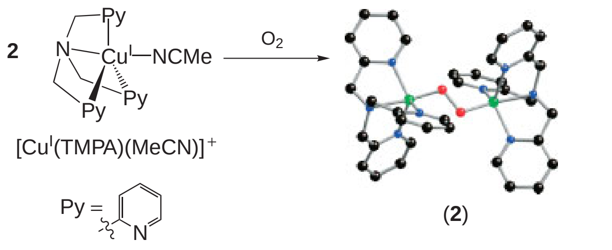

Figure 3 Crystal structure of $[\{Cu^{II}(TMPA)\}_2(O_2^{2-})]^{2+}$ (**2**) resulting from the reaction of $[Cu^I(TMPA)(MeCN)]^+$ and dioxygen at low temperature

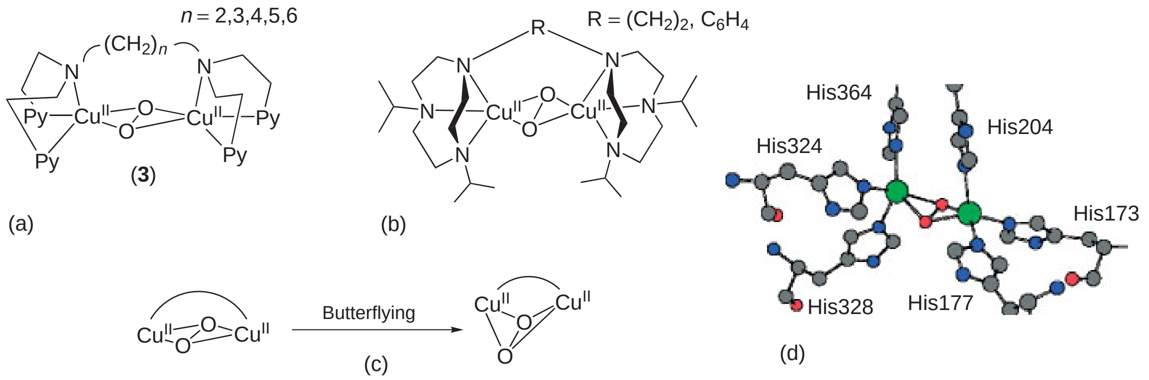

Figure 4 Aliphatically tethered Cu^{II}_2-peroxo complexes (a) and (b). Figure 4(c) depicts the distortion, or butterflying, of the $Cu_2O_2^{2-}$ core facilitated by the ligand constraints the aliphatic tether imposes on the copper complex. Figure 4(d) depicts the structure of oxyHc from *Limulus polyphemus*, which shows some degree of butterflying of the $Cu_2O_2^{2-}$ core

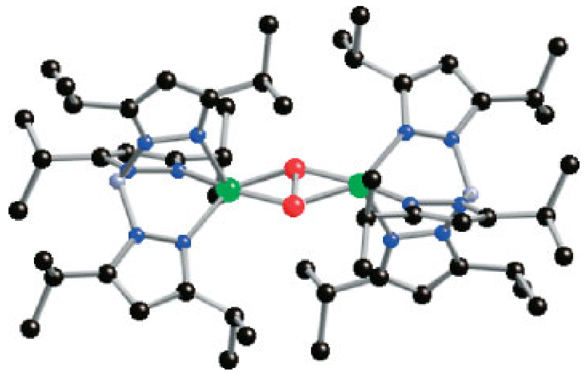
a strengthening of the O–O bond (i.e. higher O–O stretching frequencies indicating less O_2 bond activation), and has interesting consequences concerning dioxygen binding and reactivity of the peroxo core, namely that the Cu_2O_2 core is a poorer oxidant compared to the planar arrangement.[30] Available crystallographic data for oxyHc from *Limulus polyphemus* and *Octopus doflenini* suggest there is some butterflying of the O_2^{2-} ligand from the central core (see Figure 4(d)).[31] In dinuclear complexes possessing untethered tridentate Cu moieties, ligand constraints are less severe, allowing for planar μ-η^2:η^2-peroxo coordination, low ν_{O-O} values, and resulting exogenous substrate oxidation reactions (see further discussion below).

A major advance in Hc modeling chemistry was made in 1989 from the group of the late N. Kitajima when he reported on the preparation of a Cu^I complex where copper is contained in a tridentate trispyrazolyl-borate ligand environment.[32,33] Similar to the chemistry of (**1**), (**2**), and (**3**), dioxygen binds quasireversibly to the Cu^I center at low temperatures, forming a $Cu^{II}_2(O_2^{2-})$ species. The spectroscopic properties of the dioxygen adduct $[\{Cu^{II}[HB(3,5\text{-}i\text{-}Pr_2pz)_3]\}_2(O_2^{2-})]$ (**4**, Figure 5) very closely matched that of oxyHc (ν_{O-O} = 741 cm^{-1}; λ_{max} = 349 (21000) and 551 nm (790); $-2J >$ 800 cm^{-1}). Crystallographic studies on (**4**) demonstrated a side–on binding mode for the peroxo–ligand, with a Cu···Cu separation of 3.56 Å, nearly identical to the Cu···Cu distance in the enzyme as determined by EXAFS at that time, and an O–O bond distance of 1.41 Å. All of this evidence strongly suggested a similar coordination geometry for the $Cu^{II}_2(O_2^{2-})$ core in the enzyme. This was confirmed when the 2.4 Å resolution crystal structure of oxyHc was solved (see above). The work demonstrates the potential power of bioinorganic modeling, as coordination chemistry studies (employing a non-biologically relevant ligand) yielded a new compound that allowed the (correct) prediction of an important biological structure.



(**4**)

Figure 5 Crystal structure of the Kitajima/Fujisawa side-on peroxo complex $[\{Cu^{II}[HB(3,5\text{-}i\text{-}Pr_2pz)_3]\}_2(O_2^{2-})]$ (**4**)

Independent work by Tolman and Stack in the mid- and late-1990s, using cyclic and linear bi/tridentate amine-based ligands, demonstrated that the side–on peroxo ligand in $Cu^{II}_2(O_2^{2-})$ complexes can be in equilibrium with its Cu^{III}_2-bis-μ-oxo isomer (Figure 6).[10,17] This has also been supported by work performed by Karlin and Itoh using bi/tridentate pyridyl amine ligands (Figure 6).[34,35] It has been found that copper complex attributes such as ligand electronics, changes in counterion, ligand steric bulk, along with a solvent change, can influence the equilibrium position and interconversion of the Cu^{II}_2 (peroxo) and Cu^{III}_2(bis-μ-oxo) forms. The breadth of work concerning this field is far too great to be done justice here, so we will only briefly touch upon this subject, and point to relevant reviews.[10–13,17] Upon interconversion from the side-on peroxo to the bis-μ-oxo form, a change in structure is noted, with a breaking of the

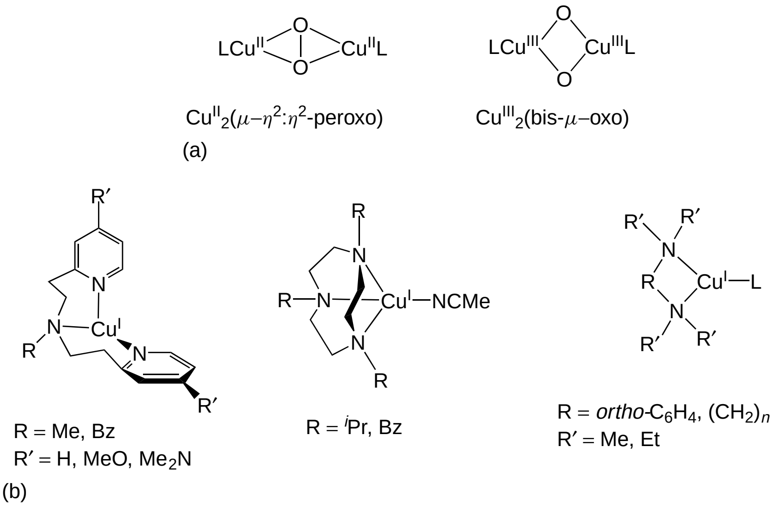


Figure 6 Depiction of the changes involved in core interconversion between Cu^{II}_2(μ-η^2-η^2-peroxo) and Cu^{III}_2(bis-μ-oxo) isomers (a), and representations of Cu^I complexes capable of forming Cu^{III}_2(bis-μ-oxo) upon exposure to dioxygen (b)

O–O bond followed by elongation of the O···O distance to ∼2.3 Å, and a contraction of the Cu···Cu distance to between 2.7–2.9 Å. The electronic absorption spectrum is also altered with the disappearance of the charge transfer peak at ∼350 nm and the appearance of two intense peaks at 300 and ∼400 nm. Breaking of the O–O bond is also evident by rR studies where the characteristic $\nu_{O\text{–}O}$ frequency at ∼750 cm^{-1} is lost, and a Cu–O vibration at ∼600 cm^{-1} appears. Variations do occur. Core interconversion may also have important consequences concerning subsequent substrate reactivity (see Section 4). It has yet to be determined if the Cu_2^{III}(bis-μ-oxo) core is a biologically relevant O_2-binding mode.

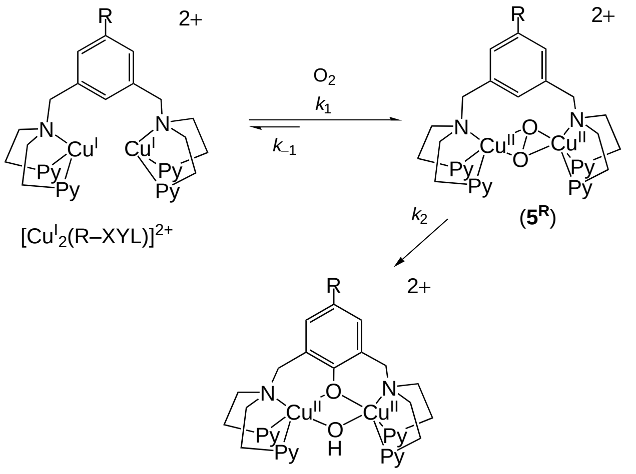

Figure 7 Formation of side-on peroxo intermediate $[Cu_2^{II}$(R-XYL)$(O_2{}^{2-})]^{2+}$ (**5**$^{\mathbf{R}}$) from O_2-reaction with $[Cu_2^{I}$(R-XYL)$]^{2+}$, followed by oxygenation of the arene bridge

3 FORMATION OF Cu_2^{II}–$O_2{}^{2-}$ ADDUCTS

As stated previously, early work into the direct observation of unstable Cu_2^{II}–$O_2{}^{2-}$ species met with little success. These species were often postulated based on both chemical logic, as well as limited kinetic information, but direct evidence pointing to the presence of such complexes was lacking. This situation changed in the mid-1980s in large part due to the utilization of low-temperature (−40 to −105 °C) stopped-flow spectroscopy where direct observation of spectroscopically identifiable copper–dioxygen intermediates was possible.[5,16] This has allowed for the direct observation of a number of elementary steps in the formation and subsequent reactions of these complexes.

One of the first model systems to undergo detailed low-temperature kinetic studies was the $[Cu_2^{I}$(R-XYL)$]^{2+}$ system of Karlin (Figure 7).[16,36] $[Cu_2^{I}$(R-XYL)$]^{2+}$ (where R = NO_2, H, F, and ^{t}Bu) will bind O_2 at low temperatures, forming $[Cu_2^{II}$(R-XYL)$(O_2)]^{2+}$ (**5**$^{\mathbf{R}}$), which contains a bridging side-on peroxo ligand. Complexes (**5**$^{\mathbf{R}}$) will then further react with itself performing an oxygenation reaction, similar to Tyr (*vide infra*). Stopped-flow measurements of (**5**$^{\mathbf{R}}$) formation at 183 K demonstrate quasireversible binding of dioxygen with k_{on} values ranging between 470 M^{-1} s^{-1} (R =^{t}Bu) to 7.2 M^{-1} s^{-1} (R = F) and k_{off} values varying from 1.5×10^{-6} s^{-1} (R = F) to 2.1×10^{-5} s^{-1} (R = NO_2).[5,16] Dioxygen binding is characterized by low activation enthalpies which are partially offset by unfavorable entropy terms ($\Delta S^{\ddagger} \sim -40$ cal mol^{-1} K^{-1}). At higher temperatures, the unfavorable $\Delta S°$ precludes observation of Cu^I dioxygen adduct formation. This appears to be a general finding for copper–dioxygen chemistry; $Cu_2^{II}(O_2{}^{2-})$ formation is driven by and favorable enthalpies, but at high temperature unfavorable entropies dominate.[16]

Another hallmark of $Cu_2^{II}(\mu\text{-}\eta^2\text{:}\eta^2$ peroxo) formation appears to be the fact that a Cu^{II}-superoxo complex is initially formed, which then reacts with another Cu^I complex forming the corresponding Cu_2^{II}-peroxo species.[16,29] This was always suspected; however, direct observation of a superoxo intermediate during the O_2-binding process was lacking. For example, the oxidation of (**3**) (Figure 4) and subsequent formation of $[Cu_2^{II}(Nn)(O_2)]^{2+}$ follows an overall quasireversible second order process.[33] However, the enthalpies of activation are very low and in some cases negative, indicative of a pre-equilibrium step involving the formation of Cu^{II}–$O_2{}^{-}\cdots Cu^I$ species followed by a 'closing' step that forms the Cu_2^{II}-peroxo products (Figure 8a). Cu^{II}-superoxo formation can in fact be directly observed using $[Cu^I(TMPA)(L)]^+$ (L = RCN or CO; Figure 8b). In a coordinating solvent (such as EtCN), formation of a $[Cu^{II}(TMPA)(O_2{}^-)]^+$ can be observed by low-temperature stopped-flow measurements,[16,37] while a flash photolysis study involving $[Cu^I(tmpa)(CO)]^+$ in a weakly coordinating solvent demonstrated superoxo formation following photodissociation of the CO ligand.[38] These results are supported by the work of Kitajima/Fujisawa[39,40] and Tolman,[41,42] who have isolated and characterized Cu^{II}-superoxo complexes bound in a side-on fashion. In other ligand systems, particularly tetradentate, there is also ample kinetic and spectroscopic evidence for Cu^{II}-superoxo complexes which are intermediates on the way towards dinuclear peroxo-dicopper(II) formation.[16,28,37,43,44]

The kinetics of $Cu_2(O_2)$ adduct formation was also followed utilizing Tolman's $[Cu^I(i\text{-}Pr_3TACN)]^+$ (**6**$^{\boldsymbol{i}\mathbf{Pr}}$) systems.[11,17,45] Oxygenation of (**6**$^{\boldsymbol{i}\mathbf{Pr}}$) in acetone affords a Cu_2-dioxygen adduct, which has been identified as being a mixture of peroxo/bis-μ-oxo complexes (Figure 9). The formation of the Cu_2^{II}-peroxo complex occurs in parallel with Cu_2^{III}-bis-μ-oxo formation, implying a rapid equilibrium involving peroxo/oxo core interconversion. It is unknown if one forms prior to the other, but see further discussions in recent reviews.[10,11]

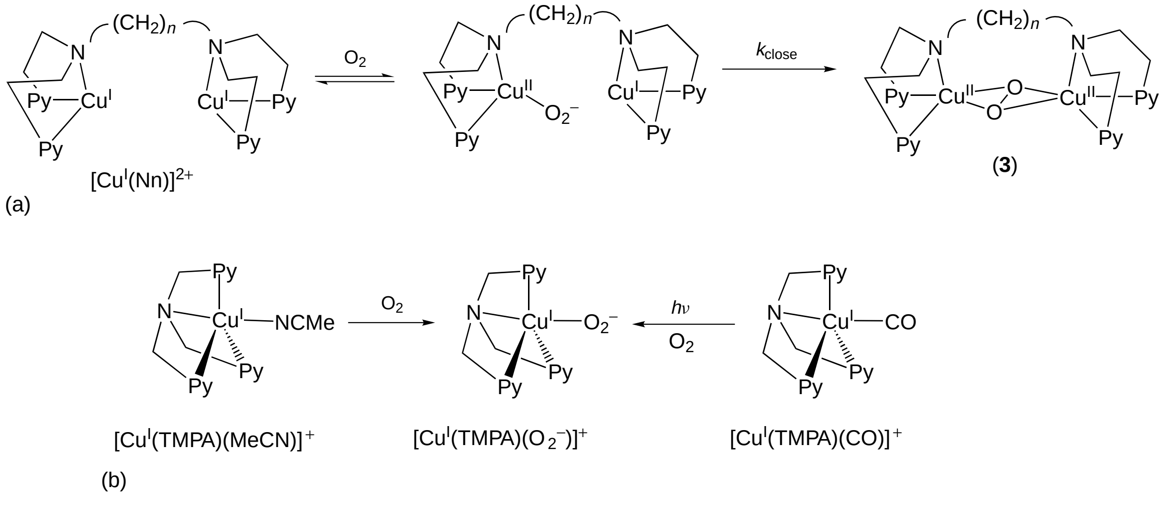

Figure 8 Formation of an initial superoxo species has been long suspected in the formation of Cu^{II}_2-peroxo species. For example the formation of (**3**) from $[Cu^{I}_2(Nn)]^{2+}$ proceeds with a very low (and sometimes negative) activation enthalpy, suggestive of the formation of an initial species $Cu^{II}–O_2{}^{-}\cdots Cu^{I}$ (a). Direct observation of such an intermediate came from dioxygen reactivity studies with $[Cu^{I}(TMPA)]^{+}$ complexes (b)

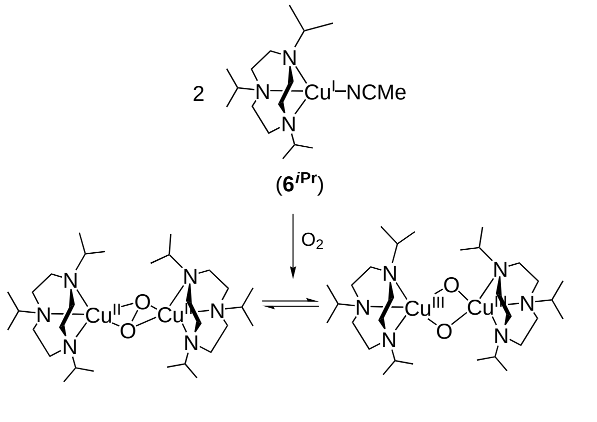

Figure 9 Oxygenation of $[Cu^{I}(i\text{-}Pr_3TACN)(MeCN)]^{+}$ (**6^{iPr}**) in acetone leads to both the corresponding peroxo and oxo-species, apparently in concert, suggesting a rapid equilibrium exists between bis-μ-oxo and μ-η^2:η^2-peroxo complexes

4 OXIDATION REACTIONS

Much of the current research performed in the field of modeling these biological dinuclear copper centers now focuses on the generation of complexes that can perform substrate oxidation reactions.[11,12] Of key interest is not only determining the identity of the reactive species in oxyCo and oxyTyr (i.e. $Cu^{II}_2(O_2{}^{2-})$ vs. $Cu^{III}_2(O^{2-})_2$), but also the detailed mechanism(s) of substrate oxidations. The best studied of the substrate oxidations is the hydroxylation of arenes by $Cu^{II}_2(O_2{}^{2-})$ species. In 1984, Karlin and coworker described the ligand hydroxylation reaction of $[Cu^{II}_2(R\text{-}XYL)(O_2{}^{2-})]^{2+}$ (**5^R**, Figure 7).[46] By varying the R-group *para* to the site of oxygenation, reaction rates (k_2) could be modulated.[5,16,36] It was determined that as R became more electrondonating, the rates of the oxygenation step increased. This is strong evidence in favor of an electrophilic attack of the peroxo moiety on the arene ring. In other words, hydroxylations appear to occur *via* an electrophilic aromatic substitution from $Cu^{II}_2(\mu\text{-}\eta^2\text{:}\eta^2$ peroxo) complexes. This is supported by the recent work of Itoh.[11,47,48]

In 2001, Itoh and coworkers reexplored the mechanism of *ortho*-phenol hydroxylations using $[\{Cu^{II}(L^{PY2})\}_2(O_2)]^{2+}$ (**7**, Figure 10).[47] This complex contains a deutero-benzylamine moiety, and can undergo ligand auto-oxidation, forming benzaldehyde, through a proton-coupled electron transfer (PCET) reaction with the μ-η^2:η^2 peroxo ligand. Perdeuteration of the methylene linker affords a relatively kinetically stable complex, which allows for the monitoring of exogenous substrate oxidations. When (**7**) is exposed to cold (−95 °C) acetone solutions of the lithium salts of *para*-substituted phenolates, clean conversion to the corresponding *o*-catechols is observed. Deuterium kinetic isotope effects (KIEs) for these hydroxylation reactions of ∼1.0 are observed, which is consistent with an electrophilic attack of the peroxo ligand on the arene ring. An electrophilic aromatic substitution is also consistent with the observation that lithium *p*-methoxyphenolate reacts substantially faster with (**7**) than lithium *p*-chloro-phenolate. Furthermore, a plot of observed reaction rates vs. *p*-chloro-phenolate concentration demonstrated that substrate coordination to the metal center is occurring prior to hydroxylation, and thus may be an important feature in these phenolate *o*-hydroxylation reactions.

Recently the oxidative coupling of *para*-substituted phenols was investigated by Itoh using both (**7**) and $[\{Cu^{III}(L^{PY1})(O^{2-})_2\}_2]^{2+}$ (**8**, Figure 10).[49] This allowed for the direct comparison of the reactivity of a Cu^{II}_2 μ-η^2:η^2 peroxo

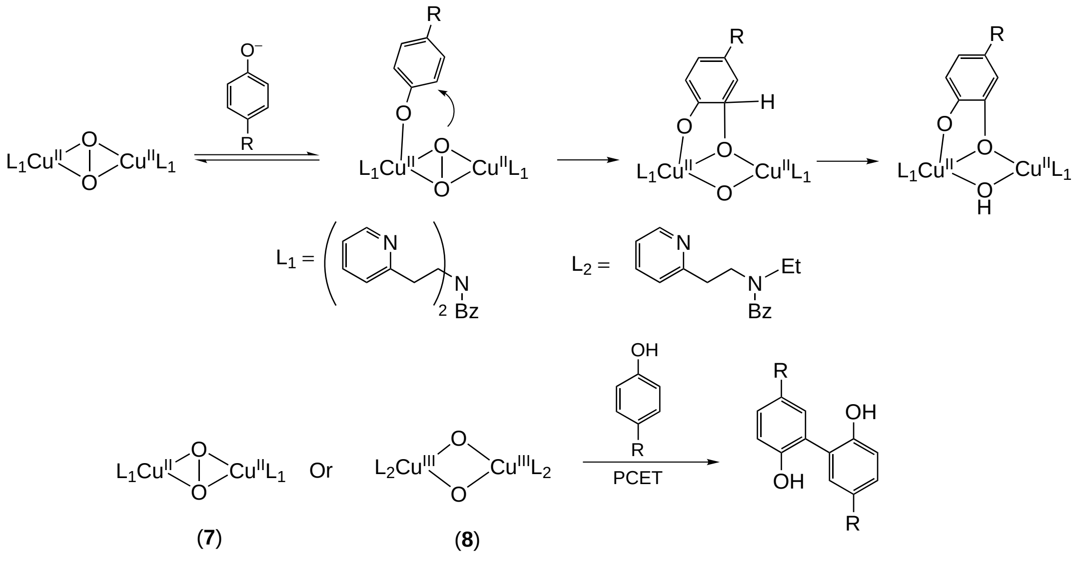

Figure 10 Reactions of phenolates with μ-η^2:η^2-peroxo complex (**7**) yields an *ortho*-hydroxylation reaction reminiscent of Tyr, while reactions of phenols by both (**7**) and bis-μ-oxo complex (**8**) results in *ortho*-phenol coupled dimers through an apparent PCET pathway

complex and a structurally related Cu_2^{III} μ-bis-oxo complex. Determination of differential reactivity between peroxo and bis-μ-oxo complexes is currently where considerable effort in this field is being directed. In the case of phenol (vs. phenolate) oxidations, pre-coordination of substrate to the copper center is less likely (owing to lack of the anionic phenolate). Furthermore, the phenol contains only a moderately strong O–H bond (~90 kcal mol^{-1}), which opens up the possibility of an O–H bond homolysis through a hydrogen atom transfer (HAT) pathway (Figure 10). However, it was suggested that both (**7**) and (**8**) will couple phenols through a PCET pathway, as opposed to a HAT pathway (i.e. the electron- and proton transfer steps are kinetically resolvable). This is in contrast to ligand hydroxylation reactions of Tolmans derivatized TACN systems (vide infra).

[{Cu^{III}(Bz$_3$-TACN)}$_2$(O^{2-})]$^{2+}$ (**9**, Figure 11) is a Cu_2^{III} (bis-μ-oxo) complex, and will undergo auto-oxidation forming benzaldehyde, following oxidative N-dealkylation of the TACN ligand.[50–52] Labeling studies with ^{18}O demonstrate the oxygen source comes from the bis-μ-oxo moiety, and experiments with deuterated ligand lead to large observable KIEs (>24) at −40 °C. This is indicative of a rate-limiting C–H bond homolysis occurring through a HAT pathway. Unlike the phenol oxidative couplings of Itoh's system, the

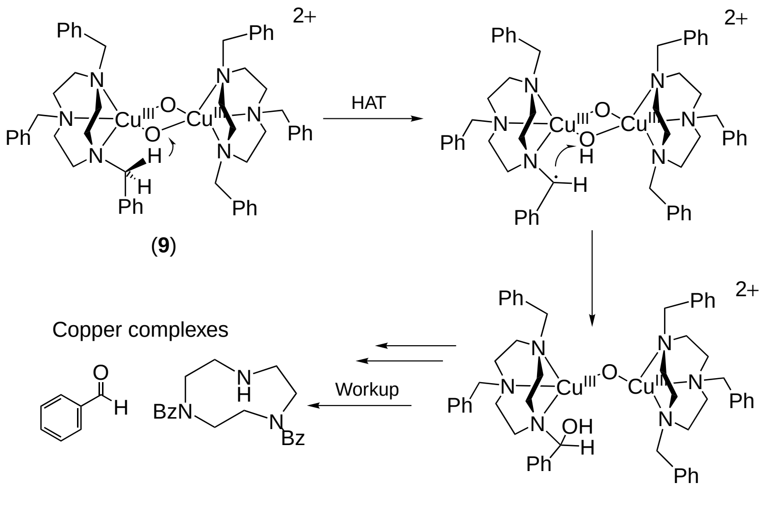

Figure 11 Cu_2^{III}(bis-μ-oxo) complex [{Cu^{III}(Bz$_3$-TACN)}$_2$ (O^{2-})$_2$]$^{2+}$ (**9**) will undergo an auto-oxidation resulting in ligand N-dealkylation of a benzyl group, forming benzaldehyde, presumably through a HAT pathway

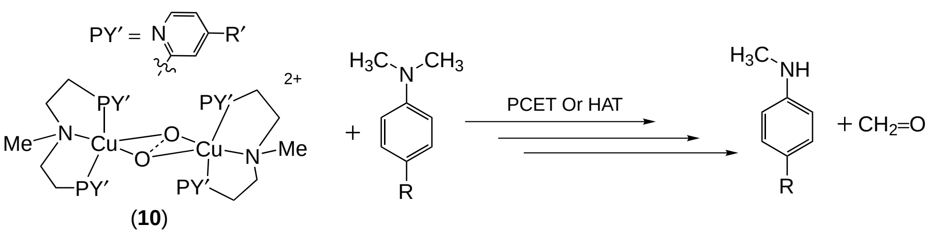

Figure 12 $[\{Cu^{II}(MePY2)^{R'}\}_2(O_2)]^{2+}$ (**10**), which exists as a mixture of both bis-μ-oxo and μ-η^2:η^2-peroxo complexes in solution, will oxidatively N-dealkylate *para*-substituted dimethylanilines through either a PCET or a HAT pathway

TACN ligands of Tolman are not easily oxidizable (due to unfavorable redox potentials), which may make a formal ET event unlikely. Molecular orbital calculations also suggest that a HAT pathway is much more likely than PCET with this system.[12] The wavefunction for the oxo acceptor orbital is of the proper energy and symmetry to accept the hydrogen atom from the ligand. If one considers the three-dimensional structure of (**9**), it appears the hydrogen that is being abstracted is in an optimal position to be transferred to the oxo-ligand. All of this strongly supports a HAT pathway for intramolecular ligand oxidation by (**9**).[11]

In an attempt to address the PCET versus HAT issue, Shearer, Karlin, and coworkers investigated the mechanism of dimethylaniline oxidations by $[\{Cu(MePy2)^R\}_2(O_2)]^{2+}$ (**10**, Figure 12).[53] Here, the complexes are not pure peroxo or bis-μ-oxo complexes, but instead are mixtures. The R'-*para* pyridyl ligand donor substituent produces more of the bis-μ-oxo tautomer as the R' group is made more electron donating (7–30% bis-μ-oxo).[54] Based upon comparisons of both intra- vs intermolecular KIEs and KIE profiles of *para*-substituted dimethylaniline oxidations (R-DMA, Figure 12), it was determined that both PCET and HAT reactions occur. For the more easily oxidizable R-DMAs, a PCET reaction is preferred, while for the more difficult to oxidize R-DMAs a HAT pathway is favored. Also, it was observed that the more bis-μ-oxo isomer that is in solution, the more likely it is that a HAT reaction will occur.

5 FUTURE DIRECTIONS/SUMMARY

Since the structures and spectroscopic correlations for both oxy and red forms of Hc, Co, and Tyr are well understood, much of the future synthetic modeling work will focus on the reactivity of Cu_2O_2 species. Tyr activity, *o*-phenol hydroxylation, seems to occur via an electrophilic aromatic substitution, but the broader scope of reaction for side-on μ-η^2:η^2-peroxodicopper(II) complexes should be further explored. Much remains to be accomplished in determining the detailed mechanism of catechol oxidase catalysis (i.e. HAT vs. PCET). The differential reactivity of peroxo versus bis-μ-oxo tautomers is still largely unknown. Although there is as yet no evidence that the Cu_2^{III}(bis-μ-oxo) core is found in nature, it could be present in low concentrations (and thus undetectable), yet still be important from a mechanistic point of view. Also, the structure of particulate methane monooxygenase has yet to be elucidated, and this enzyme may contain the Cu_2^{III}(bis-μ-oxo) moiety or related structure, possibly within a trinuclear copper center.[55,56]

1 INTRODUCTION

Copper (Figure 1) is among the 25 most abundant elements in the earth's crust, occurring at an average of about 50–100 g ton^{-1}. Copper metal has played an important role in human technological, industrial, and cultural development since primitive times. Thus, along with iron and gold, copper was one of the first metals used widely, because copper could be found in its native elemental form plus it could be easily hammered into tools and weapons. The metal and its alloys have subsequently been employed in a wide variety of applications because they exhibit a number of useful qualities such as ductility, malleability, strength, corrosion resistance, and high thermal and electrical conductivity, combined with an attractive appearance. One of the most widespread and long-standing uses of copper is for monetary purposes; thus, it is known as a coinage metal along with its fellow d-block triad members silver and gold. Copper is also an essential trace element nutritionally, being among the most abundant metals in the human body, although it is toxic to humans in large quantities (*see* ***Metal Ion Toxicity***).

Copper exhibits a rich coordination chemistry, primarily in the monovalent (+1) and divalent (+2) oxidation states. Compounds of copper have been used extensively in a wide range of practical applications, including as catalysts in both homogeneous and heterogeneous reactions, as fungicides, pesticides, and wood preservatives, as pigments for paints and glasses, and in the so-called high-temperature superconductors (*see* ***Superconductivity***).

2 HISTORY

Copper metal has been recognized and used extensively since prehistoric times (Scheme 1), probably beginning around 5000 B.C., or even somewhat earlier. The word copper and the symbol Cu are derived from *cuprum*, which is believed to have evolved from *aes cyprium* (the metal of Cyprus). The copper mine on the Island of Cyprus supplied most of the metal for the Romans from about 2500 B.C., although it is now uncertain whether Cyprus was named for the metal or vice versa.[1]

Initially the metal was mined and used primitively in weapons, tools, and, presumably, currency; this period in a civilization's evolutionary period is often referred to as the Copper Age. In ancient times, primary copper-mining sites were located in Sinai, Cyprus, Syria, Caucusus, Afghanistan, Macedonia, Iberia, and Central Europe.[2] Later, progression to the so-called Bronze Age occurred with progresses in metallurgy including the discovery that bronze, an alloy of copper with tin (an alloy is a homogeneous mixture of a metallic element and one or more other elements and is commonly made by adding the alloying element to the molten metal) first used around 2500 B.C., is stronger than copper metal alone. Brass, the alloy of copper and zinc that also imparts greater strength than pure copper, was probably developed some time later, perhaps around 300 A.D.

Significantly, copper was detected in plants and animals in the early to mid-1800s. The discoveries related to electricity that followed in the nineteenth century promoted the development of important new uses for copper metal. During approximately the same time period the ascent of the copper industry in the United States began, initially in Connecticut, then primarily in the Upper Peninsula of Michigan, and finally in the west (Arizona, Utah, Montana, New Mexico, and Nevada). The world production of mined copper ore exceeded 5 million tons by the 1960s, at that time led by the United States, which has since been overtaken by Chile. Other major producers include the former Soviet Union, Canada, China, and Zambia. There have been some recent periodic reductions in copper production due to the successful development of other competitive substitute materials, including aluminum, steel, and plastics, combined with the rising costs of the large open-pit mining operations now needed to isolate significant quantities of copper ore.

A major scientific breakthrough in the area of material science involving copper occurred in late 1986 and early 1987: the discovery of the so-called high-temperature cuprate superconductors (*see* ***Superconductivity***). These copper-oxide containing materials hold the record for the highest transition temperature (T_c, the temperature at which all resistance to electricity is lost), currently 133 K, which is significant

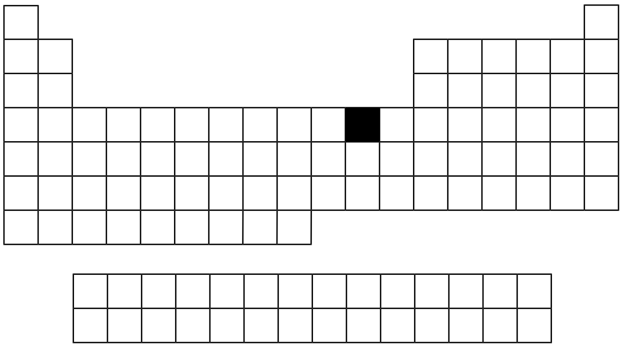

Figure 1 The place where copper is found in the conventional version of the periodic table

because liquid nitrogen can be used as the coolant to reach that temperature (77 K), instead of the much more expensive liquid helium coolant that was previously required.[3] Two-dimensional $Cu^{II}O_2$ planes might be (or might not be[4]) responsible for the superconductivity, thus, the magnetic properties (*see* ***Magnetism of Extended Arrays in Inorganic Solids***) of cuprates (*see* ***Magnetic Oxides***) have been extensively studied, for instance, for $CuGeO_3$.[5]

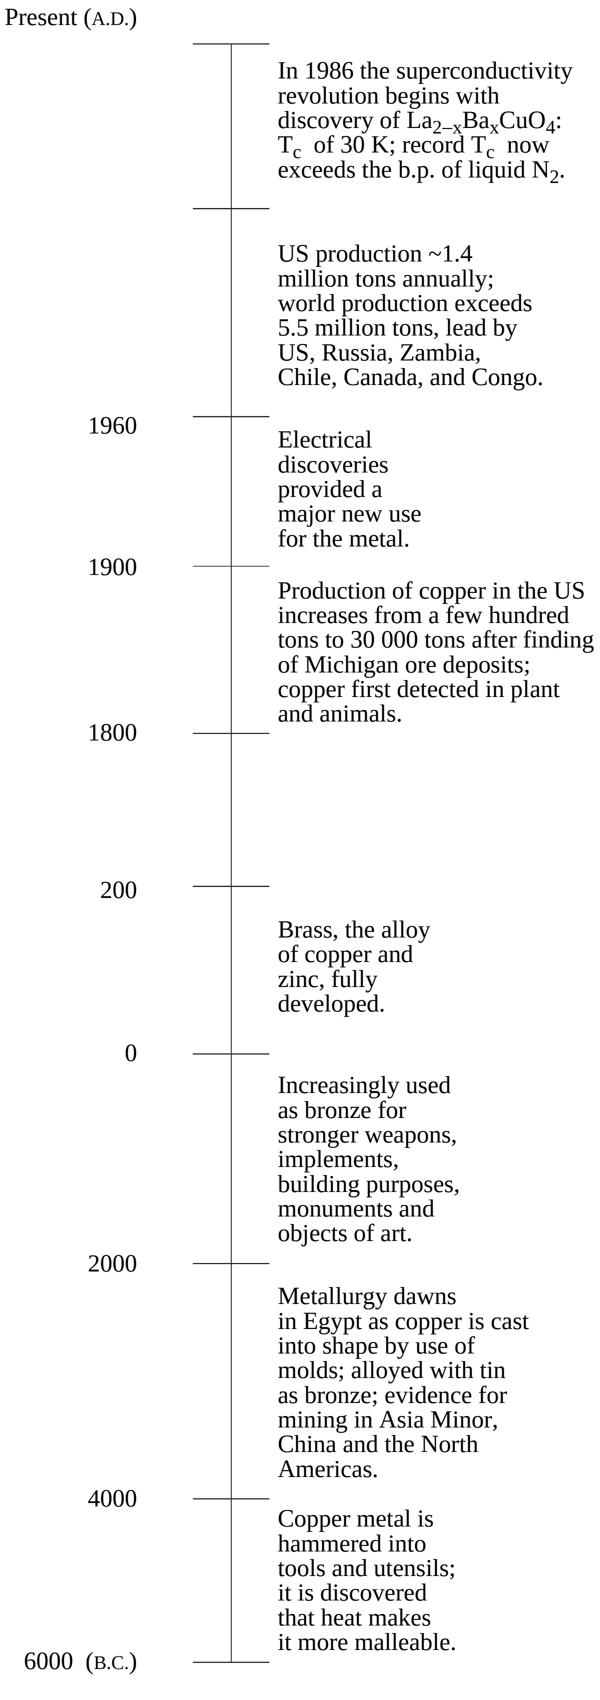
3 OCCURRENCE

Copper deposits are widely distributed over many parts of the world. Copper occurs at an average of 68 ppm in the earth's crust, 0.003 ppm in seawater, 0.7 ppm in the sun, and 1.0 ppm in the human body.[6] At one time native copper deposits (i.e. occurring as the metal) were relatively common, but now they are found infrequently. Native copper frequently contains small amounts of Ag, Be, Hg, As, and Sb impurities.[7] The present primary source of copper is the mineral ores (Table 1; Figure 2), combinations of copper cations and other ions, most commonly sulfur, iron, carbon, and/or oxygen. Although more than 150 copper minerals have been identified, much of the mined copper is composed of chalcopyrite, followed by chalcocite (Figure 3). About 90% of the known reserves are found in North America (Rocky Mountain and Great Basin areas and central Canada), South America (western slopes of the Andes in Peru and Chile) and the upper Katango region of the Congo plus the adjacent Copperbelt region of Zambia. The largest known deposit is at Chuquicamata, Chile.

4 PRODUCTION AND USES

4.1 Production

The world production of mined copper ore was 8 million metric tons in 1993; the major contributors were: Chile, 22%;



Scheme 1 An approximate timeline of copper history

Table 1 Principal copper-containing minerals[a]

Name	Chemical Formula	% Cu	Color	Specific gravity
Native elemental copper	Cu	100	Light red metallic	8.9
Sulfides				
Chalcopyrite[b] (copper pyrite)	$CuFeS_2$	34.5	Yellow metallic	4.2
Chalcocite[b] (copper glance)	Cu_2S	79.8	Dark gray	5.7
Bornite[b]	Cu_5FeS_4	63.3	Bronze-brown	5.1
Covellite (indigo copper)[b]	CuS	66.5	Indigo blue	4.7
Tennantite[b]	$Cu_{12}As_4S_{13}$	51.6	Steel-gray	4.7
Tetrahedrite (grey copper)[b]	$Cu_{12}Sb_4S_{13}$	45.8	Steel-gray	4.9
Enargite	Cu_3AsS_4	48.4	Violet-tinted gray	4.4
Oxides				
Cuprite[b]	Cu_2O	88.8	Red	6.1
Tenorite	CuO	79.9	Gray to black	6.0
Carbonates				
Malachite[b]	$Cu_2CO_3(OH)_2$	57.3	Green	4.0
Azurite (chessylite)[b]	$Cu_3(CO_3)_2(OH)_2$	55.1	Sky blue	3.8
Silicate				
Chrysocolla[b]	$\sim Cu_4H_4Si_4O_{10}(OH)_8$	36.0	Blue-green	2.2
Sulfates				
Brochantite	$Cu_4SO_4(OH)_6$	56.2	Emerald green	3.9
Antlerite	$Cu_3SO_4(OH)_4$	54.0	Green	3.9
Halide				
Atacamite	$Cu_2(OH)_3Cl$	59.5	Dark green	3.8

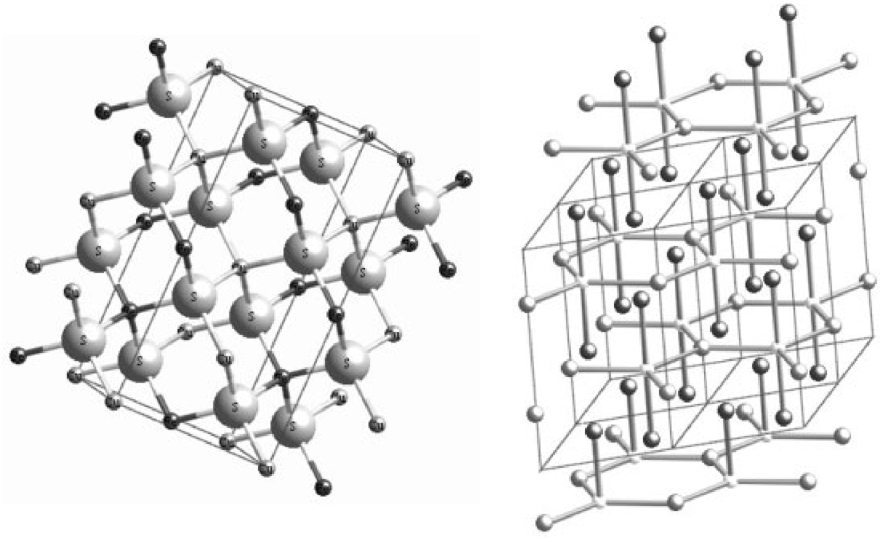
USA (primarily Arizona, New Mexico, and Utah), 20%; the former Soviet Union, 9%; Canada, 8%; China 8%; and Zambia, 5%. Presently, recycled scrap metal, or secondary copper, contributes an additional 25–35% to this yearly output. Open-pit strip mining yields most of the copper ore, which is typically 0.4–1% in copper. Underground methods are used for deeper, vein-type deposits that have a significantly higher copper content (needed to offset the increased mining costs).

4.2 Refining

The refining process[8] typically begins with crushing of the ores, then concentration by froth-flotation, which yields material that is typically 15–20% Cu. The main impurity in these concentrates is iron; however, nickel, gold, and silver are often present, along with traces of zinc, selenium, arsenic, antimony, tellurium, cobalt, tin, and lead. Silica (sand) is



(a) (b)

Figure 3 Depictions of the solid-state structures of the minerals (a) chalcopyrite the largest spheres represent sulfide ions and the smaller spheres represent copper and iron centers, represented by lighter and darker gray spheres, respectively and (b) chalcocite the lightest spheres represent sulfide ions and the darker spheres represent the two unique copper positions shown in approximately averaged positions drawn with CrystalMaker 6.1 software

added to the concentrates in a reverberatory furnace so that the mixture can be heated to 1400–1450 °C to make a melt. Roasting with added air converts most of the iron to its oxide (equation 1 or 2), which reacts with silica to form an iron silicate slag (equation 3). This slag spontaneously separates into upper layer and lower layers. The upper layer is periodically removed to give a liquid matte that is largely Cu_2S and FeS. This liquid matte is placed in a converter with more silica, and additional air is forced through it. In a similar fashion, this transforms the remaining FeS first to FeO (equation 2) and then to slag (equation 3). The Cu_2S is partially transformed to Cu_2O (equation 4), which reacts with any remaining FeS (equation 5). Finally, metallic or blister copper is produced (equation 6 and 7). The name blister copper derives from its blistered appearance that is caused by the bubbling of the SO_2 through the melt. This copper product is approximately 98–99% pure and can be further purified by fire refining (similar to the process described above), electrolysis, and/or by zone refining. The electrolytic process uses impure copper as an anode with a purified copper cathode in a solution containing H_2SO_4 and $CuSO_4$ electrolytes. The electrolysis deposits quite pure (∼99.95%) copper on the cathode. Further purification, to 99.9999% purity, can be accomplished by zone refining, if needed. Commercially significant amounts of by-products are produced in copper refining, including silver, molybdenum, selenium, tellurium, gold, and sulfuric acid.

$$2CuFeS_2 + O_2 \longrightarrow Cu_2S + 2FeO + 3SO_2 \quad (1)$$

$$2FeS + 3O_2 \longrightarrow 2FeO + 2SO_2 \quad (2)$$

$$FeO + SiO_2 \longrightarrow Fe_2(SiO_3)_3 \quad (3)$$

$$2Cu_2S + 3O_2 \longrightarrow 2Cu_2O + 2SO_2 \quad (4)$$

$$Cu_2O + FeS \longrightarrow Cu_2S + FeO \quad (5)$$

$$Cu_2S + O_2 \longrightarrow 2Cu + SO_2 \quad (6)$$

$$2Cu_2O + Cu_2S \longrightarrow 6Cu + SO_2 \quad (7)$$

Copper can also be extracted from the ores using wet processes. Examples of such processes include leaching with dilute sulfuric acid solutions, or the use of solutions containing chelating ligands.

4.3 Uses

Copper is one of the few common metals for which commercial applications use greater amounts of the pure metal than its alloys. The major uses of copper are: building construction (roofing parts, gutters) and plumbing installations (valves, pipe fittings); electrical and electronic products (wire, motors, generators, transformers, switchgears, switchboards, telephone wire, and cable); industrial machinery and equipment; transportation (in automobile pumps, compressors, radiators, heaters, and defrosters as well as in airplane and train parts); household appliances (refrigerators, washing machines, air-conditioners, radios, television sets), and other consumer-related products including cookware, art, and jewelry (some of these items are shown in Figure 4). In addition, copper is part of nearly all coinage alloys, and semiconductor companies have begun to use copper in the production of various devices.[9]

Over 1000 alloys of copper have been studied; each alloy displays slightly different properties than pure copper metal.

Figure 4 A few of the many common objects made from copper metal

The most important ones are probably brass (Cu/Zn) and bronze (Cu/Sn). Bronze is generally a stronger material than brass, however, tin is more expensive than zinc and the electrical and thermal conductivities of brass are larger than those of bronze. An excellent example of how the properties of an alloy change with composition is provided by brasses: the 90/10 (%Cu/%Zn) brass is rich bronze in color, the 85/15 brass is golden, the 70/30 brass is yellow, and the 60/40 brass is reddish yellow. Brass is used for industrial applications, plumbing fixtures, and decorative items such as lamps because it is stronger, more corrosion resistant, and more easily machined than copper itself while having an appearance that is similar to gold but being much less expensive. Some other alloys of copper worth mentioning include: the so-called nickel silver (55–65% Cu, 10–18% Ni, 17–27% Zn, and sometimes Fe, Pb, and Mn); the very corrosion resistant Monel metal (Cu/Ni usually 60/40); aluminum bronzes (Cu/Al); phosphor bronze (Cu with 1.25–10% Sn, 0.35% P); and beryllium copper (~2% Be). The addition of silicon to copper also confers enhanced strength.[10]

5 PROPERTIES OF THE METAL

Copper metal crystallizes with a close-packed, face-centered cubic structure (Figure 5). Pure copper metal has a reddish gold to orange color and is nonmagnetic, relatively dense, and resists wear well. The color of copper metal is due to the excitation of electrons from the filled d band to the s-p conduction band by the absorption of visible light corresponding to blue and green wavelengths (but not orange or red). Copper is highly valued for its strength, malleability, ductility, and corrosion resistance. However, the most important property of bulk copper (see Table 2) is probably its very high electrical conductivity (for metals the conductivity on the basis of a unit volume at room temperature is only exceeded by silver), which is, in fact, used as an international standard (the electrical conductivity of a 1.00-m long copper bar weighing 1.00 g at 20.0 °C is defined as 100% conductivity). Similarly, the very high thermal conductivity of copper leads to many of its commercial applications and again is also only exceeded by the thermal conductivity of silver. Another widely exploited trait of copper is its resistance to oxidation while carrying or storing water, for which the antibacterial properties of copper are also useful.

Both of the naturally occurring isotopes of copper are active in nuclear magnetic resonance (NMR) spectroscopy but are quadrupolar nuclei, both with $I = 3/2$ (Table 3). Copper NMR studies have been limited because most have been restricted to complexes of the Cu^I oxidation state since they are diamagnetic. In addition, the fairly large quadrupole moment for the more abundant ^{63}Cu restricts studies to complexes with nearly perfectly symmetrical environments; small distortions broaden the signal, often making it unobservable. Fewer NMR studies been reported using the second isotope, ^{65}Cu. This is because, even though it has a similar quadrupole moment, it has not only less than half the natural abundance but it also has a lower receptivity. The tetrakis(acetonitrile) complex, $[Cu(CH_3CN)_4]^+$, has most often been used as the reference (defined as 0 ppm) for the ^{63}Cu NMR studies to date.[11] A range of about 500 ppm has been observed for $[Cu(L)_4]^+$ complexes (e.g. for L = P(O-alkyl)$_3$, 70–90 ppm; L = pyridine, 110 ppm; L = PMe_2Ph, 250 ppm; L = CN^-, 480 ppm) with linewidths ranging from 100 to 3000 Hz. Solid state $^{63,65}Cu$ NMR experiments on cuprates have also been reported.[12,13]

Table 2 Properties of copper metal

Atomic number	29
Atomic weight	63.546
Electronic configuration	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^1$
Melting point	1083 °C
Boiling point	2573 °C
Crystal structure	*Fm3m*, face-centered cubic, a = 3.615 Å
Density	$8.95\ g\ cm^{-3}$ at 20 °C; $7.94\ g\ mL^{-1}$ at m.p.
Electronegativity	1.90 (Pauling); 1.75 (Allred–Rochow)
Mass magnetic susceptibility (as a solid)	$-1.081 \times 10^{-9}\ kg^{-1}\ m^3$
Ionic radius (Pauling)	0.96 Å (Cu^I); 0.73 Å (Cu^{II})
Atomic radius; covalent radius	1.278 Å; 1.17 Å
Vapor pressure	5.05×10^{-2} Pa (at the melting point)
Standard reduction potentials	+0.520 V for $Cu^+ + e^- \rightarrow Cu$
	+0.341 V for $Cu^{2+} + 2e^- \rightarrow Cu$
	+0.159 V for $Cu^{2+} + e^- \rightarrow Cu^+$
Ionization potential (1st)	7.725 Ev
Electron affinity	$M \rightarrow M^-$ 118.3 $kJ\ mol^{-1}$
Ionization energies $M \rightarrow M^+$	745.4 $kJ\ mol^{-1}$
$M^+ \rightarrow M^{2+}$	1958 $kJ\ mol^{-1}$
$M^{2+} \rightarrow M^{3+}$	3554 $kJ\ mol^{-1}$
$M^{3+} \rightarrow M^{4+}$	5326 $kJ\ mol^{-1}$
Electrical resistivity	1.675×10^{-6} ohm-cm (20 °C)
Thermal conductivity	$4.01\ w\ cm^{-1}\ °C^{-1}$ (25 °C)
Specific heat	$0.3845\ J\ g^{-1}\ °C^{-1}$ (25 °C)
Effective nuclear charge	4.20 (Slater); 5.84 (Clementi); 8.07 (Froese–Fischer)
ΔH_{fusion}	13.0 $kJ\ mol^{-1}$
ΔH_{vap}	306.7 $kJ\ mol^{-1}$
Coefficient of linear thermal expansion	$16.5 \times 10^{-6}\ cm\ cm^{-1}\ °C^{-1}$ (25 °C)
Electron (or photoelectron) work function ϕ	4.65 eV
Elastic modulus in tension	17 000 000 psi (annealed)
Poisson's ratio	0.33
Tensile strength	32 000–37 000 psi (annealed)
	55 000–61 000 psi (drawn)
Yield strength	4600–12 000 psi (0.5% extension of annealed)
	50 000–55 000 psi (0.5% extension of drawn)
Elongation, % in 2 in.	46 (annealed)
Reduction of area, %	48 (annealed)
Electrical conductivity	101.8% (annealed)
Brinell hardness number	43 (annealed); 103 (hard rolled)
Surface tension	1104 dynes cm^{-1} at 1150 °C
Viscosity	0.0341 cgs units at 1145 °C
Solidification shrinkage	4.92%
Hall effect	-5.24×10^{-4} V; 3000 to 8116 gauss
Velocity of sound	12 700 ft s^{-1} at 20 °C

Table 3 NMR Properties of the naturally occurring copper isotopes

NMR property	^{63}Cu	^{65}Cu
Abundance	69.17%	30.83%
Relative Sensitivity ($^1H = 1.00$)	9.31×10^{-2}	0.11
Receptivity ($^{13}C = 1.00$)	365	201
Magnetogyric ratio (rad $T^{-1}s^{-1}$)	7.0965×10^7	7.6018×10^7

Frequency (^1H = 100 Hz; 2.3488 T) in Hz	26.505	28.394

The two naturally occurring isotopes of copper are stable to nuclear decay. Nine synthetic radioisotopes have been reported (^{59}Cu, ^{60}Cu, ^{61}Cu, ^{62}Cu, ^{64}Cu, ^{66}Cu, ^{67}Cu, ^{68}Cu, ^{69}Cu) with half-lives of those nuclides ranging from 31 s (^{68}Cu) to 2.58 days (^{67}Cu).[6] One isotope has been used for medical diagnostic purposes (*see* ***Metal-based Imaging Agents***) to scan the brain and to study Wilson's disease. This isotope, ^{64}Cu, has a half-life of 12.7 h (decay modes: β^- at 0.571 MeV, β^+ at 0.657 MeV, and γ at 1.34 MeV) and is usually administered as copper^{II} acetate (orally or intravenously for Wilson's disease studies) or copper^{II} versenate (intravenously for brain scans).[14]

6 REACTIONS OF THE METAL

Metallic copper is stable indefinitely in pure dry air at room temperature, but forms a superficial protective green coating or patina of hydroxo carbonates and hydroxo sulfates in the atmosphere. Copper is attacked more readily by some other oxidants, including elemental sulfur and halogens. In the absence of air, copper metal does not react with nonoxidizing acids, as it is below hydrogen in the electromotive or activity series. However, copper metal dissolves in hot concentrated sulfuric acid and both dilute and concentrated nitric acid (and acidic solutions of thiourea). Copper also dissolves in aqueous ammonia or cyanide solutions in the presence of dioxygen or, more readily, when hydrogen peroxide is added.

7 USUAL OXIDATION STATES AND STEREOCHEMISTRIES

Copper complexes are known in oxidation states ranging from 0 to +4, although the +2 (cupric) and the +1 (cuprous) oxidation states are by far the most common, with the divalent state predominating. Only a relatively small number of Cu^{III} complexes have been characterized and the Cu^0 and Cu^{IV} oxidation states are extremely rare. A few mixed valence (*see* ***Mixed Valence Compounds***) polynuclear species have also been isolated; examples include a Cu^I/Cu^{II} species[15] and a Cu^{II}/Cu^{III} catenane.[16] The coordination numbers and geometries (*see* ***Coordination Numbers & Geometries***) of copper complexes vary with oxidation state. Thus, the majority of the characterized Cu^{III} complexes are square planar and diamagnetic, as is common for late transition metals with d^8 electronic configurations.

For the spherically symmetric Cu^I d^{10} ion, the common geometries are two-coordinate linear, three-coordinate trigonal planar, and four-coordinate tetrahedral. Some distortions from these ideal geometries are observed, particularly with chelating ligands; a fairly small number of pentacoordinate Cu^I complexes have been isolated and characterized as well. Cu^I compounds are diamagnetic and colorless, except where the color results from charge-transfer bands[17] or a counterion. Cu^I complexes are often fairly readily oxidized to Cu^{II} compounds; the electron-transfer kinetics of several systems have been studied.[18]

The d^9 Cu^{II} ion is commonly found in a tetragonal coordination environment, with four shorter equatorial bonds and another one or two longer axial bonds[19] or less frequently with two shorter axial bonds and four longer equatorial bonds,[20] although four-coordinate tetrahedral and planar complexes are also known, for instance, the $CuCl_4{}^{2-}$ ion, which has crystallized in geometries ranging from square planar (usually green) to almost ideal tetrahedral (usually orange).[21] Additionally, five-coordinate trigonal bipyramidal to square-planar complexes have been reported, as well as a small number of three-, seven-, and eight-coordinate complexes. Most of the Cu^{II} compounds are blue or green in color because of d–d absorptions in the 600–900 nm region; exceptions generally also have charge-transfer bands tailing into the visible, causing a red or brown appearance. Magnetic moments of monomeric Cu^{II} complexes are typically found in the range 1.75–2.20 BM (Bohr magnetons; *see* ***Magnetism of Transition Metal Ions***), consistent with one unpaired electron.

Since the Cu^{II} ion is smaller and more highly charged or harder (*see* ***Hard & Soft Acids and Bases***) than the Cu^I ion, it interacts more strongly with water molecules – the result being that the Cu^{II} ion is more stable in aqueous solutions than the Cu^I ion (in spite of the stable d^{10} configuration for Cu^I). Thus, water does not sufficiently stabilize the Cu^I ion; it is unstable toward disproportionation to Cu^0 and Cu^{II} in solution (which is usually a fast process for soluble compounds that produce the Cu^I ion in solution). However, the stability of Cu^I relative to Cu^{II} is easily altered, such that the presence of softer ligands will stabilize Cu^I (e.g. sulfur donors, unsaturated nitrogen donors, etc.). For example, the Cu^I ion is effectively solvated by CH_3CN,[22] which makes the resulting complex stable toward disproportionation (in acetonitrile Cu^{II} and Cu comproportionate to Cu^I) as well as to molecular oxygen in CH_3CN solution (as the oxidation of Cu^I by O_2 generally requires an open coordination site). There are other strategies to obtain water-stable and -soluble Cu^I complexes, for instance, by the coordination of the copper ion to a softer ligand that also incorporates very polar or charged peripheral functional groups.[23]

8 BINARY AND OTHER SIMPLE COMPOUNDS

Copper compounds containing carbon-bound ligands, such as cyanide, carbon monoxide, alkyls, and so on are covered elsewhere (*see* ***Copper: Organometallic Chemistry***).

8.1 Hydrides (*see also Hydride Complexes of the Transition Metals*)

The high-temperature reaction of Cu and H_2 yields CuH, which has been studied spectroscopically in the gas phase; the reddish-brown precipitate obtained when aqueous $CuSO_4$ is reduced by hypophosphorous acid (H_3PO_2) is probably also largely CuH.[24] CuH_2 is not isolable, as it appears to be a higher energy species than Cu + H_2.[25] The Cu^{II} cationic hydride $[CuH]^+$ has been observed by using a guided ion beam approach to study the reaction of Cu^+ and H_2.[24] The tetrahedral $Cu^IH_4{}^{3-}$ anion was found in the product from the reaction of a Ba/Cu alloy with H_2.[26] Matrix-isolation techniques combined with laser-ablated Cu + H_2 reactions appear to have formed several copper hydrides, including CuH and $CuH_2{}^-$.[27,28]

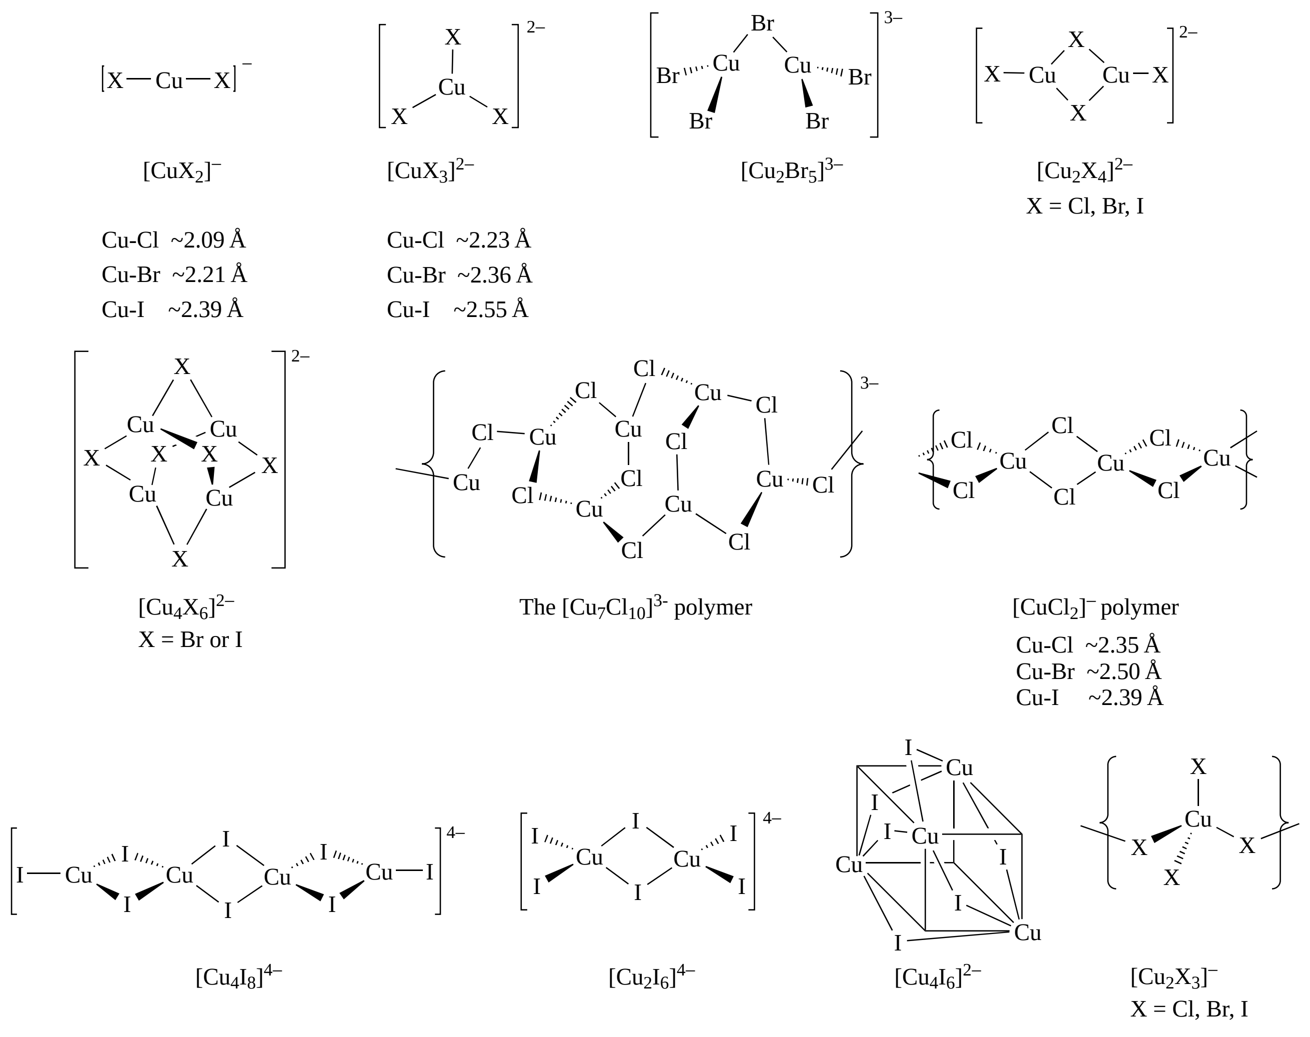
8.2 Halides

CuCl and CuBr can be synthesized by boiling an acidic solution of the Cu^{II} halide with an excess of copper metal; dilution causes precipitation of white CuCl or pale yellow to white CuBr, which are polymeric even in the vapor state (as a solid, CuCl crystallizes as the zinc blende structure with regular tetrahedral $CuCl_4$ centers, linked by bridging chlorides). Binary $copper^I$ compounds with very hard fluoride ligands are not known, undoubtedly because CuF is unstable to disproportionation to form CuF_2 and Cu.[29]

The $copper^{II}$ dihalide complexes CuX_2 (X = F, C, Br) can be synthesized from the elements. The white ionic CuF_2 compound has a tetragonally distorted octahedral structure about the copper ion with extensive bridging fluoride ligands. Anhydrous $CuCl_2$ and $CuBr_2$ are more covalent yellow-brown and black compounds, respectively, that are polymers of planar CuX_4 units with shared edges. Monomeric $CuCl_2$ and $CuBr_2$ exist in the gas phase at high temperatures; for example, $CuCl_2$ has been studied spectroscopically at 1000 °C in the presence of Cl_2 (to prevent decomposition to CuCl and Cl_2).[30] Binary $copper^{II}$ compounds with very soft iodide ligands are not known; by simply adding I^- to a solution of Cu^{2+}, CuI and I_2 are quickly formed. This reaction can be used for the volumetric analysis of Cu^{2+} in solution by titrating the I_2 produced with sodium thiosulfate (equation 8). Hydrates of the dihalides (F, Cl, Br) are common, easily prepared from aqueous haloacids, and contain coordinated water molecules.

$$2Na_2S_2O_3 + I_2 \longrightarrow Na_2S_4O_6 + 2NaI \qquad (8)$$

Copper chloride complexes can be used as catalysts in a number of organic reactions. Examples include the Wacker process, which is the oxidization of ethylene to acetaldehyde by oxygen and aqueous Cu^{II} and Pd^{II} precatalysts (or, alternatively using iron catalysts)[31] plus the synthesis of acrylonitrile from acetylene and hydrogen cyanide using CuCl. Cuprous chloride has also been used as a desulfurizing and

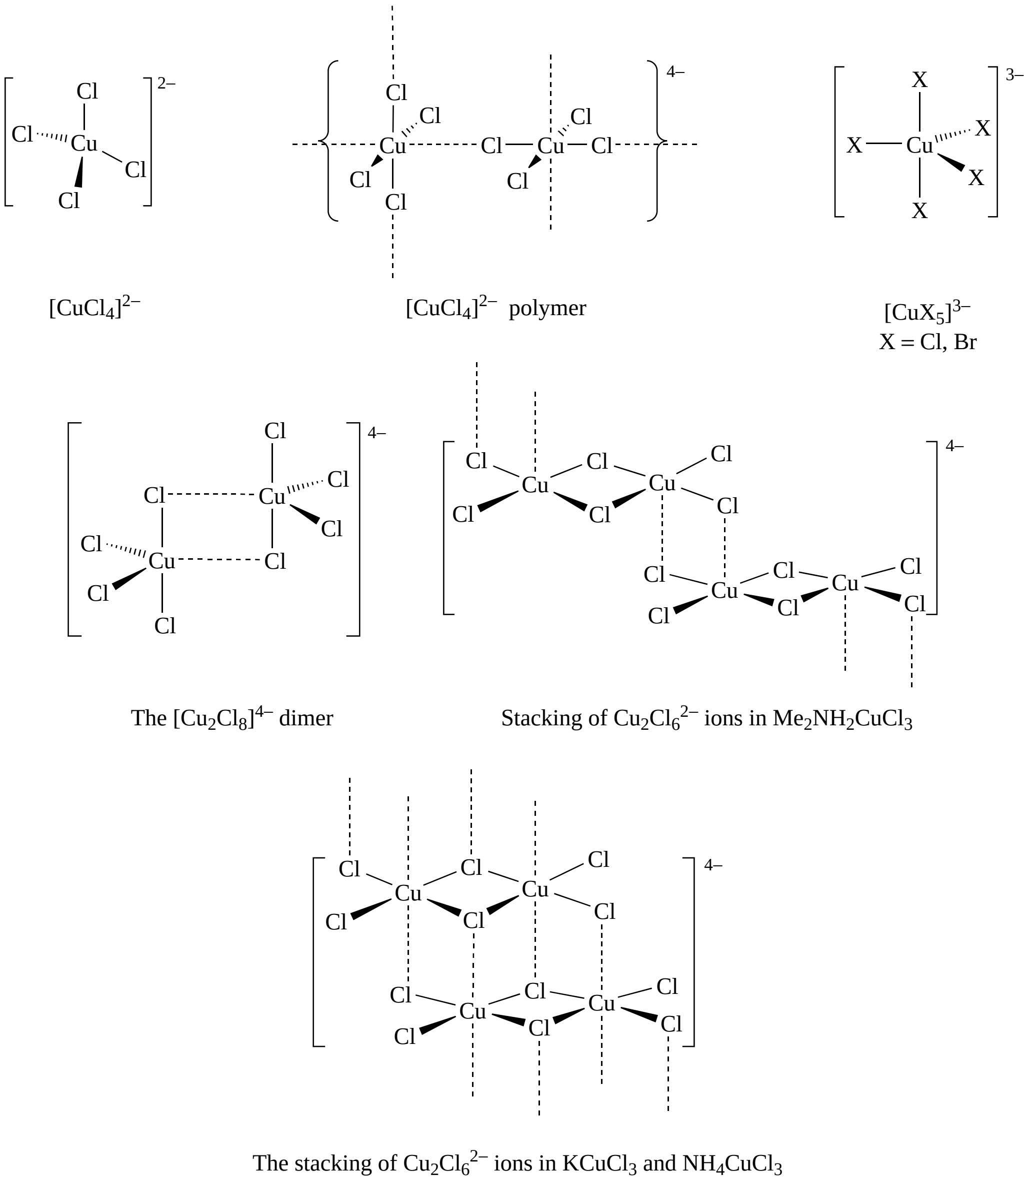


Scheme 2 Structures of selected anionic $copper^I$ halides

decolorizing agent in the petroleum industry; cupric chloride as a fixative in the dyeing and printing of textiles plus as a disinfectant, feed additive, and pigment for glass and ceramics.

Only the examination of only a few anionic cuprous halide[32] complexes (Scheme 2) is needed to clearly illustrate the geometric preferences of the Cu^I ion.[33,34] Thus, $[CuX_2]^-$ exhibits a linear structure. Trigonal-planar CuX_3 triangles are quite common, Examples include the complexes $[CuX_3]^{2-}$ and $[Cu_2Br_5]^{3-}$; the latter ion has two $CuBr_3$ triangles linked through a bridging bromide and that are folded to give a Cu–Br–Cu angle of about 73°; $[Cu_2X_4]^{2-}$, where the two of these triangles share one side; and $[Cu_4Cl_6]^{2-}$, where four $CuCl_3$ triangles have common vertices. Tetrahedral copper centers are found frequently, such as in the dimeric complex $[Cu_2I_6]^{4-}$ as well as in the tetranuclear $[Cu_4I_8]^{4-}$ complex (that also contains trigonal-planar copper centers). Polymeric copper halides are also common; examples are $[Cu_7Cl_{10}]^{3-}$ and $[Cu_2X_3]^-$. In addition, many stoichiometries can exist in more than one form depending on the nature of the counterion; for instance, $[CuCl_2]^{2-}$ is a discrete, linear monomer only with large cations, otherwise it is a linked tetrahedral polymer. Unlike the smaller halide ligands, the iodide ion can form more open structures with Cu^I ions, such as the cubane-type structure seen for $[Cu_4I_6]^{2-}$, which has a Cu_4 tetrahedron with six I^- ions bridging the Cu_2 edges.

Similarly, the cupric ion also has distinct coordination geometry preferences, which are seen when a few of the Cu^{II} halide complexes are examined (Scheme 3).[35] The Cu^{II}



Scheme 3 Typical Cu^{II} anionic halides

coordination numbers are often higher than those seen for Cu^{I}, typically from four to six, and the structures are usually distorted from ideal geometries due to the Jahn-Teller effect. Complexes with the formula $[CuCl_3]^-$ usually exist as recognizable $[Cu_2Cl_6]^{2-}$ dimers which stack in various ways, and the discrete dianion $[CuCl_4]^{2-}$ has been seen in a range of structures from tetrahedral to square planar to a polymeric form.[21] Again, the structures of the complexes are very dependent on the nature of the counterion. The polymeric form of $[CuCl_4]^{2-}$ stoichiometry comprises tetragonally elongated octahedra that are linked to create infinite layers. The pentahalide complexes $[CuX_5]^{3-}$ (X = Cl, Br) have a trigonal bipyramidal structure when large cations force it to be monomeric. The high-valent anionic copper-fluoride compounds, M_3CuF_6 and M_2CuF_6 (M = alkali metal), can be synthesized by the high-pressure fluorination of mixtures containing the proper ratio of MCl and CuCl. The pale-green K_3CuF_6 compound is paramagnetic (two unpaired electrons) and exhibits an octahedral geometry about the copper ion; the brick-red compound Cs_2CuF_6 is an example of a complex containing the rare Cu^{IV} oxidation state. A crystal structure containing a three-coordinate Cu^{II} complex ion with isolated $[CuX_3]^-$ (X = mixed Cl and Br) species was recently reported.[36]

8.3 Hydroxides

CuOH has been studied spectroscopically and theoretically.[37] The binary Cu^{II} hydroxide complex exists as either a gelatinous green-blue material with variable water content (probably with coordination to both OH^- and H_2O ligands), or as a pale-blue crystalline material of $Cu(OH)_2$ stoichiometry (Figure 6) isolated upon adding a base to a Cu^{II} solution at room temperature. The synthesis can be slightly modified to yield colloids or nanowires.[38] The Cu^{II} complex $Ba_2[Cu(OH)_6]$ has also been reported,[39] as well as the dark blue anions $[Cu(OH)_4]^{2-}$ and $[Cu(OH)_6]^{4-}$ which are formed in concentrated alkali metal hydroxide solutions.

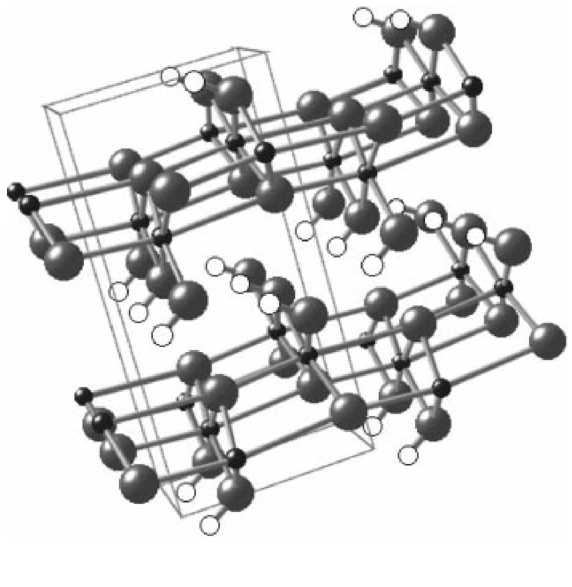


Figure 6 The structure of $Cu(OH)_2$

8.4 Oxides

The Cu^{I} oxide is more stable than the Cu^{II} oxide; thus the reaction of copper metal and oxygen yields black CuO initially when heated gently, but this compound is converted to red Cu_2O during longer reaction times and/or at higher temperatures. Yellow to reddish Cu_2O (the color depends on the particle size) can also be conveniently prepared by the reduction of a Cu^{II} salt using hydrazine or a sugar in aqueous alkaline solution; this is the basis for Fehling's test for sugars and other reducing agents. The compound Cu_2O has two-coordinate linear CuO_2 centers;[40] X-ray and electron diffraction techniques and electronic-structure calculations for Cu_2O are interpreted to indicate Cu–Cu bonding in the solid state for this compound.[41,42] Cuprous oxide is used as a red pigment in some paints, glasses, porcelain glazes, and ceramics and has been used as a fungicide. CuO is best prepared by pyrolysis of the Cu^{II} nitrate or other oxo salts; it is sometimes used as a black surface coating in solar-energy collecting devices because a thin layer transmits infrared radiation but not shorter wavelength radiation. Upon heating a mixture of K_2O and Cu_2O, the nearly colorless KCuO compound is prepared; this compound contains $[Cu_4O_4]^{4-}$ rings with coplanar Cu atoms. The Cu^{II} oxides M_2CuO_3 (M = Ba or Sr) contain linked CuO_4 planar units. The bluish Cu^{III} complex, $MCuO_2$ (M = alkali metal), can be made from CuO and MO_2 in an oxygen atmosphere; it is a low-spin, diamagnetic square-planar complex as one might predict for such a d^8 metal center. A high-pressure synthesis and an oxidizing agent were required to make Sr_2GaCuO_5, which contains only Cu^{III} ions.[43]

8.5 Sulfides, Selenides, and Tellurides

The binary Cu^{I} sulfide is more stable than the Cu^{II} compound of empirical formula CuS, which is actually better formulated as $Cu_2Cu^{II}(S_2)S$;[44] $NaCu_4S_4$ has a related structure to CuS.[45] Cu_2S can be prepared by heating copper and sulfur (or H_2S) in the absence of air or by heating CuS in a stream of hydrogen gas. CuS is produced as a black, insoluble colloidal precipitate by the action of H_2S on an aqueous solution of Cu^{II} ion, which can be dissolved by the addition of Na_2S because of the formation of $[CuS_2]^{2-}$. Cuprous sulfide is used in solar cells (or ternary chalcopyrites such as $CuInS_2$[46]), electrodes, and certain solid lubricants. The selenides and tellurides, CuX, Cu_2X, MCuX, MCu_3X (M = Na, K; X = Se, Te), and $K_4Cu_8Te_{11}$ are also known, some of which are superconductors. The polytelluride complex $K_2Cu_2(Te_2)(Te_3)$

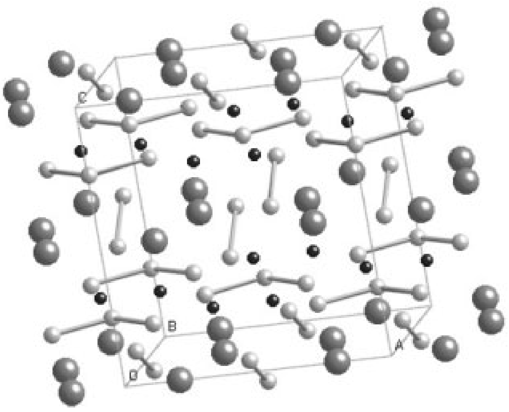

Figure 7 The solid-state structure of $K_2Cu_2(Te_2)(Te_3)$ which exhibits alternating $Cu_2(Te_3)$ planes with potassium ions with Te_2^{2-} ion containing planes. Copper centers are shown as black spheres, tellurium atoms are nearly white, and potassium ions are gray and only bonds between Te atoms are shown to aid visualization

crystallizes (Figure 7) with four Te atoms coordinated to each Cu center in an approximately tetrahedral array with Cu ions paired up and displaying short Cu−Cu distances of 2.574(3) Å.[47] The nonclassical $[CuTe_7]^{3-}$ anion has been crystallized and studied theoretically.[48]

8.6 Sulfates

The Cu^I sulfate complex, Cu_2SO_4, can be prepared from copper^I oxide (equation 9). This compound must be stored in dry conditions because moisture causes the compound to disproportionate to Cu and $CuSO_4$. The very stable Cu^{II} sulfate pentahydrate compound $CuSO_4{\cdot}5H_2O$, often called blue vitriol for its bright blue color, is the copper compound used commercially in the greatest quantity. This compound is formed in the reaction of CuO and sulfuric acid and is widely utilized for electroplating processes, as a fungicide and an algaecide, as a component of fertilizers, plus as a starting material to synthesize other copper compounds. The biuret test for proteins involves the addition of $CuSO_4{\cdot}5H_2O$ to a basic solution potentially containing protein; the hydroxide ions hydrolyze the protein at least partially to form fragments that coordinate to the Cu^{II} ion to give a characteristic violet-purple color. The solid-state structure of crystalline $CuSO_4{\cdot}5H_2O$ has four water ligands coordinated to the Cu^{II} ion in the equatorial plane and two axially bound monodentate sulfate groups, giving an overall elongated-octahedral geometry about the Cu center. The fifth water molecule is hydrogen bonded in the lattice between the bridging sulfate groups and one of the coordinated waters. Upon heating, $CuSO_4{\cdot}5H_2O$ loses water, first to give the trihydrate, then the monohydrate, and finally (above about 200 °C) producing the white anhydrous compound $CuSO_4$, which eliminates SO_3 above about 700 °C to form CuO.

$$Cu_2O + Me_2SO_4 \longrightarrow Cu_2SO_4 + Me_2O \qquad (9)$$

8.7 Nitrates

The binary Cu^I nitrate $CuNO_3$ compound is not known. The hydrated Cu^{II} nitrate complex, $Cu(NO_3)_2(H_2O)_2{\cdot}1/2H_2O$, has an unsymmetrically coordinated bidentate nitrato group; it cannot be fully dehydrated to the anhydrous Cu^{II} nitrate without decomposition. The anhydrous compound $Cu(NO_3)_2$ is instead prepared by the dissolution of copper metal in an ethyl acetate solution of N_2O_4 from which the salt $Cu(NO_3)_2{\cdot}N_2O_4$ is crystallized (which is probably formulated $[NO^+][Cu(NO_3)_3^-]$).[49] Finally, this salt is gently heated to yield the blue sublimable compound $Cu(NO_3)_2$, which exists as a gaseous monomeric planar complex with chelated nitrate ligands or as a solid with an infinite array of Cu^{II} ions linked by nitrate groups. Cupric nitrate has been used in light-sensitive reproductive papers and as a polishing/coloring reagent for iron and copper items.

8.8 Nitrites

Copper^I nitrites are unknown, in contrast to Cu^{II}, for which more than one stoichiometry has been found. In $[Cu(NO_2)_6]^{4-}$ all the nitrite ligands are N-bound (nitro groups). In contrast, the structure of the complex $K_3[Cu(NO_2)_5]$ contains all possible NO_2^- binding modes to a single metal center, including N-bound, symmetrical bidentate O-bound, and unsymmetrical monodentate binding through only one O-atom. The complex ion $[Cu(NO_2)_4]^{2-}$ in one system has been found to contain O-bound nitrite groups.[50]

8.9 Phosphates

In the Cu^{II} compound $Cu_3(PO_4)_2$, the bridging phosphate group interacts with seven (!) different copper centers; three of the phosphate oxygen atoms bridge two copper centers with the other oxygen coordinated to only one copper ion.[51] The anionic $[CuPO_4]^-$ compounds exhibit extensive Cu–O interactions as well, which vary with factors such as the associated cation.[51] The crystal structures of the pyrophosphate-containing compounds $Cs_2Cu_7(P_2O_7)_4{\cdot}6CsCl$ and $Cs_2Cu_5(P_2O_7)_3{\cdot}3CsCl$ contain square-planar CuO_4 units in open-framework structures.[52] Square planar, trigonal bipyramidal, and distorted octahedral geometries are found for the copper ions in mixed strontium-copper phosphate structures.[53] Three polymorphs for the structure of copper^{II} hypophosphite, $Cu(H_2PO_2)_2$, have been reported.[54]

8.10 Carbonates

Binary copper carbonate complexes are apparently not known; however, the basic carbonates malachite, $Cu_2(OH)_2CO_3$, and azurite, $Cu_3(CO_3)_2(OH)_2$, occur naturally. The complex ion $[Cu(CO_3)_2]^{2-}$ contains a bridging carbonate ligand that is bound in a monodentate fashion to each copper ion; the hydrated species, $Na_2Cu(CO_3)_2 \cdot 3H_2O$, is also known. Cupric carbonate ($Cu_2(OH)_2CO_3$) is prepared by the reaction of sodium carbonate and copper sulfate; this compound is used as a coloring agent and, after reaction with arsenic to form the poisonous acetate cupric arsenite compound $Cu(C_2H_3O_2)_2 \cdot 3Cu(AsO_2)_2$, a wood preservative and insecticide commonly known as Paris green.

8.11 Acetates

Cu^I acetate is a white crystalline air- and moisture-sensitive compound formed by the reduction of anhydrous Cu^{II} acetate with copper metal in pyridine or acetonitrile solvent. Cu^{II} acetate is usually found as the dimeric dihydrate complex, $Cu_2(CH_3COO)_4 \cdot 2H_2O$, which has been used as a starting compound in the sol-gel synthesis of CuO thin films.[55] The Cu^{II} ion in the crystal structure of $Cu_2(CH_3COO)_4 \cdot 2H_2O$ is approximately square pyramidal in geometry (Figure 8) with four bridging acetate ligands and a water ligand in the axial position.[56] The Cu–Cu distance of 2.64 Å in this complex, along with the fairly high magnetic moment (1.4 BM per Cu at 25 °C; compare to the spin-only value of 1.73 BM; *see* ***Magnetism of Transition Metal Ions***) suggest that there is not a formal Cu–Cu bond, although there is weak antiferromagnetic coupling. The sodium salt of the monomeric Cu^{II} tetraacetate complex crystallizes with monodentate acetate groups and a square-planar geometry about the Cu ion.[57]

8.12 Alkoxides

Copper^I alkoxide complexes are typically yellow in color and are made from Cu^I starting materials, for example, in the metathesis reaction shown in equation (10). Cu^IOR complexes are generally soluble in etheral solvents and some

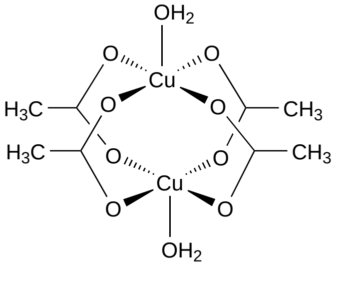

Figure 8 A depiction of the structure of $Cu_2(CH_3COO)_4 \cdot 2H_2O$

are sublimable; exceptions are polymeric complexes such as the methoxide. The triphenylmethoxocopper^I complex crystallizes as a tetramer with alkoxo bridges and the *tert*-butoxocopper^I complex crystallizes as two polymorphs, a similar tetranuclear structure plus a unique octanuclear form.[58] Cu^IOR complexes are generally reactive. Thus, Cu^IOR complexes metallate acidic hydrocarbons such as in terminal acetylenes, and will react with organic halides to give ether products, plus they will react with carbon dioxide and secondary amines to yield carbamate products.[49]

$$CuCl + LiOR \longrightarrow LiCl + CuOR \qquad (10)$$

8.13 Other Compounds

The anhydrous Cu^I sulfite complex is not known; however, hydrated species can be prepared, including the pale-yellow $Cu_2SO_3 \cdot 1/2H_2O$ compound (known as Etard's salt) and the mixed sulfites NH_4CuSO_3 and $NaCuSO_3 \cdot 6H_2O$. The blue hydrated Cu^{II} ion $[Cu(H_2O)_6]^{2+}$ is formed when the Cu^{II} hydroxide, carbonate, sulfate, or nitrate binary compounds are dissolved in water. The coordinated water ligands can be substituted for ammonia molecules; thus, equilibrium solutions of mixed aqua/ammine complexes are formed in aqueous ammonia. The average stoichiometry depends on the ammonia concentration; in concentrated ammonia solutions $[Cu(NH_3)_4]^{2+}$ is probably the predominant species, although $[Cu(NH_3)_6]^{2+}$ can been prepared in liquid ammonia and must be stored under an ammonia atmosphere to prevent decomposition. The perchlorate Cu^{II} complex $Cu(ClO_4)_2$ is known; spectroscopic results are consistent with the presence of two types of coordinated bidentate perchlorate groups. In addition, the orange perchlorate-containing complex $ClO_2Cu(ClO_4)_3$ is an isolable intermediate in the synthesis of the blue-white $Cu(ClO_4)_2$ and $Cu(ClO_4)_2 \cdot 2H_2O$.[59] The copper triflate compounds $Cu^{II}(CF_3SO_3)_2$ and $Cu^I(CF_3SO_3)C_6H_6$ have been used as starting materials for the synthesis of a number of compounds. Cu^I complexes with NO, Ar, and Xe have been studied in the gas phase.[60]

9 COORDINATION COMPOUNDS

Owing to limitations on the size of this article, plus the large number of Cu^I and Cu^{II} complexes that have been reported, only a general overview of the extensive coordination chemistry of copper can be presented with only a few of the typical and unusual complexes described. More extensive[39,61] and limited timeframe reviews[62–69] are available. Many of the homoleptic complex ions are covered along with the binary compounds in the above sections. In addition, organometallic complexes, containing C-bound ligands, are covered in another chapter (*see* ***Copper: Organometallic Chemistry***).

9.1 Copper^0

No structurally characterized discrete Cu^0 complexes are known. A few species have been observed in the gas phase, or at very low temperatures using matrix-isolation techniques, including polynuclear copper species such as Cu_2 and Cu_3 and several copper–carbon monoxide and copper-ethylene species. There have also been reports of reactive species thought to contain zerovalent copper,[70] and several clusters or other species where, arguably, some of the Cu is present in the Cu^0 oxidation state.[71]

9.2 Copper^I

The Cu^I ion is classified as a soft acid (*see* ***Hard & Soft Acids and Bases***), which predicts reasonably well the types of ligands that will be most stabilizing and are, thus, commonly observed in Cu^I complexes. The preference of Cu^I for softer ligands is quite apparent in the homoleptic complexes, for instance the halides discussed above. Polynuclear compounds are quite commonly seen in the chemistry of Cu^I. Thus, the solid-state structure cannot be reliably predicted from the reaction stoichiometry or from the empirical formula of the resulting compound. The careful selection of ligands, for instance, an appropriate macrocyclic ligand can ensure the formation of a mononuclear complex if one is desired.

9.2.1 Hydrogen Ligands

Complexes of Cu^I with hydride (*see* ***Hydride Complexes of the Transition Metals***) and other H-donating ligands are fairly rare; most of the reported examples contain phosphine coligands. For example, the stable, readily prepared copper borohydride complex, $Cu(BH_4)(PPh_3)_2$, contains a coordinated BH_4^- group (*see* ***Boron Hydrides***) and has been found to be a very selective reducing agent, for instance, in reducing acid chlorides to the corresponding aldehydes.[72] Similarly, the hexameric species $[H_6Cu_6(PPh_3)_6]$, which contains bridging hydride ligands, has been found to be a good reagent for reductive organic transformations, such as the conversion of α,β-unsaturated carbonyl compounds to saturated carbonyl compounds.[73] In addition, the in situ preparation of phosphine-ligated 'CuH' has been utilized for organic synthetic reactions.[74]

9.2.2 Halide Ligands

As predicted by the soft nature of Cu^I, very few examples of fluoride-coordination are known, and the ones that have been reported typically have additional Cu^I-stabilizing ligands, such as $[Cu(PPh_3)_3F]$. Coordination of a fluoride-containing anion, such as BF_4^- is, perhaps, more common, for instance, in the phosphine complex $[Cu(PPh_3)_3(FBF_3)]$. A completely different situation is seen for the chloride ion, in that both extensive Cu^I homoleptic compounds are known (see above) as well as complexes containing mixed chloride/other donor ligands. A fair number of bromide and iodide compounds have been prepared as well, although not nearly as many as ones containing chloride ligands. This is presumably not due to the lack of stability of those species, but rather because of choices made by researchers considering factors such as the availability of literature starting material preparations, cost, and desired reactivity.

9.2.3 Nitrogen Ligands

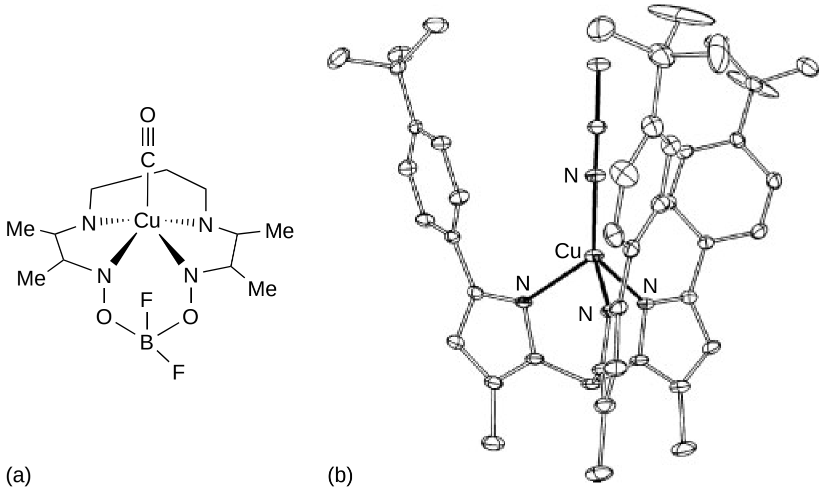
A variety of different nitrogen ligands (*see* ***Ammonia & N-donor Ligands***) have been used to synthesize Cu^I complexes. Monovalent complexes with exclusively saturated N-donor ligands are known, but are generally less stable than analogous complexes with unsaturated or aromatic nitrogen-containing ligands. Thus, the ammine complex $[Cu(NH_3)_2]^+$ can be prepared, but it is less stable than the analogous Cu^I complex with imidazole donors. In addition, accounts of Cu^I complexes with chelating nitrogen ligands outnumber those involving monodentate nitrogen ligands. $Cu(LBF_2)(CO)$ [L = difluoro-3,3′-(trimethylenedinitrilo)bis(2-butanone oximato)borate; Figure 9(a)][75] is an example of the rare, but growing number of five-coordinate Cu^I complexes. Nitrogen-ligated Cu^I complexes have also been studied for their photochemical (*see* ***Photochemistry of Transition Metal Complexes***) properties,[76] including their long-lived excited states.[77] A number of tris(pyrazolyl)hydroborate-ligated[78] Cu^I complexes have been prepared and crystallographically characterized, such as the complex shown in Figure 9(b).[79]

9.2.4 Phosphine, Arsine, and Stibine Ligands

Phosphorus is one of the best soft donor atoms for Cu^I; thus many Cu^I-phosphine complexes have been reported, including ones with other ligands that by themselves would be unlikely to sufficiently stabilize Cu^I. By far, most of the known complexes involve monodentate phosphine ligands. As one goes down the nitrogen family, progressively fewer complexes have been characterized, such that substantially less arsine-coordinated complexes have been reported and there are only a handful of stibine species.

9.2.5 Oxygen Ligands

The actual number of reported Cu^I complexes with oxygen-donor ligands (*see* ***Water & O-donor Ligands***) is much smaller than for complexes containing other kinds of ligands, such as those with halide and/or pnictogen donor atoms, but, nevertheless, a wide range of ligand types is represented. A fair number of complexes containing coordinated oxyanions can be prepared; for instance, see the sections above on sulfate, phosphate, acetate, and alkoxide ligands. Some of the



(a) (b)

Figure 9 An example of a five-coordinate Cu^I complex (a) and a copper acetonitrile complex with a substituted tris(pyrazolyl) hydroborate ligand (b)

ligands that are unknown in homoleptic compounds can be found in complexes with other Cu^I-stabilizing coligands, for instance, H_2O in $[Cu(1,4\text{-oxathiane})_3(OH_2)]BF_4$ and nitrate in $[Cu(PPh_3)_2(NO_3)]$.

9.2.6 *Sulfur, Selenium, and Tellurium Ligands*

There is extensive Cu^I chemistry with the soft sulfur-donor ligands (*see* ***S-donor Ligands***). Thus, the addition of Me_2S to a solution of Cu^{II} forms a Cu^I species. A variety of sulfur-containing ligands and kinds of complexes can be found, for instance, monodentate ligation in trigonal planar $[Cu(\text{tetraethylenethiourea})_3]SO_4$, extensive bridging in $(Ph_4P)_2[Cu_4(SPh)_6]$, the polysulfide anion as in the aggregate $(Ph_4P)_2[Cu_6(S_4)_3(S_5)]$, and the macrocyclic $[Cu(15\text{-ane-}S_5)]^+$. Selenium- and tellurium-containing Cu^I complexes are also known, but are not nearly as abundant as sulfur-ligated compounds; examples are the cluster compound $Cu_{12}(P_2Se_6)\{Se_2P(OCH_2CH_3)_2\}_8$ which contains trigonal-planar $CuSe_3$ and tetrahedral $CuSe_4$ groups as well a number of short Cu−Cu distances in the solid state[80] and polynuclear compounds containing Cu^I and halide ions plus a chelating phosphine-selenide ligand.[81]

9.3 Copper^{II}

The Cu^{II} ion is classified as a borderline hard acid (*see* ***Hard & Soft Acids and Bases***); thus, its coordination chemistry is dominated by nitrogen- and oxygen-donating ligands, followed by chloride and sulfur-containing species. Similar to the situation seen for Cu^I, ligands not normally associated with Cu^{II} can often be found in the presence of Cu^{II} stabilizing coligands. More crystal structures of Cu^{II} complexes have been reported than for any other transition metal ion.[20]

9.3.1 *Hydrogen Ligands*

Although virtually unknown in Cu^{II} chemistry, Cu-hydride species have been suggested as reactive intermediates in hydrogenation reactions.[82]

9.3.2 *Halide Ligands*

Copper-fluoro complexes are more frequently encountered for the Cu^{II} ion than for the Cu^I ion, although not to the extent one might predict. Fluoride bound in a monodentate fashion is extremely rare, while bridging fluoride ligands and coordinated F-containing anions, such as $BF_4{}^-$ and $PF_6{}^-$, are more common. Similar to that found for Cu^I, chloride is found extensively in Cu^{II} chemistry, followed distantly by bromide. Iodide coordination to Cu^{II} is, as one might expect, limited; seen only in complexes such as [Cu(bipy)I]I. The section on binary and simple compounds above also discusses a number of Cu^{II} halide compounds.

9.3.3 *Phosphine, Arsine, and Stibine Ligands*

These soft ligands are very rarely isolated in Cu^{II} complexes, however, they can occur with Cu^{II} stabilizing ligands, such as in the tetraacetate dimer $[Cu_2(O_2CMe)_4(PPh_3)_2]$.

9.3.4 *Nitrogen and Oxygen Ligands*

Nitrogen- (*see* ***Ammonia & N-donor Ligands***) and oxygen-donor (*see* ***Water & O-donor Ligands***) ligands are very prevalent in Cu^{II} chemistry and cover a wide range of ligand types, for example, N-donor ligands include saturated amines like ammonia and ethylene diamine, nitro groups (N-bound NO_2), azides, nitrogen-bound cyanates, and aromatic

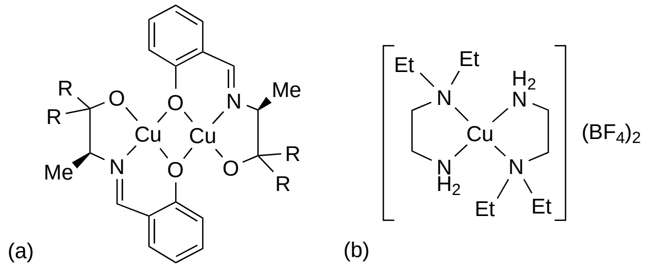


Figure 10 (a) A dimeric Cu^{II} complex with mixed oxygen/nitrogen ligation that is used as an asymmetric cyclopropanation precatalyst (R = bulky substituted phenyl group). (b) A thermochromic complex that is red at lower temperatures and is purple at higher temperatures

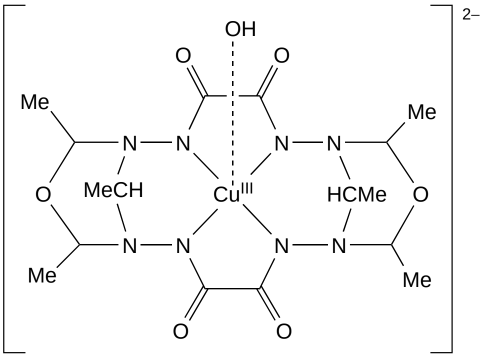

Figure 11 An example of a Cu^{III} complex that has been structurally characterized

amines such as the pyridines and imidazoles. Chelated groups are also very commonly seen. The Cu^{II} complex with a N/O-mixed donor ligand (*see* ***Mixed Donor Ligands***) shown in Figure 10(a) has been used as an asymmetric cyclopropanation[83] precatalyst.[84] The monomeric nitrogen-ligated complex shown in Figure 10(b) is interesting because it exhibits thermochromic behavior; at lower temperatures the complex is red and square planar about the Cu^{II} center while at higher temperatures the complex converts to a purple tetrahedral form.[85] Nitrogen-ligated copper, for example, complexes with N-alkylated triazacyclononane ligands have been used to model the dioxygen activation (*see* ***Dioxygen & Related Ligands***) chemistry of copper-containing metalloproteins (*see* ***Copper: Hemocyanin/Tyrosinase Models***),[86] as hydrolysis and aziridination[87] catalysts, and as DNA cleavage agents.[88]

9.3.5 Sulfur Ligands

A fair number of Cu^{II} complexes with sulfur ligands (*see* ***S-donor Ligands***) are known, dominated by dimercaptomaleonitrile and thiocarbamate-type ligands. Simple sulfides as ligands are observed almost exclusively in mixed N/S donor chelating ligands. In addition, the coordination of Cu^{II} to other miscellaneous sulfur donors, such as bridging thiolate (e.g. PhS^-) and SCN^- ligands, is known.

9.4 Copper^{III}

Copper^{III} complexes are most frequently prepared by oxidation of Cu^{I} and Cu^{II} complexes, initially accomplished with various chemical oxidizing agents, including aqueous hypochlorite (ClO^-), chlorine or fluorine gas, alkaline persulfate $[(S_2O_8)^{2-}]$ solutions, and oxidizing oxyanions such as $TeO_6{}^{6-}$ and $IO_6{}^{5-}$. Thus, this is how the pale-green octahedral paramagnetic $K_3[CuF_6]$ complex as well as the square-planar diamagnetic $Cs[CsF_4]$ fluoride complex were synthesized. The first crystal structure of a Cu^{III} complex was that of $Na_3KH_3[Cu(IO_6)_2]\cdot 14H_2O$. This complex exhibits a square-based pyramidal structure, in which the copper ion is chelated to two oxygen atoms on each of the IO_6 groups and is also coordinated to one of the water molecules with a long Cu–O bond.[89] Owing to the number of protons and water molecules in this complex, some questioned the oxidation state assignment, even though the complex was diamagnetic. However, the diamagnetic purple macrocyclic complex, (Figure 11) formed by the condensation of oxalodihydrazide and acetaldehyde in the presence of Cu^{II} ions, was crystallographically characterized and found to contain a similar square pyramidal structure,[90] leaving little question that both complexes contain Cu^{III}. A Cu^{III} complex of a doubly N-confused porphyrin was isolated from the reaction of Cu^{II} acetate and the porphyrin starting material.[91]

A more recent preparative method for Cu^{III} complexes is the use of electrochemical oxidation techniques. Oxygen, nitrogen, and sulfur ligands dominate the latest Cu^{III} complexes, which include various nitrogen macrocycle and dithiolate ligands as well as an unusual carborane complex.[92] A number of Cu^{III} peptide (*see also* ***Peptide–Metal Interactions***) complexes have synthesized and characterized;[93] these are coordinated and stabilized by deprotonated amide groups and are usually made by oxidizing Cu^{II} precursors by bulk electrolysis in a flow cell. The crystal structure of the tripeptide complex $Cu^{III}(H_{-2}Aib_3)\cdot 2H_2O\cdot 1.5NaClO_4$ ($H_{-2}Aib_3 = \alpha$-aminoisobutyryl-α-aminoisobutyryl-α-aminoisobutyric acid) contains a square-planar Cu^{III} center with the Cu–N and Cu–O bonds observed to be 0.12–0.17 Å shorter than those in analogous Cu^{II} complexes.

9.5 Copper^{IV}

The few reported Cu^{IV} compounds all contain the two most electronegative elements as ligands. The most completely characterized Cu^{IV} complex is probably the paramagnetic, presumably octahedral complex $[CuF_6]^{2-}$.[94] Some Cu^{IV} centers are believed to be present in $BaCuO_{2.63}$, which

is made by heating $BaCuO_2$ in the presence of oxygen.[95] In addition, the CuO_2 species formed in the reaction of copper metal with dioxygen has been studied spectroscopically using matrix-isolation techniques and is believed to contain linear copper-dioxo [Cu-$(O^{2-})_2$] rather than copper peroxide [Cu-$(O_2{}^{2-})$] ligation.[96]

10 COPPER IN BIOLOGY

The use of copper bracelets and ointments for the treatment of conditions such as arthritis has been part of folk medicine for a long time. Copper-containing intrauterine contraceptive devices (IUDs) have been used for more than 30 years; the increased copper concentration in the uterus resulting from the IUD appears to be toxic to sperm, inhibiting fertilization. Traces of copper are needed for the normal growth, development, and function of all life forms.[97] Copper is the third most abundant trace element in the body. In fact, the overall concentration of copper in living organisms is fairly consistent (about 0.5–3 ppm), except for in shellfish and nuts (higher) plus some microorganisms (variable). The distribution in a particular organism varies from one part to another; in plants the highest concentration is found in the seeds and in humans in the kidney, liver, brain, heart, skeleton, hair, and nails contain the most copper.

Many copper-containing metalloproteins have been identified[97,98] [some are mentioned below in passing; for more information see the articles on copper proteins (*see* ***Copper: Hemocyanin/Tyrosinase Models***; ***Copper Proteins with Dinuclear Active Sites***; ***Copper Proteins: Oxidases***; ***Copper Proteins with Type 1 Sites***; ***Cytochrome Oxidase***; ***Copper Proteins with Type 2 Sites***, and ***Copper Enzymes in Denitrification***)], these proteins carry out a number of fairly diverse functions. Thus, copper centers take an electron-transfer role in cytochrome *c* oxidase (part of the respiratory electron transport chain in most cells, contains two different copper sites), plastocyanin (part of photosystem II in plants and green algae) as well as in azurin and stellocyanin. The dinuclear copper active site in hemocyanin functions as the dioxygen (*see* ***Dioxygen & Related Ligands***) carrier for arthropods and molluscs, instead of the iron-containing hemoglobin and myoglobin biomolecules found in other species (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***). Several copper proteins act as oxidases: laccase, ascorbate oxidase, and cytochrome *c* oxidase (reducing O_2 to H_2O); amine oxidase and galactose oxidase (reducing O_2 to H_2O_2) plus tyrosinase, the particulate membrane-bound form of methane monooxygenase, plus dopamine β-hydroxylase and peptidyl α -amidating monooxygenase (monooxygenases). In addition, there are copper-containing reductases: nitrite reductase and nitrous oxide reductase (in bacterial denitrification) and superoxide dismutase (contains both copper and zinc). There is also a relationship between copper and iron metabolism. Thus, the blue plasma copper protein ceruloplasmin is a ferroxidase, which converts Fe^{II} to Fe^{III} for binding to transferrin (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). As a result of this relationship, a low copper intake can result in anemia, probably by lowering the copper ferroxidase activity.[99]

There are at least five major components of the blood plasma to which copper is known to be associated. These include ceruloplasmin (a fairly abundant glycoprotein containing the largest proportion of copper ion in most animals and humans); albumin (contains a single high-affinity copper-binding site); ferroxidase II and transcuprein (nonceruloplasmin, nonalbumin proteins); and small molecules in the plasma such as amino acids and small peptides. Within vertebrate cells there appear to be at least three proteins that contain copper; two of them, cytochrome *c* oxidase and superoxide dismutase, are described briefly above. The third, the metallothioneins (*see* ***Metallothioneins***), are small, cysteine-rich metal-binding proteins, which appear to serve in the regulation and detoxification of a number of metal ions including copper.

Copper is an essential trace nutrient, but large quantities (typically grams) are toxic (*see also* ***Metal Ion Toxicity***) to humans.[100] About 2–5 mg of copper is absorbed per day from the diet, primarily by the small intestine with 6–13% of the average daily intake coming from drinking water. Other factors influence the efficiency of copper uptake, such as the amount of fiber, zinc, and ascorbic acid in the diet.[99] Nearly all copper excretion occurs in the bile in a form that prevents reabsorption in nearly the same quantity as that taken in; the biological half-life of copper ranges from about 2 to 4 weeks. Copper deficiency can occur if there is insufficient nutritional copper and leads to low blood cell counts and osteopenia (low bone density/poor bone formation, between normal levels and osteoporosis). However, copper deficiency is rarely observed in developed countries except in individuals who have had a large segment of their bowel removed (or bypassed), or in infants given homemade formulas that are lacking in copper. Seldom are symptoms of severe deficiency observed like those seen in the genetic disorder, Menkes' disease.[101] This disease primarily occurs in boys since it is X-linked (a recessive defect in the ATP7A gene) and is usually apparent at birth, or within 2 to 3 months. The babies may be born prematurely and have unusual facial appearances and hair (kinky and colorless, or with the appearance of steel wool), plus have brain damage that results in mental retardation. Other characteristic symptoms include seizures, stunted growth, failure to thrive, subnormal body temperatures, a higher occurrence of aortic abnormalities such as blockages or aneurisms, and weakened bones that more easily fracture. Unfortunately, progressive neurological deterioration usually occurs until death, typically at six months to three years of age.[99,102] The severe prenatal brain damage that had already occurred often makes postnatal copper therapy ineffective,

except in a milder form called occipital hormone syndrome. Phase II clinical trials are under way for copper-histidine injections (*see **Metal-based Drugs***); at this time it appears that this therapy may be useful for some, but not all, Menkes' disease patients, especially when started as early as possible (including possibly before birth).

Acute copper poisoning can be fatal and has been seen after the ingestion of grams of copper from contaminated water (the U.S. Environmental Protection Agency has set a limit of $1.3\,\mathrm{mg\,L^{-1}}$ for drinking water), during hemodialysis, or in farm workers using copper sulfate as a fungicide. This condition is rare and is sometimes self-limiting, because the resulting nausea, vomiting, and diarrhea can purge the system of moderate amounts of excess copper. Copper toxicosis syndromes have been identified in some infants whose formulas were stored, prepared, and/or heated in copper or brass pots. Some believe that the afflicted infants were heterozygotes for Wilson's disease (see below), thus, would not exhibit medical problems with normal copper intakes, only with consistently elevated levels.

Chronic copper toxicity is found in some individuals; the accumulation damages the liver and then the nervous system and other organs. The primary, relatively rare disorder is called Wilson's disease,[103] which is an autosomal recessive genetic disorder caused by mutations in the ATP7B gene. This condition is usually diagnosed in children to young adults with liver disease and/or neurological problems and arises from the body's failure to excrete copper in the bile. Wilson's disease is treatable with anticopper agents including zinc acetate (Galzin™; *see **Metal-based Drugs***) which blocks copper absorption and has the lowest rate of side effects, or *D*-penicillamine (Cuprimine, Depen), or trientine (Syprine; the hydrochloride salt of N,N'-bis(2-aminoethyl)-1,2-ethanediamine) to chelate and remove the excess copper, combined with a low copper diet. Tetrathiomolybdate (*see **Metal-based Drugs***) is also being investigated to treat Wilson's disease and is currently in phase III clinical trials.

The role of copper in other disease states is being investigated. For Alzheimer's disease studies, it has been found that the amyloid precursor protein interacts with copper to produce increased oxidant damage, and trace amounts of copper promote the precipitation of the amyloid β protein. In familial myotrophic lateral sclerosis about a quarter of the cases are caused by inherited dominant mutations in the Cu/Zn superoxide dismutase that probably result in abnormal Cu binding and the generation of reactive oxygen species. Copper has also been proposed to be involved in prion metabolism and function; however, whether or not this implicates copper in the prion diseases is unclear at this time.[102]

The lowering of copper levels appears to produce antiangiogenesis (inhibition of blood vessel growth and proliferation) and, thus, is being probed for its potential anticancer effects. In addition, since fibrotic and inflammatory cytokines have been found to be copper dependent, copper-lowering therapy is being investigated in the treatment of diseases involving fibrosis and inflammation, for instance, pulmonary fibrosis and cirrhosis.[102] Thus, the copper-lowering agent tetrathiomolybdate is currently involved in several clinical trials (most Phase II at this time) for a variety of cancers, idiopathic pulmonary fibrosis, scleroderma, primary biliary cirrhosis, and psoriasis.

Glossary

Carbocupration: addition of the elements of copper and carbon across a C–C triple bond
Cyanocuprates: RCu(CN)Li, $R_2Cu(CN)Li_2/[R_2Cu]^-[Li_2CN]^+$
Gilman cuprate: R_2CuLi
Phosphine Ligands: species coordinated *via* phosphorus to copper in this case

Abbreviations

LO cuprate = A lower order cuprate; HO cuprate = A higher order cuprate; R_r = A residual or nontransferable ligand; R_t = A transferable ligand; hfa = Hexafluoroacetylacetone; acac = Acetylacetonate; EWG = Electron-withdrawing group; TfO = Trifluoromethylsulfonyloxy (triflate).

1 INTRODUCTION

Roughly 10 years ago, the discussion on copper chemistry in this *Encyclopedia* focused mainly on reactions and physical organic studies of ‘organocuprates’, or copper(I) *ate* (i.e. salt) complexes. In general, these highly valued, extensively utilized reagents ‘R_2CuLi’ are prepared in the traditional Gilman fashion (from 2RLi + CuX), or *via* ligand exchange with other organometallics (e.g. stannanes, zirconocenes, etc.). They continue to serve synthetic practitioners who have come to rely on their ability to mainly effect substitution, conjugate addition, and to a lesser extent, carbocupration reactions (Scheme 1).

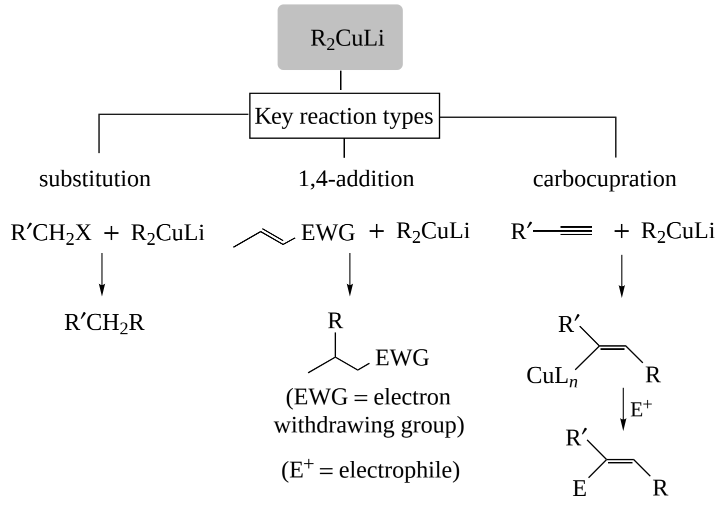
Implied in the stoichiometry of their preparation is the full equivalent of transition metal relative to substrate. Indeed, to this day, cuprates tend to be used in excess in most smaller scale reactions. Over the past decade, however, there has been a noticeable shift toward development of methodology catalytic in Cu(I). The rationale behind the emphasis is in line with the times; that is, environmental concerns have come to the fore, placing implied limits on the extent of transition metal usage. Therefore, notwithstanding favorable economic factors associated with copper, it being a ‘base’ rather than ‘precious’ metal, much effort has been devoted toward copper-catalyzed reactions, including cross-couplings to arrive at C–N, C–O, and C–H, in addition to C–C bonds. Moreover, tremendous strides have been made in asymmetric versions of perhaps the most fundamental of cuprate reactions: 1,4-additions to Michael acceptors.

A wealth of new and valuable structural information on cuprates has appeared in the recent literature. The importance of ligands on copper, which impact residues on the metal undergoing transfer to a substrate, are better understood, as are the locations of counterions ‘X’ that derive from the starting copper(I) salts (‘CuX’). Advances in technology have translated into opportunities for carrying out highly sophisticated spectral and computational studies that have provided much insight regarding the mechanistic pathways that account for these important synthetic processes.

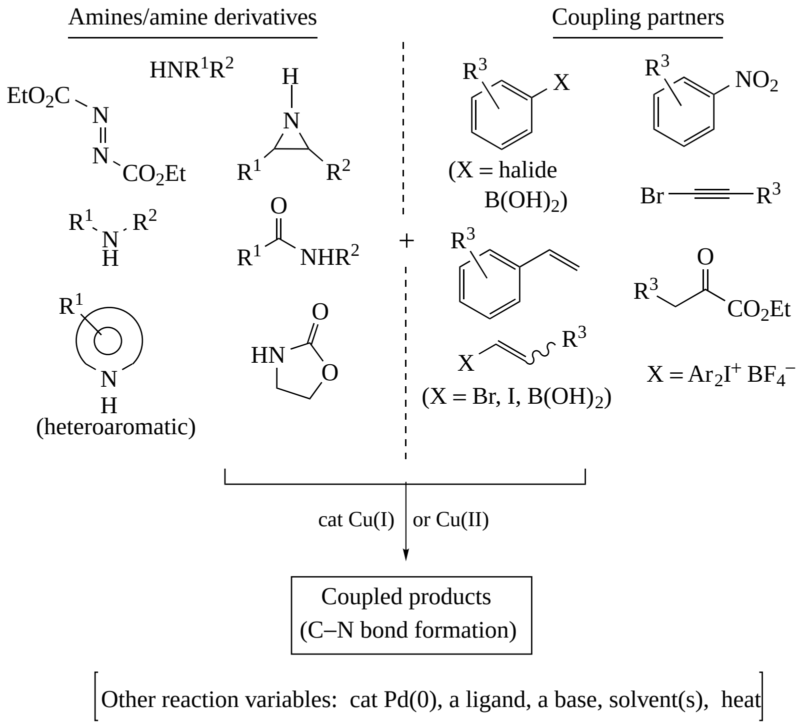
2 COPPER-CATALYZED CROSS-COUPLINGS

Copper salts have become crucial additives for bond forming reactions between carbon and heteroatoms such as N, O, S, or P. While many involve a transmetalation (*see Transmetalation*) step from Pd, Ni, Sn, B, Te, Se, Mg, and so on, several of these cross-coupling (*see Coupling*) reactions occur with copper as the only metal present. Typically, a (bidentate) ligand is used for stabilization of a copper-containing intermediate, while enhancing reactivity of the copper catalyst.

Extensive progress has been made over the past decade in C–N bond formations, including amines,[1] heteroaromatics,[2] amides,[3] oxazolidinones,[4] aziridines,[5] azodicarboxylates,[6] and hydroxylamines.[7] A variety of carbon-based substrates such as aryl and vinyl halides, alkenes, alkynes, enols, and nitroaromatics may serve as reaction partners (Scheme 2). The standard coupling reaction requires, in addition to a Cu(I) or Cu(II) source (e.g. CuCN, CuI, $Cu(OTf)_2$, $Cu(OAc)_2$, etc.), a base (e.g. Et_3N, K_2CO_3, Cs_2CO_3, K_3PO_4, or 2,6-lutidine), and a solvent (e.g. PhMe, dioxane, DME, CH_2Cl_2, THF, DMF), with reaction temperatures ranging from 23 to 110 °C. 1,2-Diamino ligands have been shown to aid in the amidation



Scheme 1

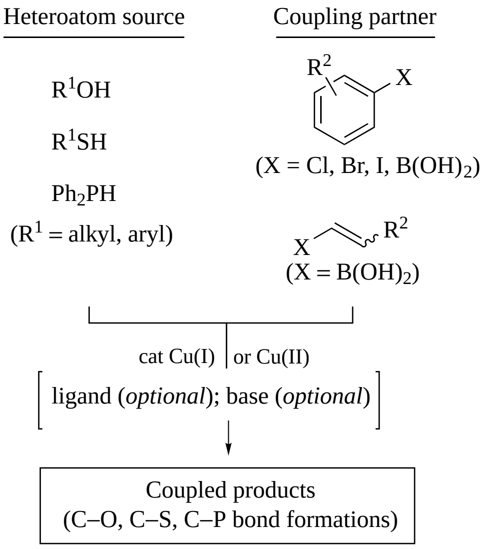


Scheme 2

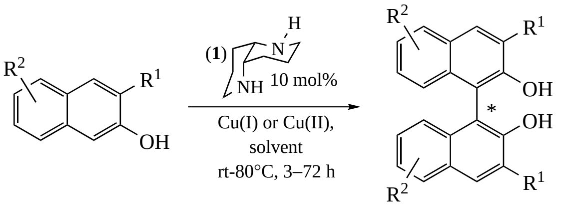
process, although use of an external ligand does not seem to be a general requirement for aminations.[3c]

As with C–N couplings, C–O, C–S, and C–P bond formations also require a Cu(I) or Cu(II) source, a base, and solvent, with reaction temperatures ranging from 45 to 195°C. Typically the couplings (*see Coupling*) are performed with aryl/vinyl boronic acids[8] and aryl iodides (Scheme 3). Use of microwave technology allows for aryl thioether formation between aryl bromides and thiophenols.[9] Inclusion of external ligands is not required for coupling, although several have been used to presumably assist with solubility/stability of the catalyst.[10]

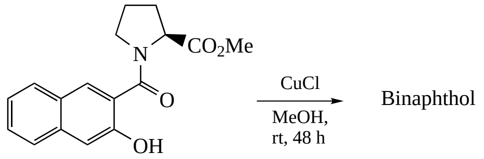
Nonracemic binaphthol (BINOL) ligands are heavily utilized in asymmetric synthesis. They can be readily fashioned from 2-naphthol precursors employing Cu(I) or Cu(II) salts. With either an external source of chirality (e.g. 1,5-diaza-*cis*-decalin, **1**),[11] or an internal chiral center (e.g. as in the proline-derived amide **2**),[12] derivatives substituted at the key 3- and 3′-sites are realized under mild conditions with ee's (*see Enantioselectivity*) up to 94%.



Scheme 3

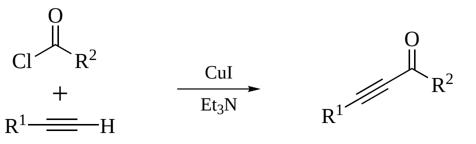


(1)

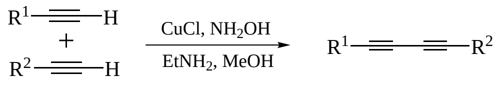


(**2**) (2)

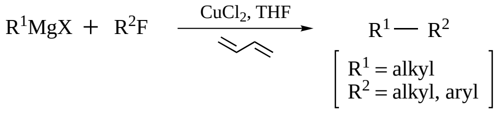
Other especially useful C–C coupling reactions wherein copper functions as the only metal catalyst present include (**1**) alkynes with acid chlorides (equation 3);[13] (**2**) alkynes with other alkynes (Glaser couplings; equation 4);[14] and (**3**) Grignard reagents with alkyl fluorides (equation 5).[15] Notably, copper mediated couplings of C_{sp3}-fluorine bonds with alkyl or aryl Grignards (*see Grignard Reagents*) indicate that usually inert fluorinated compounds can be functionalized using copper-based organometallic chemistry.



(3)



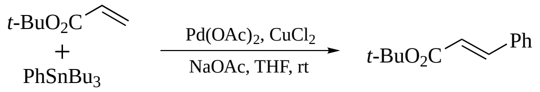
(4)



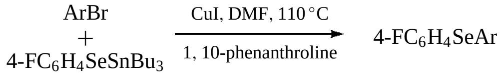
(5)

Much effort has gone into further development of Sonogashira couplings (*see Sonogashira Coupling*) between an alkyne and an aryl or vinyl halide. These palladium or nickel mediated reactions call for catalytic copper as an important additive. Variations on this theme have expanded the substrate pool to include aryl/vinyl/alkyl halides,[16] allenes,[17] and vinyl selenides/tellurides[18] as coupling partners with alkynes. Thus, in addition to the presence of a palladium catalyst (Pd(0) or Pd(II)), copper salts such as CuCl, $CuBr{\cdot}SMe_2$, CuI, Cu(3-methylsalicylate), $CuOP(O)Ph_2$, and $CuCl_2$ have all found use. As in traditional Sonogashira reactions, an amine base (e.g. pyrrolidine, diisopropylamine, or Et_3N) is required. Solvents can also vary, such as toluene, MeOH, CH_2Cl_2, or THF, and in some cases, the amine itself can be used as the medium.

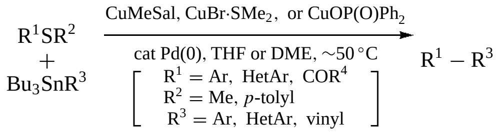
Several related cross-couplings that involve both catalytic levels of Pd and Cu have also been reported, such as Heck-like reactions (*see Heck Reaction*) of vinyl esters with arylstannanes (equation 6),[19] aryl selenenylations between $Bu_3SnSeAr$ and aryl halides (equation 7),[20] and thioarene or thioester couplings to aryl, vinyl, or alkyl stannanes (equation 8).[21]



(6)



(7)



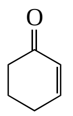
(8)

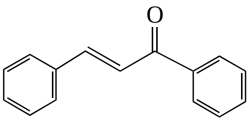
3 ASYMMETRIC CATALYSIS WITH Cu(I)

For effective use of catalytic copper in asymmetric reactions, there are many variables that must be controlled: solvents, that impact aggregation state, gegenion Lewis acidity (*see Lewis Acids & Bases*) in solution, that can greatly affect rates of couplings; the stoichiometric organometallic source of the residue to be transferred *via* copper, that must be relatively unreactive to avoid a competitive background reaction thereby reducing observed levels of induction; and the most critical parameter, the choice of chiral ligand, for given the facility with which groups on copper exchange between metal centers, chelation control is crucial for success.

Most of the focus has been on asymmetric conjugate additions to unsaturated ketones.[22] A combination of copper

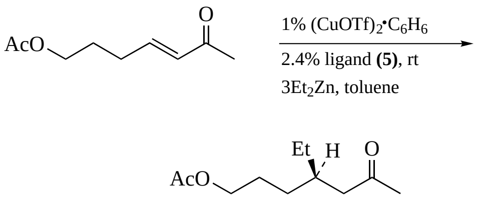
salt (usually copper triflate, $Cu(OTf)_2$), a dialkylzinc reagent (*see* ***Zinc: Organometallic Chemistry***) (which reduces Cu(II) to Cu(I) in situ and supplies the group to be transferred to the substrate), and a nonracemic ligand (which is usually a mono- or bidentate phosphine) is common, such reactions oftentimes being run in toluene or CH_2Cl_2 and can lead to very high facial selectivities. Model substrates tend to be cyclohexenone and chalcone, representative of cyclic and acyclic enones, respectively.





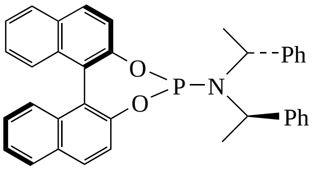
chalcone

Ligands such as phosphoramidite (**3**) and TADDOLs (**4**) have proven to be remarkably discriminating in their reactions of cyclic cases. Due to interconversion between s-cis and s-trans conformers, acyclic systems have been far more challenging. Here, optically pure peptidic phosphines (e.g. **5**) deliver products of 1,4-additions in good yields and high enantioselectivities (equation 9).

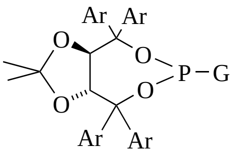


88% (89% ee)

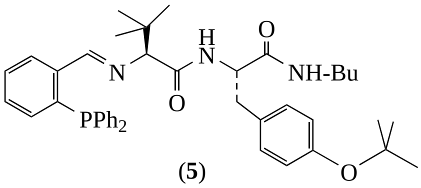
(9)



(**3**)

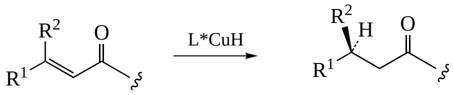


(**4**) G = OR, NR_2



(**5**)

An alternate strategy to control absolute stereochemistry at a β-site to a carbonyl calls for asymmetric addition of a copper hydride (i.e. CuH)[23] to a β,β-disubstituted carbonyl



(10)

array (equation 10). With the advent of extremely powerful biaryl bis-phosphine ligands, such as Roche's BIPHEP (e.g. **6**),[24a] Takasago's SEGPHOS (e.g. **7**),[24b] and Solvias' JOSIPHOS (e.g. **8**)[24c] series, many substrate types can now be reduced in very high ee's. Thus, in the presence of *in situ* generated CuH (from CuCl + NaO-*t*-Bu, with a silane as the stoichiometric source of hydride), the ligated CuH reduces aryl ketones (with BIPHEP or SEGPHOS),[25a] cyclic enones (with SEGPHOS),[25b] acyclic enones (with JOSIPHOS),[25c] and enoates and unsaturated lactones (with SEGPHOS and JOSIPHOS).[25d] Particularly noteworthy is the case of aryl imines (**9**), which afford nonracemic benzylic amines at ambient temperatures (equation 11).[25e]

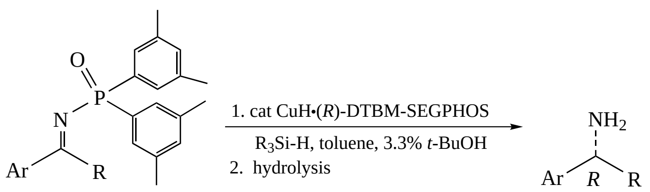
(R = *t*-Bu, Cy, etc..)



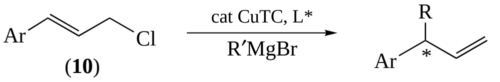
(**9**)

ee's >93%

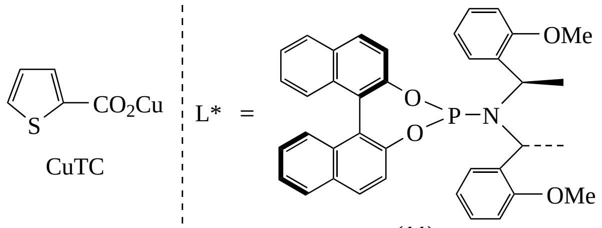
(11)

Great strides in asymmetric allylic alkylations have been made very recently, with Cu(I) playing a key role. Not

surprisingly, the ligand, to a far greater extent than the other reaction variables, determines the extent of success as measured by observed ee's. Allylic halides, including cinnamates generalized by (**10**), react with Grignards (*see Grignard Reagents*) in the presence of copper thiophenecarboxylate (CuTC) and phosphoramidite ligand (**11**).[26a] The regioselectivity (*see Regioselectivity*) (S_N2':S_N2) is usually high, and ee's in the >90% range are to be expected (equation 12).



(**10**) (12)



(**11**)

Related allylic systems, such as enoates (**12**) bearing a phosphate leaving group are susceptible to copper-catalyzed S_N2' reactions.[26b] Employing copper triflate and a dialkylzinc, peptidic ligand (**13**) is especially effective at inducing asymmetry at the newly created stereogenic carbon α to the ester in (**14**) (equation 13).

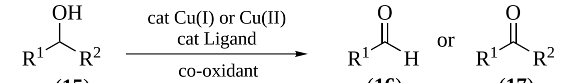
(**13**)

4 OXIDATION & CYCLIZATION REACTIONS

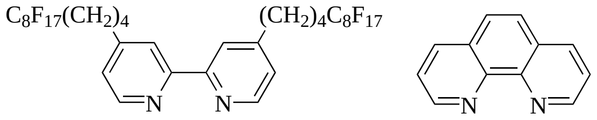
4.1 Oxidations

Oftentimes, a transition metal catalyst is needed to effect an oxidation at carbon. Both Cu(I) and Cu(II) complexes have gained recent recognition as catalysts for this purpose because of their minimal cost and relatively low toxicity. In the presence of a co-oxidant and a stabilizing ligand, oxidations of alcohols, hydroquinones, olefins, and simple hydrocarbons can be accomplished under mild conditions. Oxidants, such as TEMPO,[27] peroxides (e.g. H_2O_2, t-BuOOH),[28] or O_2[29] assist in the conversion of alcohols (**15**) to aldehydes (**16**) or ketones (**17**) in media that ranges from H_2O to biphasic fluorous in nature, and have been accomplished as well even without solvent. These oxidations are typically performed at somewhat elevated temperatures and use a variety of copper sources (e.g. CuCl, $CuBr{\cdot}SMe_2$, $CuCl_2$, $Cu(NO_3)_2$). Nitrogen-based bidentate salen-type ligands (**18**–**21**) play a key role owing to their stabilizing influence on copper during these reactions, which are typically high-yielding (>90%).

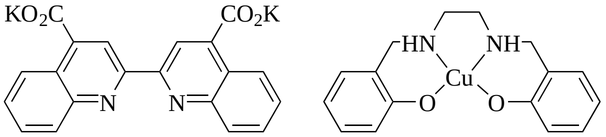


(**15**) (R^2 = H, alkyl) (**16**) (**17**) (14)

Ligands

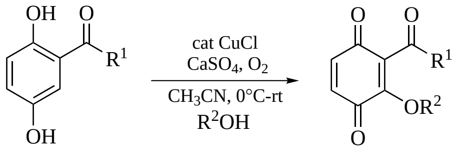


(**18**) (**19**)

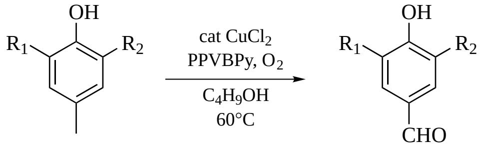


(**20**) (**21**)

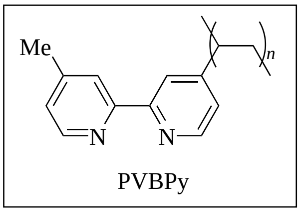
Oxidation of a phenol to the corresponding p-quinone using a copper catalyst takes place at room temperature under similar conditions as those used for alcohol oxidation, with O_2 as oxidant. Likewise, hydroquinones (**22**) can be transformed to 3-alkoxy-p-quinones (**23**) when reacted in the presence of an alcohol.[30] In the case of 4-substituted phenols (**24**), polymer-based catalysts composed of ligands (e.g. PVBPy) that chelate copper have been used at elevated temperatures to selectively oxidize a benzylic carbon to yield 4-hydroxybenzaldehydes (**25**) in good yields.[31]



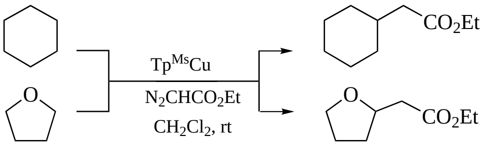
(**22**) (**23**) 71–88% (15)



(**24**) (**25**) 47–94% (16)



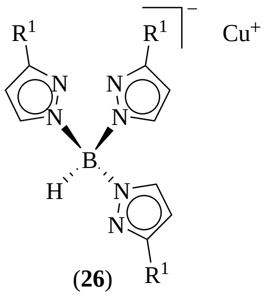
Copper catalysts, such as $Cu(CH_3CN)_4PF_6$ and $Cu(BF_4)_2 \cdot nH_2O$, have also found utility in the epoxidation of olefins using MCPBA or O_2 as the stoichiometric oxidant.[32,33] Oxidations of C–N and C–H bonds are also successfully carried out under such catalytic conditions. For example, aldehydes are readily converted in one pot to the corresponding nitriles, by way of the initially formed imine, upon treatment with ammonia and aqueous hydrogen peroxide with CuCl or $CuCl_2$ as catalyst.[34] Primary amines are converted to nitriles, and secondary amines to imines, when treated with Cu(I) or Cu(II) catalysts and O_2 as oxidant.[35] Oxidation of a C–H bond is much more difficult, although such processes are of increasing importance in organic chemistry. Typically, expensive ruthenium, or toxic iron complexes are used, although $Cu(OH)_2$, $Cu(OAc)_2$, and $CuCl_2$/18-crown-6 show considerable promise as alternatives.[36] Turnover numbers (TON) on the order of 27 000 were reported for the $Cu(OAc)_2$ catalyzed oxidation of cyclohexane to cyclohexanol and cyclohexanone (~1:1) with O_2 as oxidant.[36] C–H oxidation can also occur *via* transient metal carbene complex insertion. Recently, $Tp^{Ms}Cu$ (**26**) and ethyl diazoacetate (as the carbene source) were shown to activate cycloalkanes and cyclic ethers to afford substituted carbo- and heterocycles, respectively,[37] highlighting useful chemistry on very basic starting materials (equation 17).



(17)

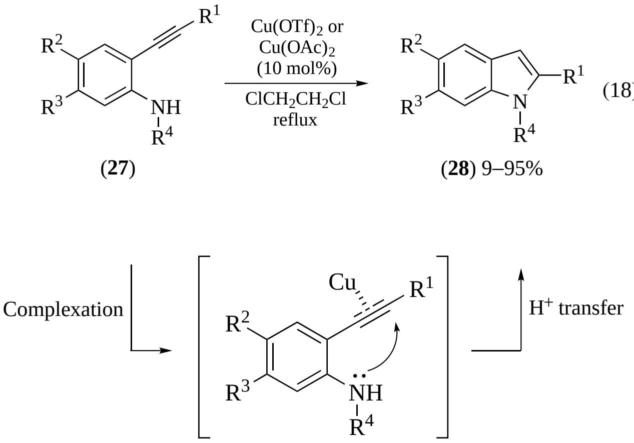
4.2 Cyclizations

Cyclization reactions, where Cu(II) serves as a Lewis acid, have been utilized in the formation of substituted indoles (**28**)



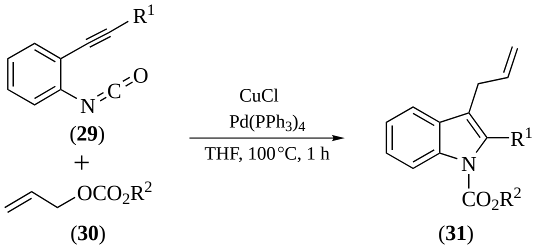
(**26**)
$Tp^{Ms}Cu$
$R^1 = 2,4,6\text{-}Me_3C_6H_2$

from 2-ethynylaniline derivatives (**27**).[38] The combination of isocyanates (**29**) and allylic carbonates (**30**) also leads to substituted indoles (**31**), in this case relying on both catalytic



(**27**) (**28**) 9–95% (18)

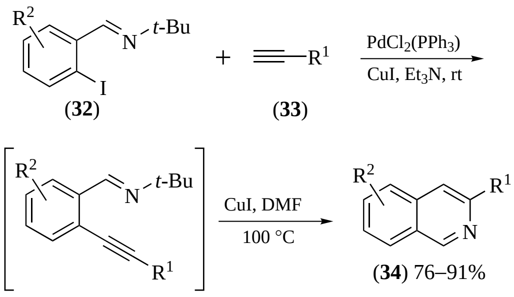
amounts of Pd(0) and Cu(I).[39] Here, a π-allylpalladium intermediate between the metal and allylic fragment, is followed by insertion into the isocyanate. Proposed Lewis acid complexation of the alkyne by CuCl and ultimately reductive elimination (*see Reductive Elimination*) from palladium provides 2,3-disubstituted indoles.



(19)

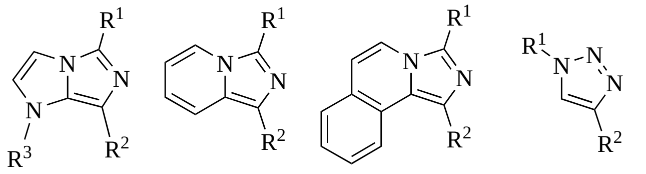
Cu(I)-mediated cyclizations to substituted isoquinolines (**34**),[40] or their monocyclic pyridyl analogs, take place in one pot following a Pd/Cu catalyzed Sonogashira coupling (*see Sonogashira Coupling*) between an aryl halide (**32**) and

alkyne (**33**).



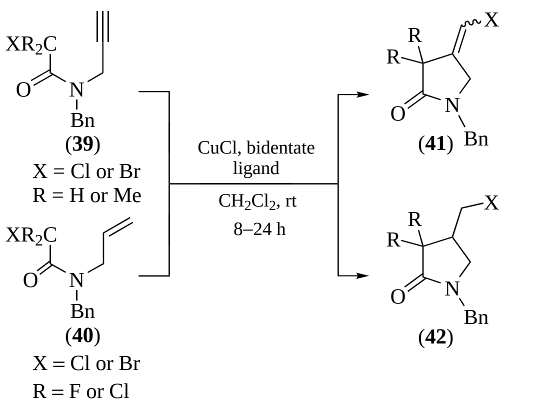
(20)

Various imidazo[1,5-a]imidazoles (**35**), imidazo[1,5-a] pyridines (**36**), and imidazo[5,1-a]isoquinolines (**37**), important ligands or precursors to pharmaceuticals,[41] can be constructed *via* copper-catalyzed heterocyclization of Schiff's bases. A stepwise cycloaddition between azides and terminal alkynes is also catalyzed by copper salts in what has now been termed 'click' chemistry, producing 1,4-disubstituted triazoles (**38**) in excellent yields.[42]



(**35**) (**36**) (**37**) (**38**)

As an alternative to radical cyclizations induced by tin reagents (e.g. R_3SnX) that typically require elevated temperatures for activation, bidentate ligated CuCl leads to ring formations at ambient temperatures (as with **39** to **41** and **40** to **42**).[43,44]



(21)

Insertion by copper(II) into a diazo derivative such as (**43**), thus forming an intermediate metallocarbene, leads to cyclized products with high stereoselectivity (e.g. **44**; after decarboxylation).[45] Diazo ketone (**45**) produced quinolizidines (**46**) and (**47**), which arise from initial metallocarbene formation, nitrogen ylide formation, and lastly, a ring-expanding 1,2-shift to complete the cyclization.

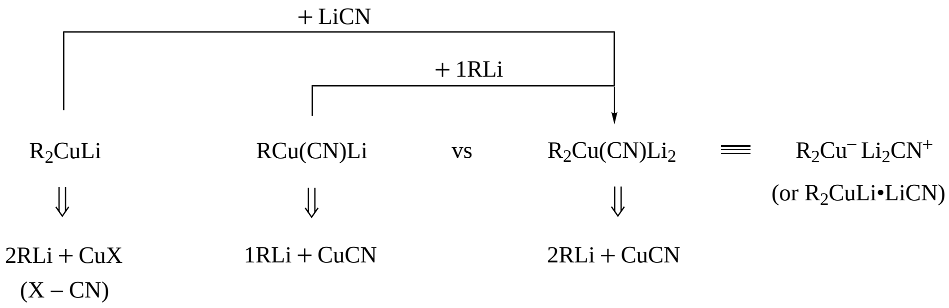
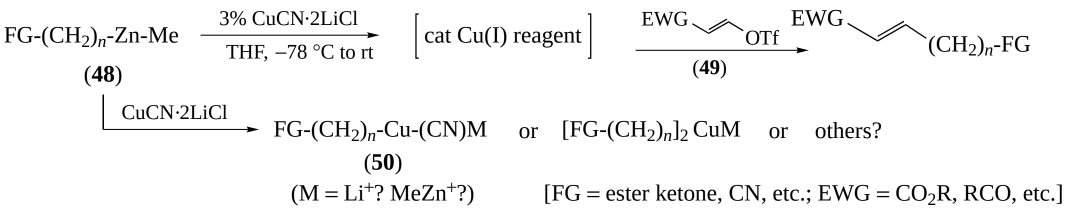
5 CYANOCUPRATE TECHNOLOGY

The lively debate that took place in print throughout the 1990s regarding the structure of cyanocuprates (*see* ***Cyanide Complexes of the Transition Metals***) (i.e. lower order (LO) monoanionic reagents RCu(CN)Li and $R_2CuLi{\cdot}LiCN$ *vs.* higher order (HO) dianionic cyanocuprates $R_2Cu(CN)Li_2$; Scheme 4 and vide infra)[46] had little impact on their already widespread use in synthesis. While reliance on stoichiometric cuprates, whether cyano ligand-containing or otherwise, is still commonplace in organic synthesis, academicians are the main consumers of these synthetic developments as new processes only truly catalytic in transition metal stand a chance at acceptance in industrial circles.

Use of CuCN in catalytic fashion implies that another organometallic must be present bearing the desired transferable ligand (in quantities equivalent to the educt). Upon transmetalation, a complicated mix of reagents may well result, the total composition of which is likely to be unknown. For example, when solubilized catalytic $CuCN{\cdot}2LiCl$[47] is added to a preformed mixed organozinc reagent (**48**) (Scheme 5), the presumed ligand exchange occurs to afford a copper(I) species which is ultimately followed by alkylation, for example by vinyl triflate (**49**). What is the nature of the copper reagent doing the chemistry? If the cyanide ligand remains on copper, then a LO cyanocuprate is formed (**50**), with a gegenion of ill-defined nature (is it the R_rZn^+, and/or the Li^+ in the pot from the CuCN·LiCl used to solubilize the copper(I) salt?). With excess mixed reagent R_tR_rZn (e.g. **48**) present relative to CuCN, does the CN group reside within the cluster but not on copper, forming a 'Gilman-like' species $R_2Cu^-{\cdot}M_2CN^+$? Related questions apply to the case of catalytic CuCN plus Grignard reagents (*see Grignard Reagents*),

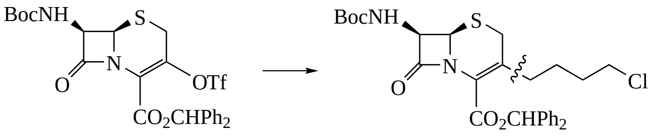


Scheme 4



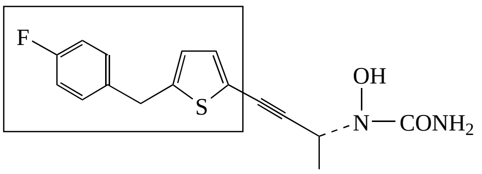
Scheme 5

the precise nature of the species involved here as well is far from certain. Nonetheless, highly selective and mild couplings can be carried out, as represented by the functionalization of β-lactam (**51**) to derivative (**52**) (equation 24).[48a]



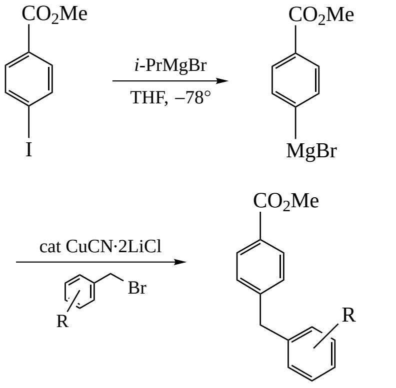
(**51**) (**52**) 86%

(24)



(**53**) ABT-761

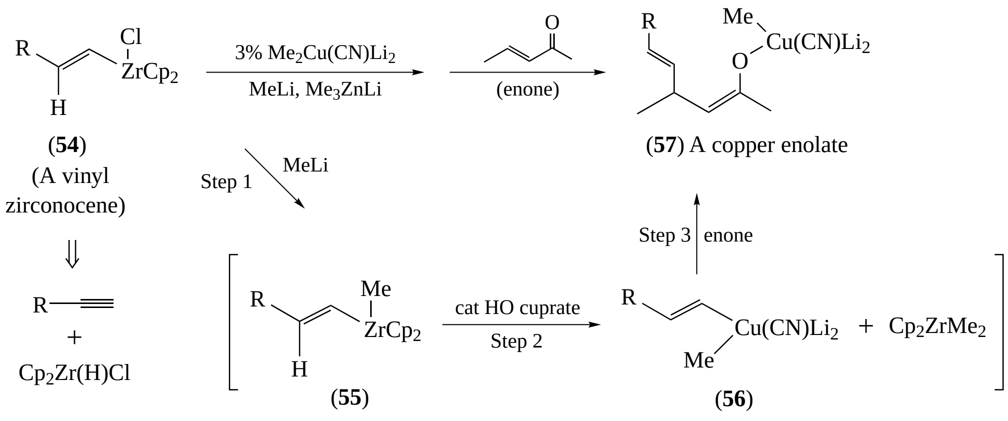
While such questions of reagent composition remain, advances on the synthetic front have responded to the challenges of minimizing levels of copper required, whether in the form of a salt (CuCN), a halocuprate ($CuCN{\cdot}2LiCl$ = (Cl)Cu(CN)Li), or as a cuprate (RCu(CN)Li or '$R_2Cu(CN)Li_2$'). Thus, in addition to the example above (equation 24), functionalized aryl Grignard reagents undergo alkylations with primary iodides and benzylic bromides mediated by CuCN (equation 25).[48b] The latter give rise to the diarylmethane (or diheteroarylmethane) subunit, a common theme found in many active pharmaceuticals, such as with ABT-761 (**53**), a very potent 5-lipoxygenase inhibitor.[48c]



(ca. 60%)

(25)

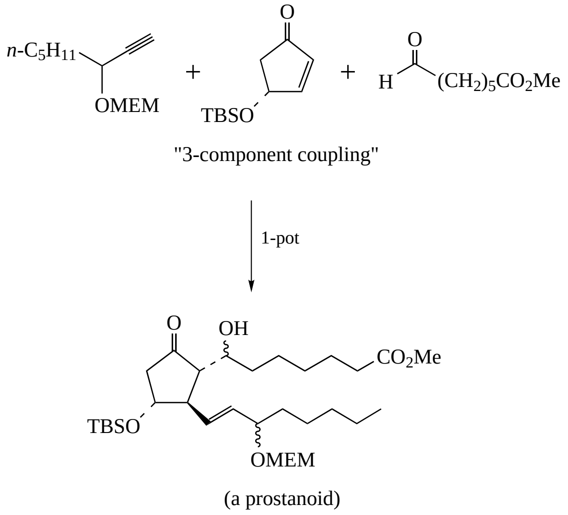
Transmetalations (*see Transmetalation*) between various organometallics (e.g. vinyl zirconocenes, stannanes, tellurides, alanes, etc.) and HO cyanocuprates, as discussed previously,[49] generate stoichiometric mixed cuprates that are well-behaved; they transfer the desired residue R_t and usually afford good yields. The problem, again, is that they rely on stoichiometric copper. To derive the benefits of HO cyanocuprate chemistry while 'downsizing' copper,[50] an organometallic 'shuttle' was developed that supplies R_rLi so as to maintain copper at the far more reactive *ate* stage.[51a] Thus, using only a few percent $Me_2Cu(CN)Li_2$ along with zincate Me_3ZnLi as a relatively unreactive source of MeLi, vinyl zirconocenes can now be added in a conjugate manner to enones (Scheme 6). The presumed sequence calls for step (1): conversion of the initially formed vinyl zirconocene (**54**) to its methylated



Scheme 6

derivative (**55**) with MeLi; step (2): transmetalation from Zr to Cu, where a methyl moiety goes to Zr in return for the vinyl residue going to copper; step (3): the mixed cuprate (**56**) adds and transfers the vinyl reside to the enone to give the transient copper enolate (**57**). In step (4), Me_3ZnLi, presumably exchanges readily with the weak Cu–O bond in (**57**), providing the elements of MeLi and thereby reforming the catalytic species $Me_2Cu(CN)Li_2$ for recycling (Scheme 7). The by-product Me_2Zn remains associated with oxygen as the resulting zinc enolate (**58**).[51b]

Once the zinc enolate has accumulated, it can be used further in a net '3-component coupling', which has been found advantageous for quick entries to prostaglandins (e.g. equation 26).[51c]



(26)

The concept of using mixed zincates to moderate the reactivity of organolithiums in solutions containing catalytic copper species can be extended to other organometallics. Transfer of a silyl group such a $PhMe_2Si$, well known to be a hydroxyl surrogate, has been routinely delivered to substrates stoichiometrically *via* the corresponding cuprate. Masking $PhMe_2SiLi$ within the mixed zincate $PhMe_2Si{-}ZnMe_2Li$, however, and using only 3% of a simple HO dimethylcyanocuprate leads to silyl ligand exchange between zinc and copper, ultimately delivering the desired silyl residue to various electrophilic coupling partners (equation 27).[52] In the case of enones, although these 1,4-additions go very smoothly at low temperatures, inclusion of catalytic amounts of $Sc(OTf)_3$ leads to extremely rapid conjugate additions.

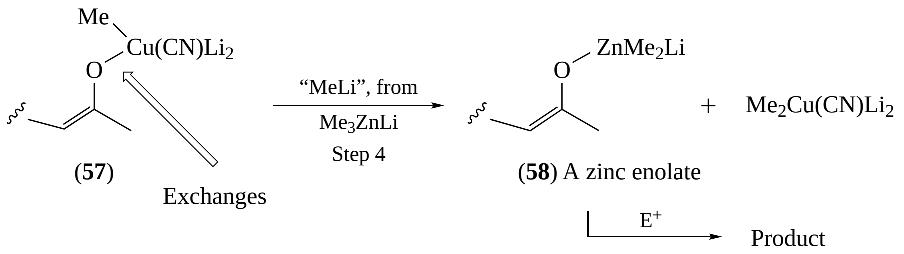
6 SPECTROSCOPIC & STRUCTURAL STUDIES

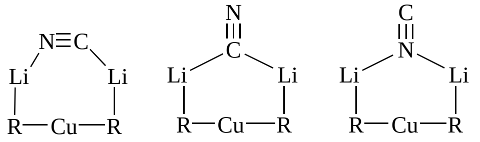
As previously mentioned[49] and remains true today, NMR spectroscopy is the primary tool for accessing information regarding the composition of cuprates in solution. Advancements in NMR technology of late have encouraged highly sophisticated labeling experiments, leading to a far better appreciation for cuprate structure and mechanism. Some of the recent NMR work has focused on cuprate complexation of enones and/or enoates, but most has been in direct response to the controversial 'higher order'/'lower order' debate in the literature regarding the structure of cyanocuprates. Excellent reviews on this subject are now available.[53]

^{15}N NMR spectroscopy has been applied to cyanocuprates $BuCu(C^{15}N)^6Li$ and $Bu_2Cu^6Li{\cdot}^6LiCN$, both reagents derived from labeled *n*-butyllithium and copper cyanide.[54] In this study, ^6Li and ^{15}N NMR spectra were obtained in THF-d_8 and Et_2O-d_{10} at −80 °C for cuprates with a lithium:copper ratio of

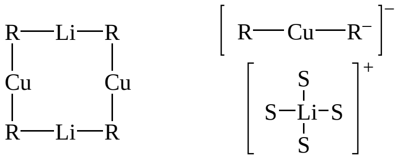


Scheme 7

1:1, 1.3:1, and 2:1. That no $^6LiC^{15}N$ or ^6Li-^{15}N couplings were observed in any of the cuprate mixtures strongly suggests that CN is not bound to copper. From these data and associated calculated cyanide IR stretching frequencies, several cyclic arrays for 'higher order' cyanocuprates were proposed (**59**–**61**), with structure (**59**) being energetically favored.



(**59**) (**60**) (**61**)

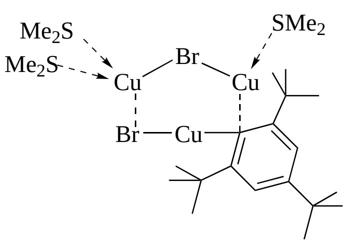


(**62**), A Gilman cuprate (**63**)

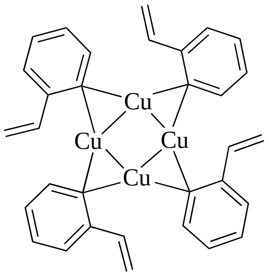
The coupling patterns of ^1H and ^1H-coupled ^{13}C NMR spectra of ^{13}C-labeled cuprates Me_2CuLi, Me_3CuLi_2, and $Me_2Cu(CN)Li_2$ in THF were compared. It was found that Me_3CuLi_2 and $Me_2Cu(CN)Li_2$ behave like that of Me_2CuLi.[55] However, no coupling was observed for the cyanide ligand (*see Cyanides*) in $Me_2Cu(CN)Li_2$. Heteronuclear Overhouser effect spectroscopy (HOESY) was also used to analyze lithium's connectivity in these cuprates. Doubly labeled MeLi (^{13}C and ^6Li) served as the precursor to each cuprate, which yielded ^6Li–^1H and ^6Li–^{13}C HOESY spectra. The HOESY spectra showed a correlation between lithium and the protons; however, no correlation was seen between lithium and carbon thus indicating that Li^+ is mainly localized apart from anionic copper in these species.[56]

^1H,^6Li HOESY NMR techniques likewise led to the hypothesis that contact ion pairs (CIPs, **59** and **62**) and/or solvent-separated ion pairs (SSIPs, **63**) are present for cyanocuprates in solution.[57] Both MeCu(CN)Li and *t*-$Bu_2CuLi{\cdot}LiCN$ appear to be monomeric SSIP in THF owing to the strong solvating effects of this solvent on lithium atoms. This is also evident from the HOESY spectra by the lack of dipolar interactions between lithium and the organocopper species. ^1H,^6Li HOESY spectra conducted in Et_2O for these same two cuprates, however, show a definite dipolar interaction, indicating a CIP. For $Me_2CuLi{\cdot}LiCN$ and $[(Me_3Si)CH_2]_2CuLi$[58a] a temperature-dependent equilibrium was detected in THF between SSIPs and CIPs which helps to explain the relative reactivity of various cuprates in different solvents, and in the presence of additives.[52] Cuprates formed in the presence of crown ethers (*see Crown Ethers*) lead to SSIP's and are much less reactive toward 1,2- and 1,4-additions, indicating that cuprates which are able to form CIPs (i.e. dimers) are the reactive species in addition reactions.[58] Further studies on $Me_2CuLi{\cdot}LiCN$ and Me_2CuLi using SYM-BREAK-NOE/ROE-HSQC NMR experiments have shown that these two cuprates have homodimeric structures (similar to **62**) in Et_2O through ^1H–^1H dipolar interactions and ^1H,^6Li HOE spectra.[58]

Several new structures of organocopper and cuprate reagents have been provided by X-ray crystallography. Complex (**64**), containing a CuX:CuR ratio of 2:1, crystallizes as a six-membered ring containing three copper atoms, two bromines, and an *ipso* carbon of the Mes* group.[59] A homoleptic organocopper tetramer $[Cu_4(viph)_4]$ (viph = *o*-vinylphenyl, **65**) has been prepared which further supports the square-planar nature of organocopper species fundamental to copper chemistry.[60]

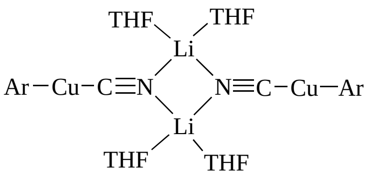


(**64**)



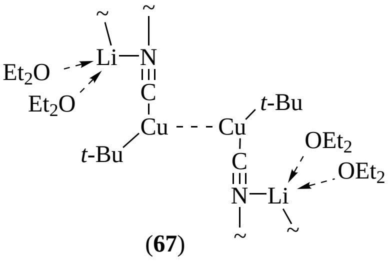
(**65**)

The crystal structure of an aryl cyanocuprate $[Li(THF)_2\{Cu(CN)C_6H_3\text{-}2,6\text{-}Trip_2\}]_2$ (**66**) (Trip = -C_6H_2-2,4,6-*i*-Pr_3) revealed a LO species with cyanide bridging both copper and lithium atoms.[61] Cyanocuprate (**67**), isolated from Et_2O rather than THF, likewise shows a LO nature, while (**68**)

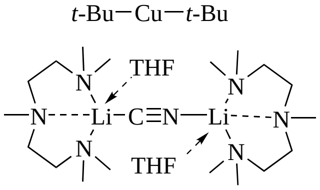


(**66**)

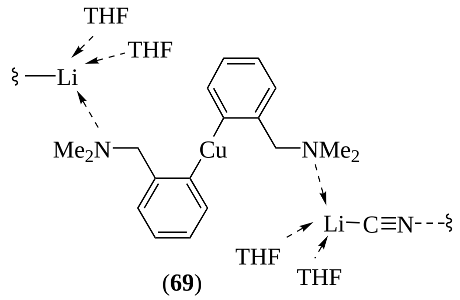
(from CuCN and 2*t*-BuLi) clearly reveals the expected linear arrangement of the two alkyl groups on copper(I), with the cyano group sequestered by two lithium ions. The same linear array is found in diaryl cuprate (**69**), where the tertiary benzylic amine functions as an internal chelating agent for Li^+ and is thus, ionic in nature. This species is representative of those typically abbreviated as $[R_2Cu]^-$ $[LiCNLi]^+$.[62]



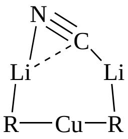
(**67**)



(**68**)



(**69**)



(**70**)

Several other techniques have been used to determine the structure or aggregation state of organocuprates. Cryoscopic studies in THF found that discrete monomeric species were formed when RLi (R = Me, *t*-Bu) was added to CuCN in various ratios.[63] A dimeric species resulted, however, when PhLi was used for cuprate formation. X-ray absorption spectroscopy (XAS) was utilized in an investigation of CuI- and CuCN-based dimethyl cuprates.[64] Both extended X-ray absorption fine structure (EXAFS, *see Extended X-ray Absorption Fine Structure*) and X-ray absorption near edge structure (XANES, *see XANES*) indicated that dimethyl cuprates Me_2CuLi and '$Me_2Cu(CN)Li_2$' are two-coordinate, and hence, cyanide does not reside on copper. In a separate but related study using XAS, it was found that dimethyl cuprates formed from CuI are dimeric (i.e. $[Me_2CuLi]_2$) in Et_2O and Me_2S.[65] Electrospray mass spectrometry[66] suggests that several cuprate complexes are present in solution, many of which cannot be detected on the NMR timescale.

With advances in computational chemistry, many theoretical studies addressing structural aspects of organocuprates have been undertaken. Calculations using density functional theory (DFT)[67] or at the MP2/II perturbation level,[68] indicate that 'higher order' cuprates are structurally along the lines of (**61**) and (**70**), respectively. The latter study used XANES and EXAFS spectroscopic data to support their theoretical cuprate structure.[68] A recent report on organocuprate structures and energies using the B3LYP and MP2 methods found that while MP2 structural calculations correlated well with X-ray data, the B3LYP method was superior for reaction pathway studies of organocopper intermediates.[69]

Computational investigations on linear $(CH_3)_2Cu^-$ indicate that the HOMO (*see HOMO*) $Cu(s + d_{z^2})$ and $C(s + p)$ orbitals are involved in cuprate S_N2 alkylation reactions. Bent carbon–copper bonds allow $Cu(d_{xz})$ and $C(s + p)$ orbitals to mix, thus forming a HOMO that can interact with π^* orbitals of alkynes and alkenes.[53] Related studies suggest that dialkylcuprates of type (R_2Cu^-) act as metal centered nucleophiles owing to their high lying d orbitals versus carbon-based alkyl nucleophiles, which explains their S_N2/1,4-addition capabilities.[70]

A chemical reactivity scale has been created to reflect electron transfer abilities of various methylcopper reagents in conjugate additions, using trimethylethylene-1,1,2-tricarboxylate as acceptor.[71] The reported order is; $Me_3CuLi_2 > Me_2CuLi \gg Me_2Cu(CN)Li_2 > MeCu > MeCu(CN)Li$. The corresponding butyl cuprates are more able to effect electron transfer, the order found to be: $Bu_2CuLi > BuCu(CN)Li \approx Bu_2Cu(CN)Li_2 > BuCu$, in this case using 3-cyclopropyl-2-methoxycarbonyl-3-phenyl-2-propenoate as substrate.[71]

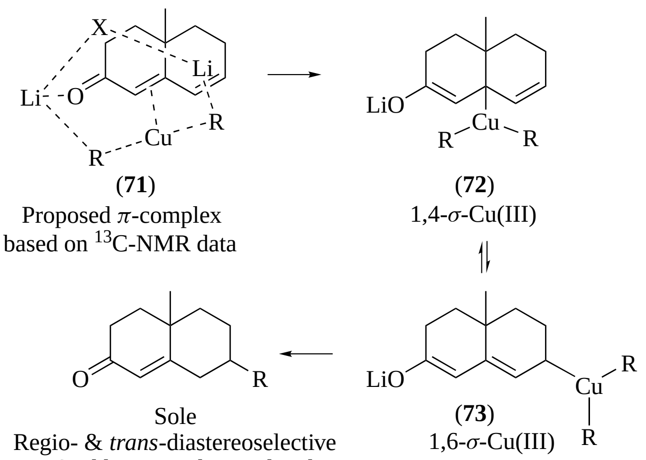
7 MECHANISTIC ADVANCES

Although organocuprate chemistry has already celebrated its 50th year since the discovery by Gilman,[72] the mechanisms by which transformations of organocopper reagents take place are still not fully understood. Significant progress, however, in particular from theoretical treatments, has been made.[73]

Cuprate conjugate addition to α,β-unsaturated carbonyl compounds involves an initial π-complexation of the α,β-unsaturated double or triple bond by copper followed by an oxidative addition (*see Oxidative Addition*) resulting in a

σ-Cu(III) species that reductively eliminates (*see Reductive Elimination*) to yield the conjugate addition product. From low temperature NMR techniques, π-complexation can be observed for enones, ynoates, as well as for their more highly conjugated analogs.[74] ^{13}C-NMR studies show that complexation is reversible, where the C2 and C3 carbons of α, β-unsaturated carbonyl systems shift upfield due to rehybridization of the sp^2 to sp^3–like carbons, and downfield for sp to sp^2–like atoms as a direct result of d-π^*-complexation by copper at low temperatures.[75] Typically, a downfield shift for a carbonyl carbon is also observed and is associated with complexation of oxygen with lithium ion within the cuprate.[75] Through rapid-injection NMR experiments at $-100\,°$C of $Me_2CuLi{\cdot}LiX$ (X = I or CN) and 2-cyclohexenone, significant enolate character of the π-complex was postulated and rate of formation data suggest a two-step process is involved in π-complex formation.[76]

Ynoates in the presence of $Me_2CuLi{\cdot}LiI$ show syn-addition of the cuprate followed by a rapid isomerization of a lithium allenolate to the Z-substituted alkene.[74] Removing LiI can decelerate E- to Z-alkene isomerization, and the allenoate can be trapped by TMSCl if present in the reaction mixture.



(**71**) Proposed π-complex based on ^{13}C-NMR data

(**72**) 1,4-σ-Cu(III)

(**73**) 1,6-σ-Cu(III)

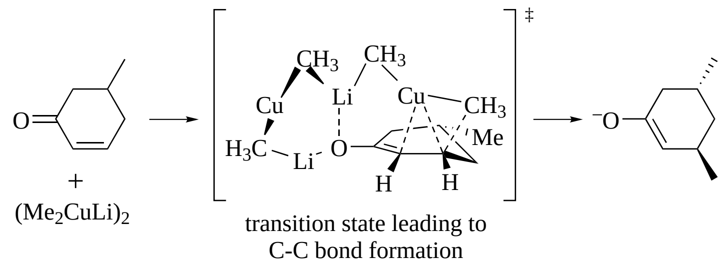
Sole Regio- & *trans*-diastereoselective 1,6-addition product isolated

Scheme 8

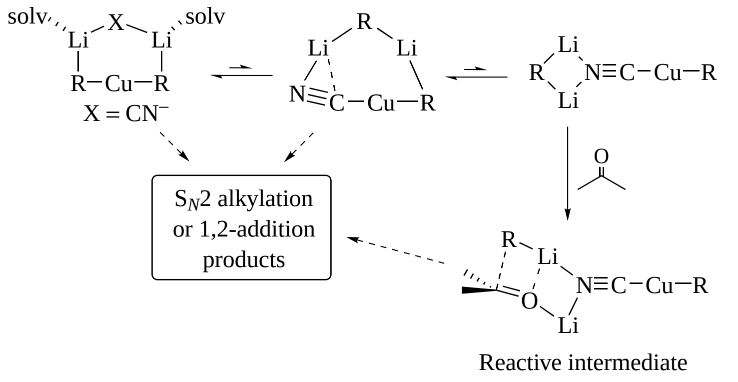
A cyclic dienone also showed a characteristic C2–C3 ^{13}C-NMR shift due to π-complexation (*cf.* **71**; Scheme 8).[74] The 1,4- and 1,6-σ-Cu(III) species (**72**) and (**73**), respectively, are proposed to be in equilibrium, and *via* kinetic measurements, the suggested rate-determining step of conjugate addition involves an intramolecular π-complex rearrangement.[75] An extensive ^{13}C-labeled 1-D and 2-D-NMR study of 1,6-addition to an ynenone supports π-complex formation and shows that the C-Cu–C orientation must distort from the typical square-planar conformation in order to react.[74]

Computational work applied to cuprates has provided plausible pathways for conjugate addition to enones (e.g. 5-methylcyclohexenone; Scheme 9), S$_N$2 alkylations, and carbometalation reactions. It has been hypothesized that the copper(I) anion donates electron density to a substrate enone, thus aiding in Cu(III) intermediate formation.[53] The role of the lithium atom as a Lewis acid is essential in cuprate additions, whereas non-Lewis acidic (*see Lewis Acids & Bases*) TMSCl is believed to lower the energy of the final C–C bond forming step *via* stable silyl enol ether formation, or acting as a stabilizer in the transition state leading to the π-complex.[77] Calculations also indicate that nontransferable 'dummy' ligands on the metal accelerate reductive elimination of a Cu(III) intermediate, enhancing reactivity of the cuprate by simultaneously binding to Cu and Li.[53] Through B3LYP density functional calculations, reductive elimination (*see Reductive Elimination*) of a π-allylcopper(III) species leading to C–C bond formation occurs *via* a π-allyl enyl[$\sigma + \pi$]-type transition state, instead of through a simpler σ-allylcopper(III) intermediate. Electronic effects on a substituted π-allylcopper(III) species account for the regioselectivity of reductive elimination, which also correlates well with Hammett σ_p^+ constants.[78]

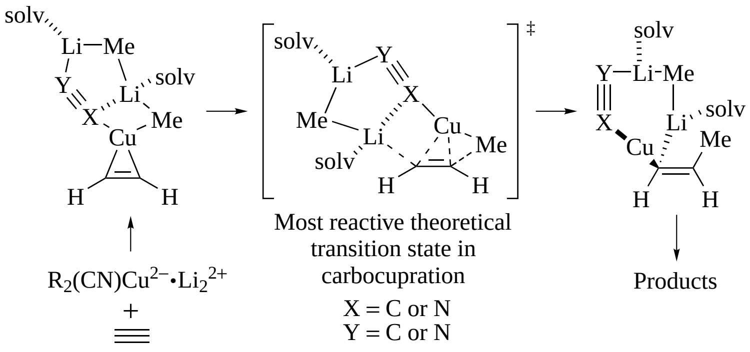
Theoretical studies on S$_N$2 alkylations of cyanocuprates with alkyl halides or epoxides indicate electronic as well as structural effects are due to the presence of the $[Li_2CN]^+$ cation, leading to increased reactivity of 'higher order' cuprates as compared to 'lower order' Gilman reagents (Scheme 10).[53] Bridging by this cation is important in cuprate alkylations, as is solvent polarity and coordination ability. Calculations show that geometry and transition state energy are not affected by a solvated copper atom, although solvent does participate following alkylation. Without solvent, the S$_N$2



Scheme 9



Scheme 10



Scheme 11

alkylation involves the nucleophilic Cu(d_{z^2}) and $H_3C(2s + 2p)$ orbitals of the cuprate, where cleavage of the C–LG (LG = leaving group) bond is the rate-determining step.[53]

Computational investigations on carbocupration of acetylene indicate that negative charge transfer occurs from copper to the acetylene unit (Scheme 11). Lithium atom participation in this reaction is similar to that in conjugate addition to an enone, where Li^+ stabilizes negative charge buildup in the alkyne and facilitates electron flow from copper.[53] Molecular orbital (*see Molecular Orbitals*) analysis of Me_2Cu^- addition to acetylene (π^*-orbital) shows that the Cu($3d_{xz}$) orbital back donation is responsible for the nucleophilicity of organocuprates.[79] It has also been suggested that cyanide on copper (i.e. R(CN)CuLi·LiR) in the carbocupration is a more reactive species than when it is associated with lithium (i.e. R_2CuLi·LiCN), and that both complexes are present in solution according to high-level calculations.[53]

1 INTRODUCTION

This review is based on a former one from K. Lerch[1] in a previous edition of this work. While that article summarized the results up to 1995, this article will be focused on the time after and concentrate more on the structural features and less on the spectroscopic ones. Nevertheless, some former but updated parts of Lerch's review will be included without special indications. In addition, the selection of references can only be very limited and some important ones may not be included.

During the last twenty years, it became obvious that quite a few proteins belong to the protein family designated as 'copper proteins with dinuclear active sites'. As described previously,[1] the first of these proteins were discovered during the nineteenth century: the respiratory protein hemocyanin and the enzyme tyrosinase. In 1878, Fredericq[2] described a colorless protein in the blood of the mollusc *Octopus vulgaris*, which turned deep blue in the presence of air. He introduced the name hemocyanin (Hc) derived from the greek words $\alpha'\iota\mu\alpha$ (blood) and $\kappa\upsilon\nu\alpha\nu o\zeta$ (blue). The enzyme tyrosinase (Ty) was discovered in 1895 by Bertrand and Bourquelot[3] who demonstrated that the darkening of certain varieties of mushrooms is due to the oxidation of the aromatic amino acid tyrosine. The identification of Hc and Ty as copper proteins, however, took place several decades later. In 1928, Redfield[4] showed that Hc's both from arthropods and molluscs bind one molecule of oxygen per two copper atoms. A few years later, the same stoichiometry was found for the binding of carbon monoxide.[5] In 1937, Kubowitz[6] observed a linear relationship between the copper content and enzymatic activity of potato Ty. The most highly purified enzyme had a copper content of 0.2% and the activity was inhibited by cyanide, diethyldithiocarbamate, and carbon monoxide. He showed that the copper was essential for catalytic activity by removing it reversibly with cyanide. Moreover, the substrate-reduced enzyme was found to bind carbon monoxide with the same stoichiometry reported earlier for Hc. Thus, Kubowitz was the first to realize a clear relationship between the two copper proteins Hc and Ty.

These pioneering studies on Hc and Ty were followed by a period in which the two proteins were investigated extensively in terms of their protein architecture and oxygen binding (Hc) and catalytic activity (Ty).[7–12] In the 1970s, the relationship of the two copper proteins was further corroborated by numerous spectroscopic studies showing unequivocally the dinuclear nature of their copper active sites. Several reviews have appeared on the chemical and spectroscopic properties of the unique dinuclear copper complex.[13–20] Since about 1980 to now many dozens of sequences of type 3 copper proteins were solved from many different sources, shedding new light on the evolution of this diverse class of copper proteins.[19–28] It turned out that not only hemocyanins, tyrosinases, catecholoxidases, but also pseudohemocyanins, cryptocyanins, and hexamerins belong to this family.[29–31] The three latter ones, however, have lost the ability to bind copper. In addition, complete gene sequences were published.[32,33] Several high resolution 3-D structures based on crystals and electron microscopy also became available.[34–43] During the last few years, it was unequivocally demonstrated that hemocyanins can be converted to enzymes exhibiting phenoloxidase activity.[44–51] As a result of these studies, a rather detailed picture of the molecular and copper active-site structures of Hc and Ty became available. Various review articles on copper proteins with dinuclear sites were published since 1995.[25–28,51–57] In addition, recent developments on this topic were presented at a recent international conference in Mainz in fall of 2003 being published in a special issue of Micron 2004, 35, Volumes 1 and 2.

2 DINUCLEAR COPPER SITE

The active site of type 3 copper proteins consists of two copper atoms. Each of them is bound by three histidines provided by an antiparallel alpha-helix pair (Figure 1). Cu-A denotes the copper-binding site closer to the N-terminus, whereas Cu-B is the copper-binding site closer to the C-terminus. According to crystal structures of arthropod[34–38] and mollusc[39,40] hemocyanins, the coppers bind a dioxygen molecule in the same way as a peroxide in μ:η^2-η^2 side-on coordination between the coppers (Figure 1) and as found in a synthetic dicopper complex.[58] The binding of dioxygen as a peroxide results in a change of valency of the two copper atoms from Cu(I) to Cu(II).

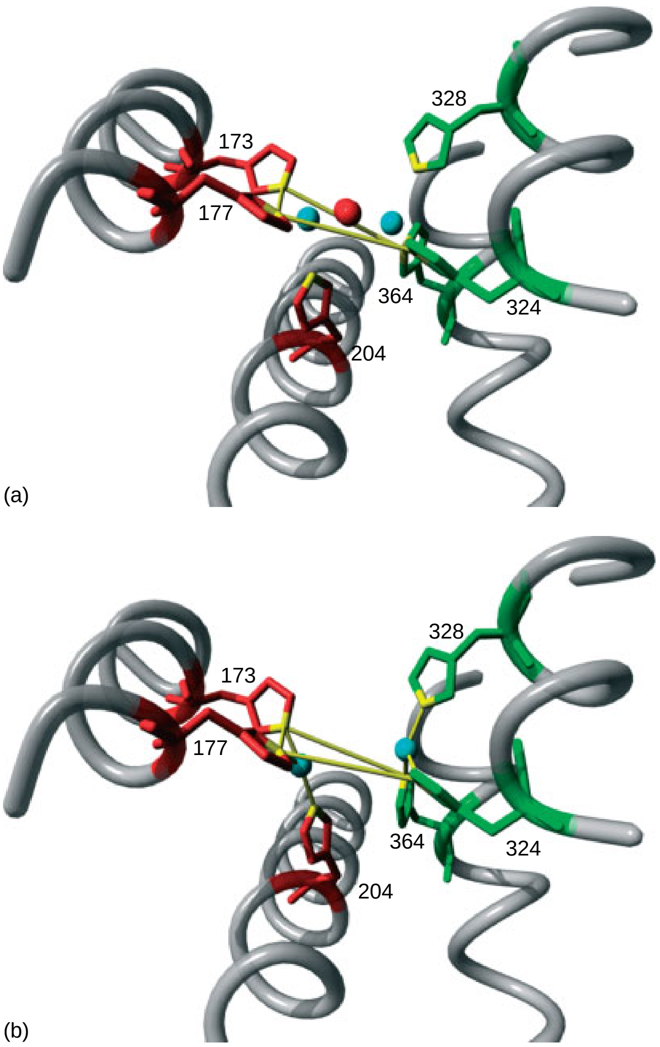

Figure 1 Oxy (a) and deoxy (b) states of the active sites of subunit II of *Limulus polyphemus* hemocyanin. The three histidines coordinating Cu-A are colored red, those coordinating Cu-B green. The two copper atoms are colored blue and oxygen red. Yellow lines connect the four histidines forming the plane on which the coppers and the dioxygen are often discussed to be placed. Two axial histidines are perpendicularly oriented to this plane: His204 coordinates the Cu-A site, His328 the Cu-B site. The channel to the surface for substrates to the active sites is located on the top of the active sites

Various spectroscopic methods applied to hemocyanin and phenoloxidases strongly favored a very similar oxy-structure of the active site for many years.[1] In addition, the X-ray data and sequences of type 3 copper proteins reveal that two different classes exist, which differ in their Cu-A and Cu-B[28] environment. While the Cu-B environment remains more or less unchanged, the environment of Cu-A is different in arthropod and mollusc (Figures 1, 2). As in mollusc Hc and catecholoxidase, one helix binding the copper atom is shorter. One of the Cu-A coordinating histidines is located at the end of an alpha-helix (His109 (*Ipomea*), His2563 (*Octopus*), His61 (*Rapana*)) and is stabilized by a conserved covalent bond to a cysteine,[39–41,59,60] a bond that is very seldom observed in nature (Figure 2).

During the late 1970s, Solomon and collaborators prepared and extensively characterized a series of derivatives leading to models of the copper active-site structure and it function that are summarized in several articles.[61–63] While decades ago the end-on coordination was favored when interpreting the spectra, now great effort is applied to interpreting the spectra on the basis of the results of the recently resolved X-ray structure,[63–67] which clearly show that dioxygen is bound in a side-on coordination between the two copper atoms.[38,39] Several other contributions in this book will focus this point (*see* ***Copper: Hemocyanin/Tyrosinase Models***).

Hemocyanins and tyrosinase can exists in various states, the oxy-state (dioxygen is bound between the two copper atoms), deoxy-state (no dioxygen is bound), apo-state (no copper is bound) and met-state (the two copper atoms are bridged by a hydroxyl group). The former article by Lerch[1] reviewed the met and apo forms intensively. However, some features of the oxy and deoxy structures should be mentioned.

Oxy-form. While deoxygenated hemocyanin can bind dioxygen reversibly as a peroxide, oxy-Ty is only formed after treatment of met-Ty with reducing agents (hydrogen peroxide, a number of different reducing agents, such as hydroxylamine, ascorbic acid, sodium dithionite, sodium borohydride, and *o*-diphenols) in the presence of molecular oxygen. However, the molecular reason is not known yet owing to the lack of any structure of a tyrosinase.

Because of the highly unusual and unique spectral features of oxy-Hc's and Ty's, these forms have been studied in great detail by many different groups: Resonance Raman Spectroscopy has shown that, in oxy-Hc's and oxy-Ty, dioxygen is bound as peroxide to the dinuclear site. All data imply that the two copper ions are in the copper(II) oxidation state, which was confirmed by XAS studies. Like the met forms, oxy-Hc's and Ty's are EPR nondetectable and show strong antiferromagnetic coupling between the two Cu(II) ions ($2J > 600\,\text{cm}^{-1}$), as demonstrated by magnetic susceptibility studies. The large coupling requires orbital overlap between the two Cu(II) ions, which based on a Cu–Cu distance of <3.6 Å from EXAFS measurements, must involve a superexchange pathway through a bridging ligand, which, however, was not found yet within a distance of 0.5–0.7 nm. Oxy-Hc and oxy-Ty are characterized by unique spectral features. The absorption spectrum shows two bands at <590 nm ($\varepsilon < 1000\,\text{M}^{-1}\,\text{cm}^{-1}$) and an extremely intense transition at <345 nm ($\varepsilon < 18–20\,000\,\text{M}^{-1}\,\text{cm}^{-1}$). The CD spectrum shows in addition to the intense transition at 345 nm a positive band at <520 nm. These absorption and CD bands are absent in the met forms and hence have been assigned as peroxide-to-Cu(II) charge-transfer transitions.

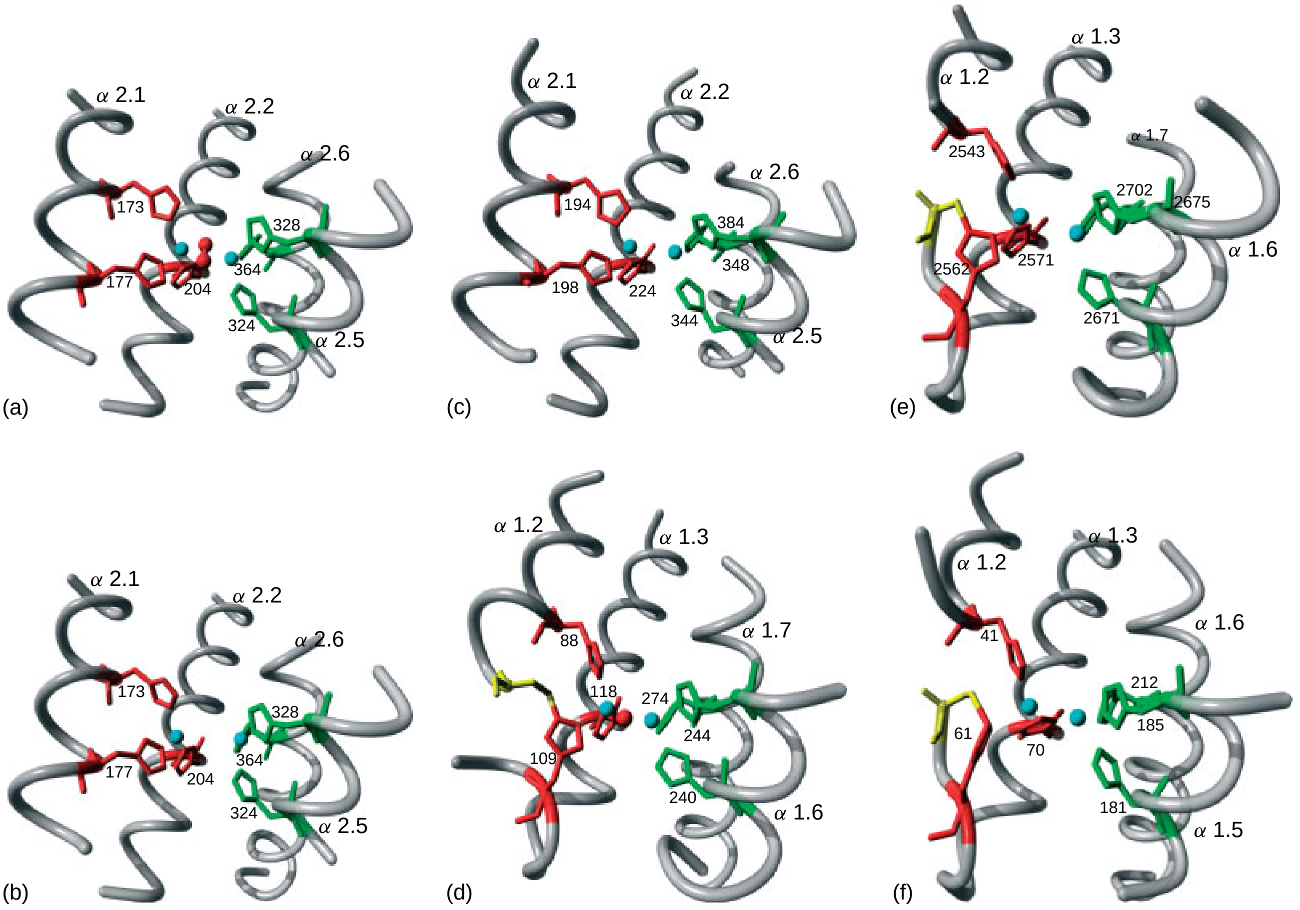

Figure 2 Active sites of hemocyanins from horseshoe crab *L. polyphemus* (a: oxy; b: deoxy), spiny lobster *Panulirus interruptus* (c), sweet potato *Ipomoea batatas* (d), *Octopus dofleini* (e), *Rapana thomasiana* (f). Cleary the four alpha-helix bundle motif with the metal center can be seen. The three histidines coordinating Cu-A are colored red, those coordinating Cu-B green. The two copper atoms are colored blue and oxygen red. The cysteines binding covalently a histidine at the Cu-A site are colored yellow. In the case of *Ipomoea,* a water molecule connects the two copper atoms

At the same time when the first X-ray structure of an oxy-hemocyanin was published[38] a side-on peroxo complex has successfully been prepared by Kitajima's group, which was commonly accepted but after strong discussions.[58] This complex was found to be diamagnetic and showed spectral features remarkably similar to those of oxy-Hc's and Ty's. These also include the unusually low peroxo O–O stretching frequencies ($<750\,\text{cm}^{-1}$) that appear to be characteristic for the $\mu{:}\eta^2\text{-}\eta^2$ structure. Finally, the side-on peroxo structure is also consistent with theoretical studies of different copper–peroxide complexes.

Deoxy-form. The deoxy-forms of Hc's and Ty's are colorless and EPR silent. In agreement with XAS studies, both coppers are present in oxidation state +I. The X-ray structure of *P. interruptus* deoxy-Hc showed that the two Cu^{I} ions are separated by <3.6 Å, which is in agreement with EXAFS studies of deoxy-Hc indicating most probably a 3,3-coordination of the coppers, which is also in agreement with the data from X-ray structural analysis. A thorough analysis of the electronic structure of the deoxy structure is presented by Solomon *et al.*[61]

3 TYPE 3 COPPER FAMILY

Provided here is only a short overview of type 3 copper proteins.

3.1 Hemocyanin

Hc's are very large oxygen-binding copper proteins freely dissolved in the hemolymph of many invertebrates of the two phyla of Arthropoda and Mollusca. Hemocyanin accounts for up to 80–98% of the total protein in the hemolymph. A more detailed description of the distribution of Hc's in Arthropoda and Mollusca can be found in reviews.[23,27,28,52,53,68,69]

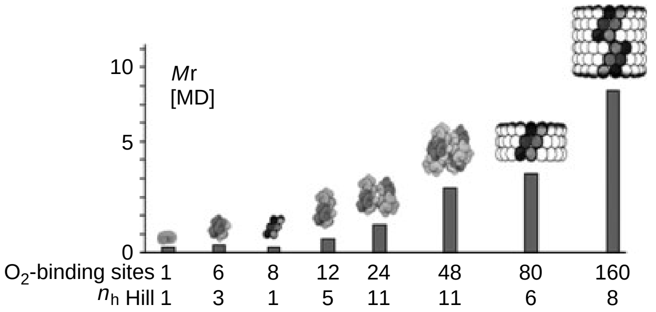

Figure 3 Hierarchies in the structures of hemocyanins from arthropods and molluscs. A kidney shaped arthropod subunit (Mr ∼ 72 kDa) binds one molecule of dioxygen. Depending on the species, the subunits associate to 1 × 6, 2 × 6, 4 × 6, 6 × 6 and 8 × 6-meric hemocyanins found freely dissolved in the hemolymph. A molluscan hemocyanin subunit (Mr ∼ 400 kDa) folds into eight functional units each carrying one active site (two cannot be seen being hidden in the interior of the cylinder). Ten of these subunits form cylinders. Depending on the species, decamers or didecamers are found. Thus, hemocyanins can bind up to 160 dioxygen molecules with a cooperativity n_h of over 11

To summarize, ultrastructural studies (ultracentrifugation, electron microscopy, small-angle X-ray scattering, immunochemistry, analysis of sequences and genes) have revealed that Hc's from the two phyla have unique and completely different quaternary structures[18,37–43,69–78] (Figure 3). Thus, arthropodan Hc's typically consist of hexamers (Mr 400–450 000) or multihexamers (2·6, 4·6, 6·6, and 8·6). From protein chemical studies, it has been found that the subunit Mr is about 75 000, consistent with the presence of one dinuclear copper activesite per polypeptide chain. Numerous studies have also indicated a widespread subunit heterogeneity in arthropodan Hc's. Molluscan Hc's consist of 10 or 20 large subunits (Mr 350–450 000), which form a hollow cylinder with Mr up to ca. $8–9 \cdot 10^6$ Daltons. Proteolytic digestion of the purified proteins showed that the subunits are composed of seven or eight oxygen-binding functional units with an Mr of ca. 45 000–55 000. These results are again in agreement with one dinuclear copper active site per functional unit (FU). Like arthropodan Hc's, molluscan Hc's also show substantial heterogeneity both on the subunit and the functional unit levels, being essential for the self-assembly process to yield species-dependent oligomers and being essential to develop cooperativity and allostery.[79]

3.1.1 Arthropod hemocyanins

Primary structure of hemocyanins. Many hemocyanin subunits were sequenced and analyzed (see latest reviews of Burmester and coworkers[23,24,68,69]). However, only for a few Hcs are all subunits composing the native structure sequenced. In most cases, a sequence identity of only about 30% is found between the subunit types of native hemocyanins within one species as well as when compared with those from different species. Most conserved is domain II carrying the active site. These sets of data allow the study of evolution of hemocyanins within a species and between species as well.

A few completely sequenced hemocyanins should be discussed: The 6-mer from the spiny lobster *P. interruptus* (Figure 4) consists of three different subunits a, b, c.[80,81] The hemocyanin of the European spiny lobster *Panulirus elephas* (synonym: *Panulirus vulgaris*) is also a hexamer composed by four closely related but distinct subunits.[82] Assuming a constant evolution rate, the *P. elephas* hemocyanin subunits emerged from a single hemocyanin gene around 25 million years ago. The alpha-type hemocyanins of *P. elephas* and the American spiny lobster *P. interruptus* split around 100 million years ago. This is about five times older than the assumed divergence time of the species and suggests that the genera may have split with the formation of the Atlantic Ocean.

The 4 × 6-meric tarantula Hc from *Eurypelma californicum* consists of 7 different subunit types.[83] In contrast to crustacean hemocyanin, the chelicerate hemocyanin subunit lost the alpha 1.2 helix (Figure 4, 5d, e), which then allows the assembly of larger hemocyanins than hexamers.[18,69,70] Each hexamer contains subunit a, d, e, f and g. The sixth position is taken by subunit b or c. Thus, the smallest structurally identical units are the 2 × 6-meric half-molecules, which dimerize

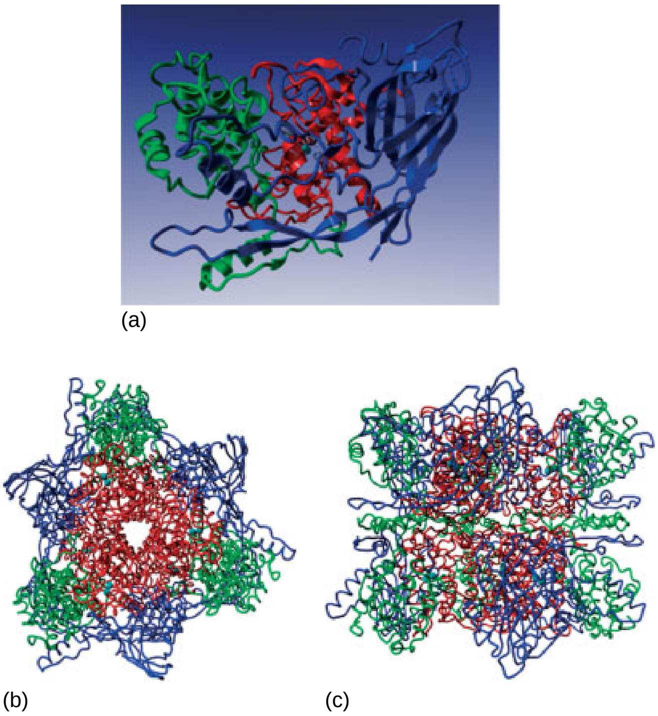

Figure 4 Structures of a crustacean hemocyanin subunit and the hexamer (*P. interruptus*). The three domains are colored differently (green: I; red: II; blue: III). Alpha-helix 1,2 will be missing in the chelicerate subunit compared to a crustacean subunit (a). The top view shows the threefold symmetry along the central channel (b), the side view (c) shows that the two trimers are isologously dimerized

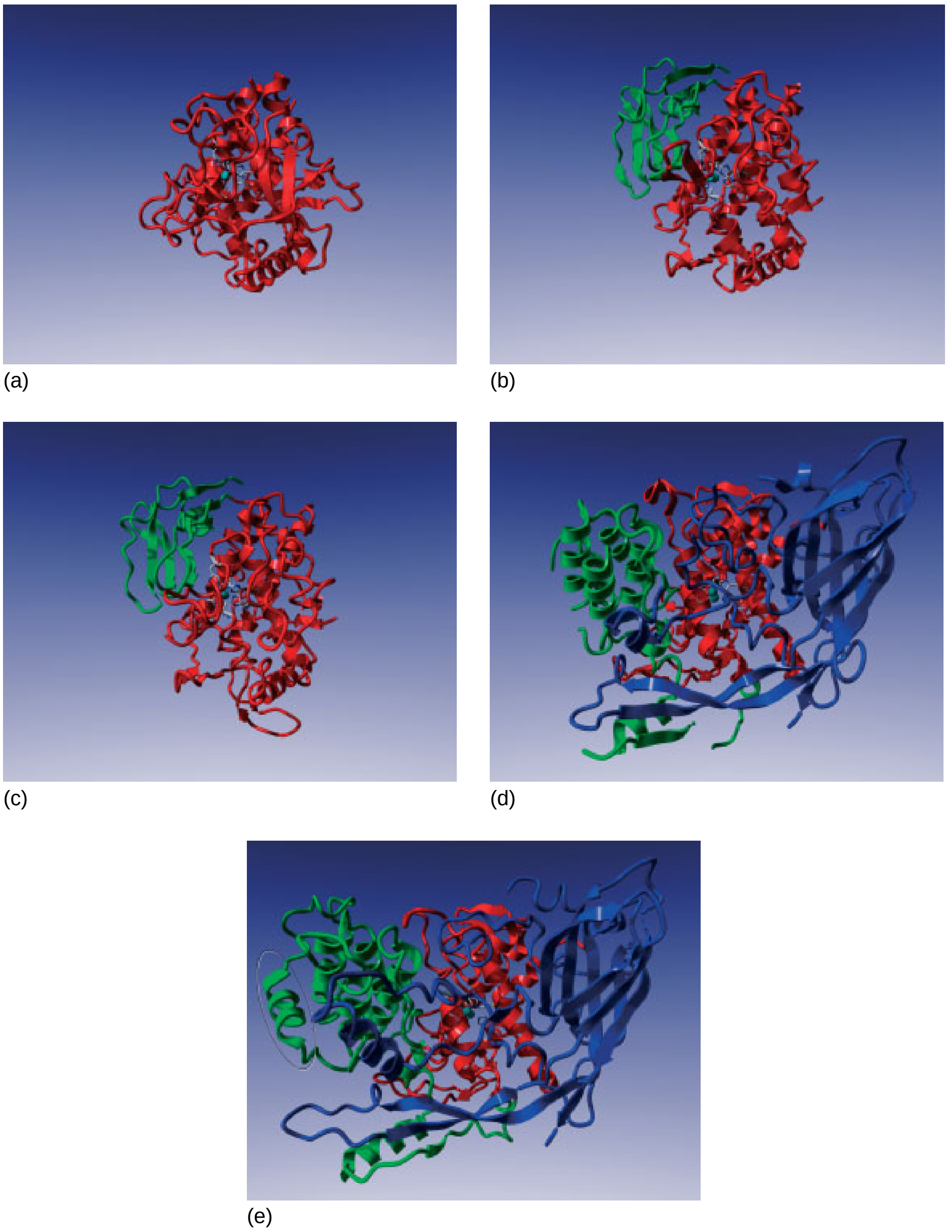

Figure 5 Comparison of the tertiary structures of a catecholoxidase from a sweet potato *Ipomea* sp. (a), functional units of molluscan hemocyanins (*O. dofleini* (b) and *R. thomasiana* (c)) and arthropod hemocyanin subunits from *L. polyphemus* (d) and *P. interruptus* (e). All structures are centered with respect to domain II (red) carrying the active site, domain I is colored green, domain III blue. The histidines are colored gray. In the *Limulus structure* (d) the alpha 1,3 helix is missing compared to the *Panulirus* (e) structure (ellipse)

isologously by forming two noncovalent bonds between the two subunits b and c.

Six distinct hemocyanin subunits were also identified in the red-legged golden orb-web spider *Nephila inaurata madagascariensis*.[84] The complete cDNA sequences of six subunits were obtained that corresponded to a-, b-, d-, e-, f-, and g-type subunits of the tarantula hemocyanin from *E. californicum*. A thorough evaluation of sequence comparisons revealed that subunit type a diverged first, followed by the common branch of the dimer-forming b and c subunits, while subunits d and f, as well as subunits e and g form common branches.[84]

Although being intensively investigated, only very few subunit types were sequenced of the 4×6-meric scorpion Hc (*Androctonus australis*, subunit Aa6 of eight subunit types[85]), and the 8×6-meric horseshoe crab (*L. polyphemus*, subunit II of more than ten subunit types[86]).

Scorpions and orthognath spiders, which possess highly conserved 4×6-mer hemocyanins, seem to possess at least six distinct subunit types (termed a to g). But many ‘modern’

entelegyne spiders such as *Cupiennius salei* differ from the standard arachnid scheme and have 2 × 6-mer hemocyanins. Six distinct subunit types (1 through 6) and three additional allelic sequences were identified.[87] Each 1 × 6-mer half-molecule most likely is composed of subunits 1–6, with subunit 1 linking the two hexamers via a disulfide bridge located in a C-terminal extension.

Insect hemocyanin. In the phyla Arthropoda, one class, the insects, are thought not to have oxygen carriers such as hemocyanins, since the oxygen supply by trachea is very effective. However, recently some hemocyanins were also detected in insects. An embryonic hemolymph protein (EHP) was found being expressed during early stages of development in the grasshopper embryo. EHP is a 78-kDa soluble protein present initially in the yolk sac content, and later in the embryonic hemolymph. Peptide sequencing was used to identify it being related to cheliceratan hemocyanins and prophenol oxidases and was therefore proposed to function as an oxygen carrier or storage protein during embryonic development.[88] Just recently in the hemolymph of nymphs and adults of the stonefly *Perla marginata*, a hexameric Hc was identified, which consists of two distinct subunit types of 659 and 655 amino acids. This Hc displays a cooperative oxygen binding with a moderately high oxygen affinity.[89]

Myriapod hemocyanin. The presence of hemocyanins in the diplopod Myriapoda was reported during the last few years, demonstrating that these proteins are more widespread among the Arthropoda than previously thought.[90–92] The hemocyanin of *Spirostreptus* sp.(Diplopoda: Spirostreptidae) is composed of two immunologically distinct subunits in the 75-kDa range that are most likely arranged in a 36-mer (6 × 6) native molecule. *Spirostreptus* hemocyanin is structurally similar to the single known hemocyanin from the myriapod taxon, *Scutigera coleoptrata* (Chilopoda), indicating a rather conservative architecture of the myriapod hemocyanins.[92] The 6 × 6-mer is composed of four distinct subunit types that are 49.5–55.5% identical. The cDNA of a fifth, highly diverged, putative hemocyanin subunit was identified that is not included in the native 6 × 6-mer hemocyanin. Phylogenetic analyses show that myriapod hemocyanins are monophyletic, but at least three distinct subunit types evolved before the separation of the Chilopoda and Diplopoda more than 420 million years ago.[92]

Hc related proteins in Arthropods. Some members of the type 3 copper protein family are closely related to hemocyanins and phenoloxidases but lost the ability to bind oxygen any more. In most cases they are known as pseudohemocyanins, hexamerins, and hexamerin receptors. In the case of cryptocyanin, three of the six highly conserved copper-binding histidine residues of hemocyanin are lacking.[93] The concentration of cryptocyanin in the hemolymph is closely coordinated with the molt cycle and reaches levels higher than hemocyanin during premolt.[94] A nonrespiratory pseudohemocyanin PHc of *Homarus americanus* consists of two different subunit types of 660 and 661 amino acids, respectively, that share a 94.4% sequence identity. Here only one of the histidines was mutated that coordinates the copper atom at the active site. It should be pointed out that Hc and PHc are synthesized in different tissues in the same species. Whereas *Homarus* hemocyanin is produced in the hepatopancreas, PHc is synthesized by the ovaries and the heart tissue.[94]

Evolution. Based on over 100 sequences of hemocyanins and related phenoloxidases, hypotheses for the evolution of this protein family were suggested.[23–25,28,95] Based on thorough investigations and analysis of the data by Burmester and coauthors the following scenario is proposed for the evolution of type 3 copper proteins in arthropods: Within the arthropod hemocyanin superfamily, the phenoloxidase probably emerged early in evolution. The respiratory hemocyanins evolved from these enzymes before the radiation of the extant euarthropodan subphyla. The results were consistent and indicated the separation of the cheliceratan and crustacean hemocyanins close to 600 MYA. The different subunit types of the multihexameric cheliceratan hemocyanin have a rather conservative structure and diversified in the arachnidan stemline between 550 and 450 MYA. By contrast, the separation of the crustacean (malacostracan) hemocyanin subunits probably occurred only about 200 MYA. The nonrespiratory pseudohemocyanins evolved within the Decapoda about 215 MYA. The insect hemocyanins and storage hexamerins emerged independently from the crustacean hemocyanins. The time of divergence of the insect proteins from the malacostracan hemocyanins was estimated to be about 430–440 MYA, providing support for the notion that the Hexapoda evolved from the same crustacean lineage as the Malacostraca.

Occurrence of hemocyanin related proteins in organisms. While textbooks tell that Hcs occur only in arthropods and molluscs, recently Hcs were also found in other phyla. The velvet worms (*Onychophora*) are considered living fossils and are closely related to the Euarthropoda. Onychophora possess a tracheal system for respiratory function, thus oxygen transport proteins have been considered unnecessary. In the hemolymph of the *Epiperipatus sp.* (Onychophora: Peripatidae), an arthropod-type hemocyanin was found, demonstrating that such proteins exist outside the Euarthropoda.[96]

Although four hemoglobin genes are present in the tunicate Ciona, two cDNA sequences from Ciona encoding for 794 and 775 amino acids have been identified to belong to the arthropod hemocyanin superfamily.[97] All amino acids required for oxygen binding and other structurally important residues are conserved. However, phylogenetic analyses and mRNA expression data suggest that the Ciona hemocyanin-like proteins rather act as phenoloxidases,

possibly involved in humoral immune response. Based on these surprising results, it can be deduced that the hemocyanin superfamily emerged before the Protostomia and Deuterostomia diverged and support the idea that respiratory hemocyanins evolved from ancestors with an enzymatic function such as phenoloxidases.

3.1.2 Molluscan hemocyanin

Some subunits of mollusc hemocyanins were also completely sequenced. The first completely sequenced subunit of a mollusc hemocyanin subunit was that from *O. dofleini*.[60] The protein subunit has 2896 amino acids and contains seven functional units with *M*r of about 45 000–55 000, each carrying two sets of three invariant histidine residues constituting the binding sites (A and B) for two copper atoms. An accompanying paper[39] presents the structure of a functional unit (Odg). This allowed the organization of the long sequence. The sequences of the seven units exhibit high similarity, averaging about 40% identity, with a concentration of conserved sequences in the region surrounding the copper-binding sites. The sequences around the B-site show significant homology to the sequences of arthropod hemocyanins. A number of putative N-linked carbohydrate binding sites can be recognized in the sequence. In contrast to this hemocyanin, the hemocyanin subunit from the gastropod *Haliotis tuberculata* HtH1 folds into eight FUs, a-h.[32,33] With 3404 amino acids (392 kDa) it is the largest polypeptide sequence ever obtained for a respiratory protein. The cDNA comprises 10 758 base pairs and includes the coding regions for a short signal peptide, the eight different functional units, a 3′-untranslated region of 478 base pairs, and a poly(A) tail. The predicted protein contains 13 potential sites for N-linked carbohydrates (one for HtH1-a, none for HtH1-c, and two each for the other six functional units). Multiple sequence alignments show that the fragment HtH1-abcdefg is structurally equivalent to the seven-FU subunit from *Octopus* hemocyanin. However, an additional FU h is fused at the C-terminus. The gene organization of two molluscan hemocyanins has been resolved and discussed thoroughly.[33]

3.1.3 Stability

The quaternary structures of Hc's are strongly dependent on pH and the presence or absence of divalent cations such as Ca^{2+} or Mg^{2+}. Thus, most arthropodan Hc's can be dissociated to functional units by simply raising the pH above 9 with the concomitant removal of divalent cations by chelating agents (e.g. EDTA). This dissociation can be reversed by dropping the pH and/or addition of divalent cations (>10 mM). A very similar behavior is also observed for Hc's from molluscs. Hc's from both phyla typically exhibit cooperative oxygen binding. The extent of cooperativity is dependent upon several parameters such as pH, temperature, and the presence of divalent cations such as Ca^{2+} and Mg^{2+}.[93,94,98]

The observed heterogeneity can be ascribed to the fact that Hc's are glycoproteins.[99–101] Typically, molluscan Hc's have a carbohydrate content of 8–10%, compared to 1–4% for arthropodan Hc's.

3.2 X-ray Structures of Hemocyanins

Several X-ray structures of hemocyanins and of one catecholoxidase were solved during the last decade. The main features are presented in Figure 5.

Hc from the spiny lobster *P. interruptus* consists of a single hexamer with a *M*r of ca. 460 000 (Figure 4, 6). Using monoclinic crystals grown at pH 4.5 (one hexamer per asymmetric unit), Hol and his associates have successfully

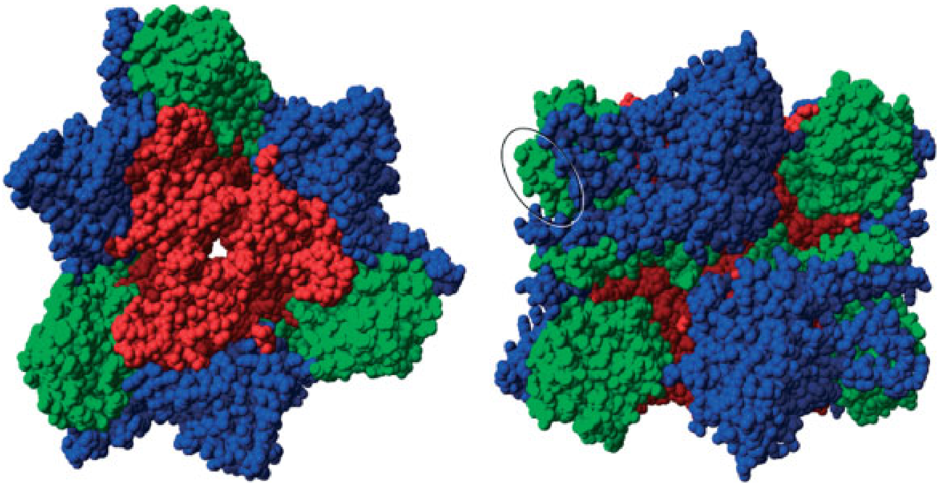

Figure 6 Top and side view of the hexameric structure of *P. interruptus* hemocyanin. The three domains of the six subunits are colored green (I), red (II), and blue (III). The six domains II (red) form the central channel. Alpha-helix 1.2 is marked by an ellipse

solved the 3-D structure at atomic resolution.[34] Recently, the structure has been refined to 3.2 Å using restrained least-squares procedures.

The crystal structure studied is that of the deoxy-form, as was shown by spectroscopic techniques (copper X-ray absorption spectroscopy, UV–visible spectroscopy, and electron paramagnetic resonance). The polypeptide chain of a subunit of *P. interruptus* Hc is folded into an irregular ellipsoid with three distinct domains. Domain I (comprising 175 amino acid residues) consists of seven helices and two beta-strands, one of which forms a beta-sheet with two strands from the third domain. The second domain (comprising residues 176–398) is also mainly helical and globular. The oxygen-binding site is located in the center of this domain surrounded by four helices: 2.1, 2.2, 2.5, and 2.6. The two copper ions (Cu-A and Cu-B) are each ligated by three histidines, which originate from the four helices. Two of the ligands of Cu-A and Cu-B come from successive turns of helix 2.1 and 2.5, respectively. The third ligand of each copper is provided by the remaining two helices. The helical pair consisting of 2.1 and 2.2 (Cu-A) is related to the helical pair 2.5 and 2.6 by an internal pseudo-twofold symmetry.[102] Three histidines (His194 and 198 of Cu-A and His344 of Cu-B) are tightly bound with N_ε–Cu distances smaller than 2 Å. A slightly less tightly bound ligand, His348, is found at a distance of 2.1 Å to Cu–B. The N_ε atoms of the four histidines together with the Cu-A and Cu-B are approximately arranged in a plane. His224 and His384 are located perpendicular to this plane, at opposite sides, with Cu–N_ε distances of ca. 2.7 Å to the two copper ions. The average Cu–Cu distance of the six subunits in deoxy-Hc is 3.54 Å, in good agreement with the value obtained by EXAFS.

The third domain (comprising residues 399–657) consists of a seven-stranded beta-barrel with two long loops. These loops function as arms holding the three domains together. The beta-barrel of domain 3 was found to be structurally very similar to those of Cu, Zn-superoxide dismutase and the immunoglobulin domains.

Hc from Limulus polyphemus Subunit II. In a recent study by Magnus and associates,[36,37] subunit II from *L. polyphemus* Hc was crystallized in the oxygenated and deoxygenated forms. The blue oxygenated crystals were found to contain one subunit of *M*r of 73 000 per asymmetric unit. The present model of the *L. polyphemus* crystal structure is based on X-ray data at 2.4 Å resolution (Figure 1). In the deoxy structure, two histidines each are bound to Cu-A (N1 and N2) and Cu-B (N5 and N6) at a distance between 2.0 and 2.1 Å. The other two histidines (N3 and N4) are located perpendicular to the equatorial plane formed by the other four histidines, and at opposite sides to the plane formed by N1, N2, N3, N4, Cu-A, and Cu-B. The Cu–N distances are 2.4 Å for both histidines. The two oxygen atoms of molecular oxygen are clearly distinguishable in the active site as two extra electron density peaks. The dioxygen molecule is bound in the μ:η^2-η^2 conformation with regard to the copper atoms. The Cu–Cu distance in oxy-Hc from *L. polyphemus* is 3.6 Å, in good agreement with the values measured by EXAFS spectroscopy of arthropod and mollusc hemocyanins.[103] The O–O distance of 1.4 Å is in the range typically found for a peroxide ion bound to a transition metal ion. Finally, no evidence for an endogenous bridging ligand was found from the map as predicted from the spectroscopical analysis. The closest nonprotein electron density peak at ca. 4–5 Å from the copper ions was suggested to be a water molecule or a hydroxide ion.

Comparing this structure with the deoxy-homohexamer of *Limulus* subunit II,[37] three main structural movements can be observed during the deoxygenation. The distance between the two copper atoms enlarges to 4.2 Å, a rotation of the first domain with respect to the other three domains by 8° is observed and the highly conserved Phe49 is withdrawn from the active site by about 3 Å.[36,37] A metal ion such as calcium is supposed to be located at the concave site of domain III.

Molluscan hemocyanins. Two FUs from molluscan hemocyanins were resolved, the oxy-form of *O. dofleini* Hc FU g[39] (Figure 5b) and the deoxy-form of *R. thomasiana* Hc (Figure 5c[40]). Each FU consists of two domains. The N-terminal domain II carries the active site with a four alpha-helix bundle folding motif with two copper atoms. The C-terminal domain III replaces topologically the domain I in arthropod subunits and looks like a squeezed beta-barrel. Although the *Rapana* structure is not resolved as well as the *Octopus* FU, two different conformations can be deduced. In the oxy FU of *Octopus* hemocyanin, domain III covers the entrance to the active site completely while in the deoxy-form this domain is shifted a few degrees so that the channel to the active site becomes completely uncovered.

Catechol oxidase from sweet potato. Only one structure of a-phenoloxidase is available yet: the crystal structure of a catecholoxidase from sweet potato (*I. batatas*; the met form and with a bound inhibitor) was recently presented[41] (Figure 5a). This catecholoxidase is more similar to mollusc hemocyanin with respect to sequence similarity (about 25%) and the active site (Figure 2d).[26,41,104–107] As in mollusc hemocyanin in catecholoxidase one of the Cu-A coordinating histidines is covalently linked to a cysteine, a bond that is very seldom seen in nature (Figure 2d, yellow). This monomeric catecholoxidase seems to be only capable to catalyze the oxidation of diphenols. In contrast to mollusc hemocyanins, purified catecholoxidase from *I. batatas* consists of only one monomer with an open entrance to the active site in the activated form.[41] A part of the C-terminal sequence is not resolved yet and is absent in the activated form. Comparing similar sequences of catecholoxidase and mollusc hemocyanins, a homology modeling of the C-terminal sequence revealed that it most likely covers the entrance to the active site[106,107] supporting the hypothesis of

an oxygenation-dependent conformational transition of the C-terminal domain.

4 PHENOLOXIDASE

Tyrosinase catalyzes two reactions, the hydroxylation of phenolic compounds in ortho-position (cresolase activity) and subsequently the oxidation of the diphenolic products (catecholase activity).[2–4] Tyrosinase as well as another enzyme that catalyzes only the oxidation reaction, catecholoxidase (EC 1.10.3.1), belongs to the group of phenoloxidases. The monooxygenase nature of Ty was established by Mason and coworkers[8] in a pioneering study using ^{18}O-labeled oxygen. The two-electron donor required in the hydroxylation reaction is the *o*-diphenol, which is generated internally from the monophenol substrate.

The presence of phenoloxidase in all phyla of living organisms demonstrates that their origin is very early in the history of life.[23,24,28] It is involved in the biosynthesis of melanins and other polyphenolic compounds. Depending on the species, phenoloxidases are involved in the primary immune response, wound healing, sclerotization, and coloring processes. In mammals, L-tyrosine is the initial substrate in the pathway leading to the final products of black–brown eumelanins, red–yellow pheomelanins, or a mixture of pheo- and eumelanins.[1,108]

Ty initiates melanin synthesis by the hydroxylation of L-tyrosine to 3,4-dihydroxyphenylalanine (Dopa) and the oxidation of dopa to dopaquinone. In the presence of L-cysteine, dopaquinone rapidly combines with the thiol group to form cysteinyldopas, which undergo nonenzymatic conversion and polymerization to pheomelanin via benzothiazine intermediates.[1] In the absence of thiol groups, dopaquinone very rapidly undergoes conversion to dopachrome, which is transformed to 5,6-dihydroxyindole-2-carboxylic acid (DHICA) by dopachrome tautomerase. Alternatively, dopachrome is converted nonenzymatically to 5,6-dihydroxyindole (DHI). Oxidation of DHICA and DHI to the corresponding quinones and subsequent polymerization leads to eumelanins. It is still questionable if Ty is involved in this step.

Depending on the source of the enzyme, the Mr's vary between 29 000 and 450 000 with subunit Mr's from 29 000 to 67 000. To date, the enzyme from the bacterium *Streptomyces glaucescens* was found to have the smallest functional unit with one copper pair per polypeptide chain of 29 000. Ty's from microorganisms and plants are generally present as soluble proteins; in contrast, those from mammals are bound to specific organelles (melanosomes) in cells termed melanocytes.

In contrast to Hc's, which can be easily purified in large amounts, Ty's are present in low concentrations in all organisms studied. Furthermore, they are difficult to obtain in pure form owing to pigment contamination and the occurrence of multiple forms. It is therefore not surprising that, to date, Ty from only one species (*Neurospora crassa*) has been sequenced by classical protein chemical means. With the advent of recombinant DNA technology, however, several amino acid sequences have become available recently.[1] These include Ty's from the bacteria *S. glaucescens* and *Streptomyces antibioticus* as well as mouse and man. All Ty molecules sequenced so far are single-chain proteins with calculated Mr's of 30 900 (273 amino acid residues) for *S. glaucescens* and *S. antibioticus*, 46000 (407 amino acid residues) for *N. crassa*, 57 900 (480 amino acid residues) and 58 550 (515 amino acid residues) for mouse, and 58 000 (515 amino acid residues) and 62 600 (548 amino acid residues) for man.

Amino acid sequence comparison of the different Ty's shows that they are structurally related. The sequence identity is 24% between bacterial and fungal Ty and 26% between mouse and *N. crassa* Ty. A comparison of all three types of Ty (bacterial, fungal, and mammalian) reveals a sequence identity of only 8.7%.

Although many phenoloxidases are described in arthropods, only very few are proven to be tyrosinases such as those from *Pacifastacus leniusculus*,[109] *Astacus leptodactylus*,[110] and *P. elephas*.[110]

As already known at the time when Lerch wrote his review,[1] mammalian Ty's (mouse and man) are synthesized as proforms containing a typical signal peptide at the amino-terminal ends. This peptide is required for the translocation of the molecule into the melanosomes, the sites of melanin biosynthesis. In addition, mammalian Ty's are glycosylated (5–6 putative glycosylation sites) and are rather rich in cysteine. From 17 residues, 10 are clustered within the first 100 amino acid residues and 5 are found in the middle of the molecule. In the form of disulfides these residues contribute significantly to the unusually high resistance of mammalian Tys towards digestion by proteases. Nevertheless, still no structure is available although structural features were deduced from comparisons with hemocyanins.[111] In addition, a recent paper describes catalase and peroxygenase activities of tyrosinases.[112]

The field of phenoloxidases is absolutely unclear with respect to the structure. Mammalian tyrosinases have transmembrane parts and are glycosylated,[111] in arthropods they are freely soluble.[110] The aggregation is unclear as well. In mammals and prokaryotes, tyrosinases seem to be monomers,[111] in arthropods they occur as hexamers and look like hemocyanins.[110] The fact that not much knowledge is available on the structure and function of tyrosinases is surprising especially since tyrosinases are of major concern in medical and cosmetic research.

Copper-binding Regions of Hemocyanins and Tyrosinases. In the previous review by Lerch,[1] the similar copper centers of hemocyanins and phenoloxidases were thoroughly discussed on the basis of sequence comparisons. Thus, the surroundings of Cu-A and Cu-B are different as already

discussed in this report. Nevertheless, it should be pointed out that the tertiary structure of the various domains of hemocyanins and phenoloxidases are very similar and in most sections superimposable although the sequence identity is less than 30%.

Comparing the most conserved parts, the active site, reveals two different types of type 3 copper proteins, an arthropod hemocyanin-like one and a molluscan hemocyanin-like one. While the Cu-B site is highly conserved in both types, the Cu-A site differs. In the case of molluscan hemocyanins, one helix is too short for stabilizing the important histidine complexing Cu-A so that it has to be tied down by an unusual His–Cys bond as shown in Figure 2 (d–f).

5 PHENOLOXIDASE ACTIVITY OF HEMOCYANIN

The obvious structural similarity between hemocyanins and phenoloxidases is also supported by the fact that for almost all hemocyanins a-phenoloxidase activity can be induced by detergents or proteases as discussed in previous papers.[54,55] In most cases, especially in crustaceans, the activity is very weak.[113]

However, in some chelicerates, strong phenoloxidase activities have persisted in hemocyanins to date. Tarantula hemocyanin from *E. californicum* is very much comparable to phenoloxidases based on activation mechanism, substrate specificity, and inhibition.[45] The same holds for the hemocyanins from the horseshoe crabs *L. polyphemus* and *Tachypleus tridentatus*.[47,50] All three are ancient chelicerate species and unlike in more modern crustaceans, myriapods, and insects, no phenoloxidases have been found in their hemolymph to date. Thus, it may be that the hemocyanin fulfills the functions of the phenoloxidase in these chelicerates.

Activation of hemocyanins. Recently, quite a few papers reported the conversion of the oxygen-binding function of hemocyanins to phenoloxidase activity, that is, the conversion of the oxygen carrier hemocyanin into an enzyme.[44–51,114] These groups confirm older observations, which were hardly trusted for many years.[115,116] Many hemocyanin subunits can be activated by in vitro effectors, which are normally used for denaturation.[113] During this unfolding, access to the active site for phenolic substrates will be possible for a short period before the structure will be destroyed completely. This would explain that all subunits from crustacean hemocyanins show catecholoxidase activity in native PAGE. Meanwhile different ways of activation of hemocyanins are accepted and summarized in various articles.[26,28,54,55]

One way for activation to occur is the induction by in vivo factors. The inactive prophenoloxidase from hemocytes can be activated by a defense cascade. The defense cascade of insects and crustaceans, however, is different from that of the horseshoe crab *L. polyphemus* and most likely from chelicerates in general. Nagai and Kawabata[50,51] reported a clotting enzyme from the horseshoe crab *T. tridentatus*, that converts hemocyanins to phenoloxidase by forming a complex with a stoichiometry of 1:1 without proteolytic cleavage.

Activation mechanism. What happens during activation in hemocyanins and how can we use them as model systems to understand tyrosinase/catecholoxidase activity? Arthropod and mollusc hemocyanins have to be considered separately, although the processes are similar.

Here, I would like to present our hypothesis on the activation as published in various articles:[26,45,47,54,55] The activation of an arthropod hemocyanin opens a large entrance for phenolic substances to the active site by removal of an N-terminal peptide cleaved at a similar position as in prophenoloxidase of arthropods. This pulls a phenylalanine out of the substrate-binding pocket, which is highly conserved among hemocyanins and phenoloxidases. In the case of the horseshoe crab *L. polyphemus* hemocyanin it is Phe49 (Figure 7). As a result, a channel is opened and the dinuclear copper active site becomes accessible also to nongaseous bulky phenolic substrates. A phenolic substrate can be modelled into this pocket exactly like Phe49 from *Limulus* hemocyanin (Figure 8). This hypothesis is supported by a synthesized inhibitor of phenoloxidase activity carrying a phenylalanine that takes the position of Phe49. Phenylalanine is an ideal amino acid in this respect since it is inert with respect to any enzymatic activity at the active site. The flexibility of the substrates is constrained by hydrophobic interactions between its phenyl ring and the axial His328 on Cu-B and a Thr351 residue next to Cu-A in the *Limulus* structure. The phenyl ring of the substrate is almost perpendicular to the Cu-O_2-Cu plane, with close contacts of its hydroxyl group to Cu-A and of its ortho-position to one of the two oxygen atoms of the dioxygen ligand. This suggests bonding to Cu-A, in agreement with earlier concepts assuming direct coordination of the phenolic substrate to one Cu center, preferably Cu-A. Consequently, the vicinity of the ortho-position of the aromatic ring to dioxygen then allows the hydroxylation reaction.

Independent of in vivo or in vitro activation, the opening of the entrance by pulling out the placeholder Phe49 seems to be crucial and is achieved by proteolysis or a conformational transition of the first domain carrying Phe49.

A similar substrate-binding pocket was identified for molluscan hemocyanins, which was not surprising since the active site of mollusc hemocyanins and that of arthropod hemocyanins and catecholoxidases are very similar. Therefore, we proposed the following mechanism for the activation of the molluscan hemocyanin based on the recently solved X-ray structure of a functional unit of the hemocyanin from the molluscan *O. dofleini*.[39] The C-terminal domain covers the entrance to the active site located on the N-terminal site by sticking Leu2830 into the entrance door. Detergents

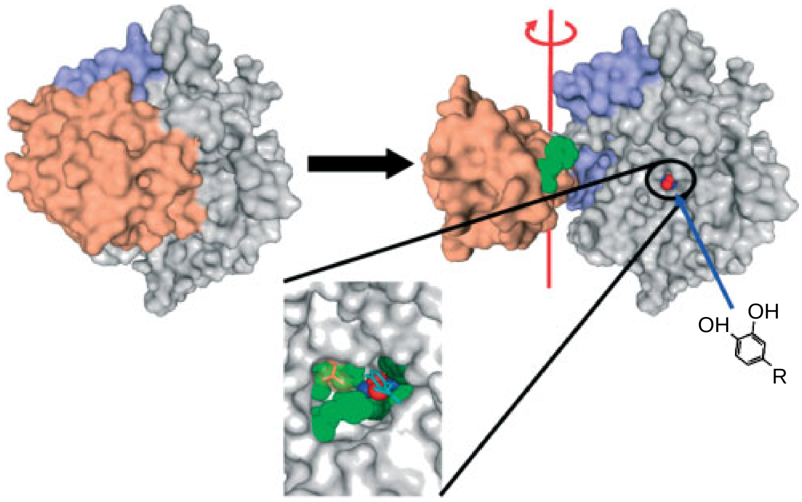

Figure 7 Scheme of the activation of the phenoloxidase activity of hemocyanins. A part of domain I (brown) is turned away together with the conserved Phe49 (green). This opens a view into the active site, which is enlarged. The copper atoms are colored blue, the oxygen red, a hypothetical substrate light blue. The amino acids forming the channel are drawn green[55]

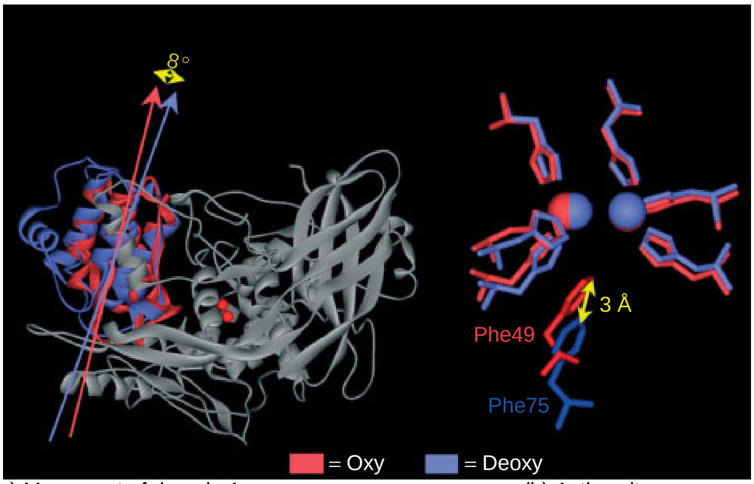

Figure 8 Proposed mechanism of phenoloxidase activity in arthropod hemocyanins based on two X-ray structures of the oxy- and deoxy-forms of the *Limulus* subunit II[55]

might disrupt these interactions to open the entrance to the active site by tilting upward the compact β-rich domain. Thus, Leu2830 will also be pulled out from the substrate-binding pocket opening an access route to the active site. This also can be accomplished by a conformational transition deduced for the two resolved functional unit structures, the one being in the oxy-state (*O. dofleini*) and the other being in the deoxy-state (*R. thomasiana*).[40] In the latter state, an open channel to the active site becomes visible. In addition, the hypothesis of a conformational transition may explain the pH-dependent activation of *O. vulgaris* hemocyanin.

This idea agrees well with a similar hypothesis presented for the solved structure of the catecholoxidase from *I. batatas*[41] after superimposing the C-terminal sequence, which is not structurally resolved, on the known structure of the *Octopus* FU.[26,106,107] Here a leucine residue, Leu439 in *Ipomoea* catecholoxidase, corresponds to Leu2830 in *Octopus* hemocyanin, which blocks the entrance.

Are hemocyanins tyrosinases or catecholoxidases?. All crustacean hemocyanins seem to exhibit only catecholoxidase activity. Only two hemocyanins from chelicerates, the

4 × 6-meric hemocyanins of the tarantula *E. californicum* and scorpion *Pandinus imperator*, seem to hydroxylate tyramine after proper activation.[45] However, further experiments are in progress to reveal the mechanism.

Evolution of two phenoloxidases, an arthropod and molluscan type. A close relationship between phenoloxidase and hemocyanin was deduced based on their similar sequences, physico-chemical properties and similar functions. But sequence comparisons also revealed that there is not a common phenoloxidase type: the enzymes found in animals, plants, and fungi are different with respect to their sequences, size, glycosylation, and activation. Two different types of tyrosinases can be distinguished based on their sequences, structure, and function. One type (*m*-phenoloxidase) is more related to molluscan hemocyanin with respect to the active site. The other type (a-phenoloxidase), which is very similar to arthropod hemocyanins, is found in arthropods together with hemocyanins (Figure 9).[54,55]

Comparison of the arrangements of the domains within an arthropod hemocyanin subunit and the functional unit of a molluscan hemocyanin also suggests two different types of phenoloxidases, the a-phenoloxidase and the *m*-phenoloxidase. Cleavages of the N-terminal domain of a-phenoloxidase and the C-terminal domain of m-phenoloxidase open the entrances to the active sites for bulky substrates. The key amino acids are indicated in Figure 9.

Reaction mechanism of phenoloxidases. Although no structure of any tyrosinase or an oxy-catecholoxidase is available, similar spectroscopic features indicate similar active sites compared with hemocyanins as discussed above and summarized in various reviews and other articles. In addition, several models about the chemistry of the two reactions were presented based on synthetic tyrosinases being published

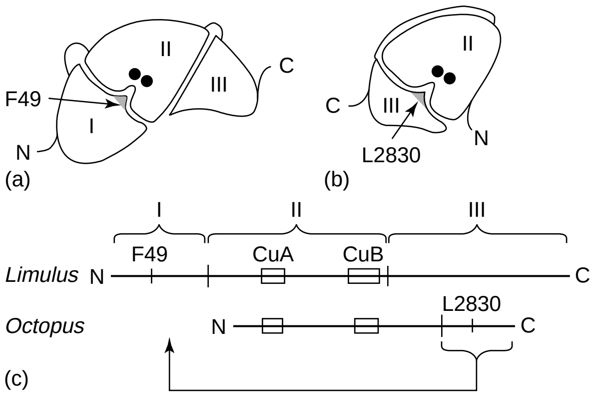

Figure 9 The orientation of the domains from an arthropod and a functional unit from a molluscan hemocyanin are compared. In the first case (a) F49 in the N-terminal domain blocks the entrance to the active site, in the latter one (b) L2830 located in the C-terminal domain[55]

recently. Only a few are mentioned.[61–67,117–121] However, this part is not the focus of this article but will be discussed in other contributions in great detail. Nevertheless, it should be noted that most presented models are based on synthetic copper compounds in order to mimic the catecholoxidase and cresolase activity. However, they do not respect the influence of the protein matrix. No particular electronic interactions between the copper atoms, the dioxygen, and the amino acids are discussed owing to the lack of any structure. Although when steric hindrance is discussed, it should be remembered that the protein structure limits the degree of orientation of the substrates at the active site and therefore limits the proposals on the chemistry of catalysis.[117] Thus, as long as there is no structure available for tyrosinases or for the oxy-catecholoxidase, the chemical description of the catalysis still remains a hypothesis as presented in the previous article of Lerch.[1]

AO = Ascorbate oxidase; (h)Cp = (human) Ceruloplasmin; CT = Charge transfer; Hp = Hephaestin; GPI = Glycosyl-phosphatidylinositol; Lac = Laccase; MCO = Multicopper oxidase; T1(2,3)D = Type 1 depleted (and/or type 2 or type 3); Tf = Transferrin.

1 INTRODUCTION

Here we summarize the structures and functions of the class of copper enzymes known as multicopper oxidases (MCOs). These copper enzymes are characterized by containing three types of copper prosthetic groups. These three types, themselves distinguished by specific electronic and ligand coordination features, are: type 1 Cu(II), often referred to as a 'blue' copper due to its intense absorption at ∼600 nm (*see* ***Copper Proteins with Type 1 Sites***); type 2 Cu(II), whose electronic structure is comparable to that of simple, square-planar Cu(II) complexes (*see* ***Copper Proteins with Type 2 Sites***); and type 3, binuclear Cu(II)–Cu(II), whose diamagnetism and strong absorption at ∼330 nm is due to efficient spin (charge) transfer involving an oxygen atom (or OH) that bridges the Cu(II) pair (*see* ***Copper: Hemocyanin/Tyrosinase Models*** and ***Copper Proteins with Dinuclear Active Sites***). Thus, multicopper oxidases are unique in that they possess each of the three spectrally distinct types of copper sites found in biology.[1–4]

The three copper sites – which represent a total of four one-electron acceptors – place the multicopper oxidases in the small family of enzymes that can couple the oxidation of four equivalents of a one-electron reducing substrate to the four-electron reduction of dioxygen to $2H_2O$. The other members of this family are the heme-containing terminal oxidases (*see* ***Cytochrome Oxidase***), whose exergonic turnover of O_2 is typically linked to an endergonic process, thus transforming the oxidation-reduction free energy released into a more biologically usable form.[5] The multicopper oxidases differ in this respect, playing roles that more closely conform to ones in intermediary metabolism on the one hand, and in metal resistance on the other.

The copper prosthetic groups common to the multicopper oxidases result from another feature shared among the eukaryotic members, that is, their synthesis and processing in the cell's vesicular trafficking pathway. It is in these membrane-continuous compartments that the newly synthesized apoprotein acquires the four copper atoms. Some of these eukaryotic oxidases are synthesized fully within the lumen of these compartments (they are not membrane-bound) and so are secreted from the cell as soluble proteins, whereas other members have an encoded transmembrane domain and thus, as mature proteins, associate with either the plasma membrane or, in fungi, with the vacuolar membrane as well. In partial contrast, all of the known prokaryotic oxidases are soluble, secreted proteins, taking up residence in the bacterial periplasmic space, the compartment between the inner and outer membranes that characterize this organismal superkingdom. 'Where' in the bacterial cell the apoprotein obtains its prosthetic group copper atoms is not known. Teleologically, the ultimate cellular locale of any of the multicopper oxidases is integral to the physiologic function of each.

In fact, multicopper oxidases do appear to fall into two functional classes. That is, although all multicopper oxidases use aromatic phenols and amines as reducing substrate (e.g. dimethoxyphenol, hydroquinone, phenylenediamine), a few exhibit an equally robust activity towards Fe^{2+}, and, in an increasing number of cases, towards Cu^{1+} and/or Mn^{2+}, as well. This latter select group is therefore known more precisely as ferroxidases, or, even more broadly, as metallo-oxidases. These include ceruloplasmin (Cp), Fet3p, and CueO, but, as summarized in the next section, it is likely that several other ferroxidases (metallo-oxidases) exist in both pro- and eukaryotic genomes. What is also becoming clear is that these enzymes, particularly those with metallo-oxidase activity, are linked to severe and eventually lethal disorders of metal metabolism. Thus, aside from providing us with a 'primer' on the properties of the 'types' of copper found in biology, these proteins also offer insights into fundamental aspects of the biology of at least three of the nutritionally essential, but potentially cytotoxic, first-row transition metals (*see* ***Metal-related Diseases of Genetic Origin***). The reader is encouraged to review the first edition of the Encyclopedia for references to the earlier literature on the members of the multicopper oxidase family.[6] The review of much of that literature will not be duplicated here.

2 STRUCTURAL GENOMICS

2.1 Structural Signatures: Sequence and Copper-site Properties

MCOs possess a fairly easily recognizable sequence motif pattern that includes four elements that together comprise the copper-binding sites in the protein. The first two such elements are HXH motifs located within the first one-quarter of the protein sequence, typically separated by ca. 50 residues. Some examples are shown in Figure 1(a). There is a pattern within these two motifs, also, namely, the ‘X’ in the first is most commonly a bulky nonpolar residue (V, W, or F) while the ‘X’ in the second is a residue generally found in turns, for example, P, G, or S. The third motif is an HXYHZH sequence that is found in the carboxyl-terminal quarter of the protein. Again, within this motif there is a clear pattern in which X is a residue found in a bend, most commonly P (occasionally T); and Y and Z are bulky nonpolar residues, for example, L, I, and F. Although not part of the coordination spheres of any of the four copper atoms in the MCO, the four residues carboxyl-terminal to this third motif are also strongly conserved with GHXF seen in ca. 80% of ORFs that likely encode MCO proteins.

The last motif, HCHXYZH, resides 60–90 residues carboxyl-terminal to the third one and, except in the case of those MCOs that are type 1 membrane proteins (with a carboxyl-terminal transmembrane domain), is found within 30–50 residues of the C-terminus. Although there is no pattern to the ‘XYZ’ in this motif, two features are conserved to either side of it. First, the three residues immediately amino-terminal to the HCH element are typically nonpolar with W as a highly conserved $n-3$ residue. Second, the residue in the $n+5$ position relative to the carboxyl-terminal H is either M or L/F in >90% of MCO sequences. The significance of this second conserved feature is that the sulfide –S– of an M at this position occupies a fourth coordination site in the distorted tetrahedral ligand field (alternatively described as trigonal pyramidal) of the type 1 Cu(II) in those proteins with that sequence. In some cases, the limited S $\rightarrow$ Cu CT from this thioether group appears to modulate the redox potential of the coordinated Cu(II).[3,4,7–10]

The four motifs described fold into a canonical MCO ligation scheme for each protein’s four copper atoms. In Figure 1, this fold is illustrated in two ways. The first, Figure 1(a), illustrates the characteristic fold via alignments of four members of the protein family; these alignments are presented in terms of the four sequence motifs summarized above. The sequence spacing of the ligands in each motif is highlighted in this presentation. For example, note that the type 2, type 3 trinuclear cluster is assembled from four sets of HXH elements, one from each of the four conserved motifs. Also, note that the type 2, type 3 coordination spheres are assembled via what appears to be a nucleotide sequence duplication. So, as illustrated for hCp in Figure 1(b), the first three H residues (from motifs 1 and 2) provide one ‘side’ of the trinuclear cluster while the last two H residues of motif 3 and the first of motif 4 assemble to constitute the other ‘side’. The binuclear, type 3 and ‘blue’ type 1 Cu(II) sites share a similar clustering of ligands within the sequence via the HCH triad that is the most representative of the multicopper oxidase sequence homologies. As discussed below, the backbone within this HCH motif that links the type 1 cysteine residue to these two histidine ligands – one each at each of the two type 3 Cu(II) sites – is likely to provide the route of the intramolecular electron transfer from the T1 Cu to the T3 binuclear cluster during substrate turnover. That is, in all MCOs, the intermolecular electron transfer from reducing substate to enzyme occurs at the type 1 Cu(II) while the electron transfers to dioxygen occur at the trinuclear cluster. The H $\leftarrow$ C $\rightarrow$ H provides the extension cords that couple these two redox processes.[1,2,4]

As noted in the next section, MCOs are encoded in the genomes of organisms in all three superkingdoms – Archaea, Bacteria, and Eukarya. This identification is based on the presence of the four motifs summarized above. However, there are striking differences among this collection of nearly 600 proteins. For example, their size varies from ~400 to over 1800 residues. As implied, some are soluble proteins, while others are type 1 membrane proteins with carboxyl-terminal ‘extensions’ that tether the MCO domain to the luminal face of a cell compartment or to the extracellular surface of the plasma membrane. Less obvious in the primary sequence are those protein folds that confer the specificity that some MCOs have for bulky aromatic phenols and amines and other MCOs have for low-valent first-row transition metals like Mn^{2+}, Fe^{2+}, and Cu^{1+}. Lastly, there are a few MCOs in which the order of the four motifs in the primary sequence are ‘inverted’ so that the HXYHZH and HCHXYZH motifs are encoded to the amino-terminal side of the two HXH ones. One of these bacterial proteins, the mnxG protein from *Bacillus* sp. strain SG-1, is a manganous oxidase;[11,12] an MCO from *Nitrosomonas europaea* (a chemolithoautotroph that can obtain all of its energy from the oxidation of ammonia to nitrite) is proposed to have the same metallo-oxidase specificity[13] as is the CumA protein from *Pseudomonas putida*.[14,15] These and other prokaryotic MCOs will be reviewed in Section 5.

Multicopper oxidases owe their characteristic and striking ‘sky blue’ color (captured in ‘ceruloplasmin’, from the Latin *caeruleus*, or deep blue (azure) sky) to the type 1 Cu(II) that all possess. The ligand field at type 1 Cu(II) can be qualitatively described as distorted tetrahedral or better, perhaps, as trigonal (bi)pyramidal even if the coordination sphere lacks ligands at one or both of the apical positions.[1,3,10,16] Type 1 Cu(II) that have an apical ligand (the Sδ of Met), as in plastocyanin (a simple blue copper electron-transfer protein, *see* ***Copper Proteins with Type 1 Sites***) conform more closely to tetrahedral geometry. ‘Loss’ of this apical ligand, as in *Trametes versicolor* Lac, for example, results in the Cu moving down into the ‘equatorial’ ligand plane, resulting

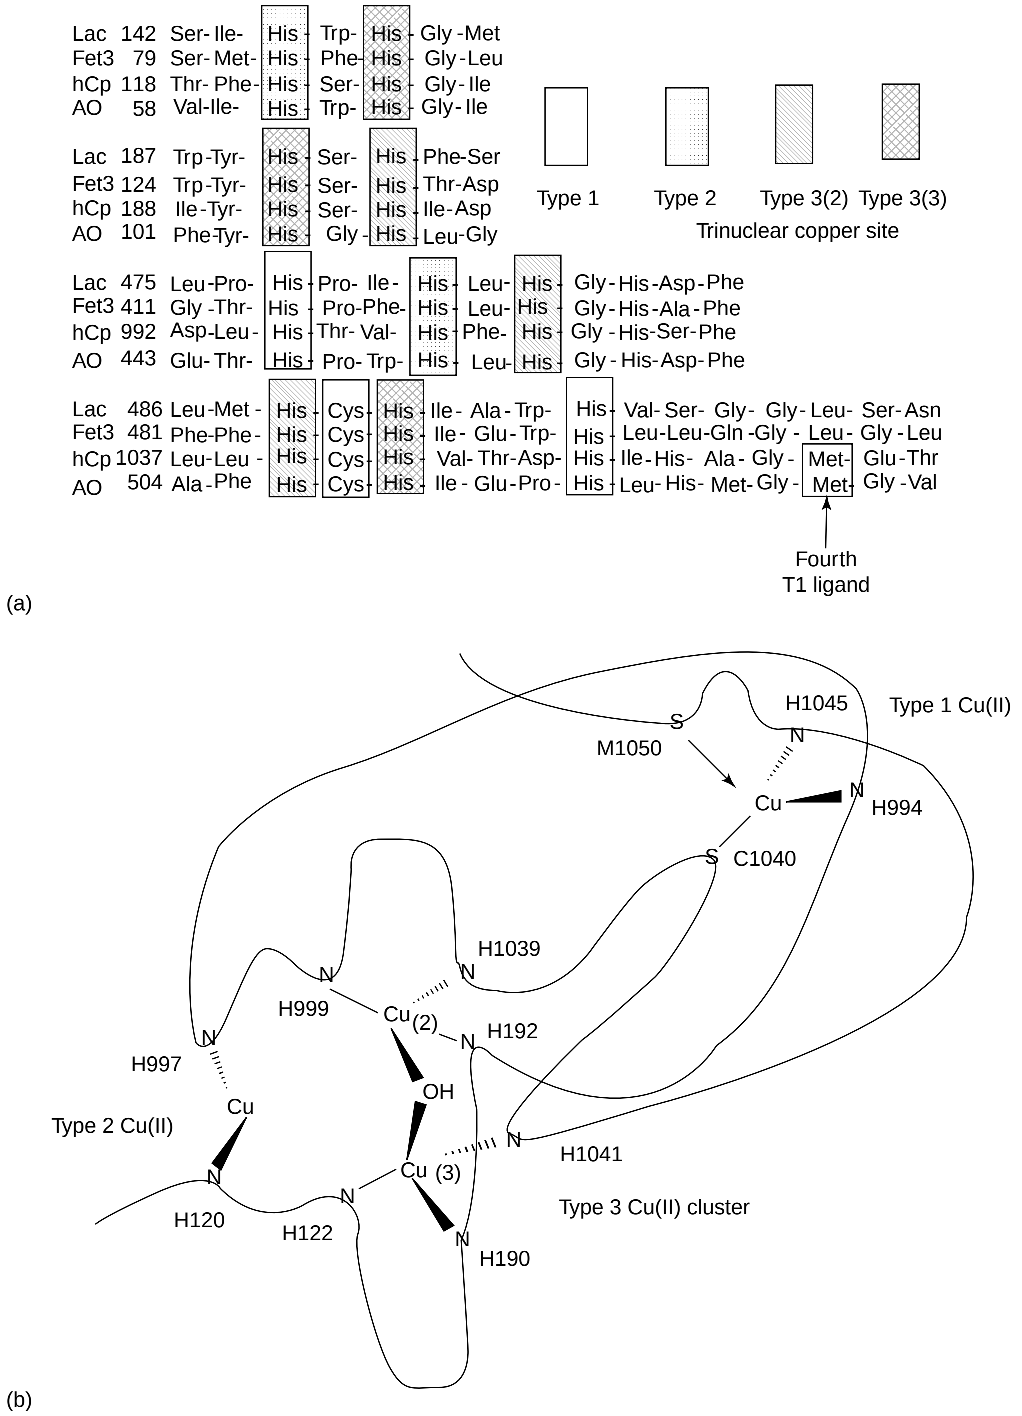

Figure 1 (a) The four signature Cu-binding sequence elements are aligned for four MCOs. The copper site associated with each ligand is indicated. (b) A strand diagram shows the connectivity of the copper-binding elements in hCp

in a geometry that more closely conforms to slightly distorted trigonal planar. These geometries are illustrated in Figure 2 (adapted from Reference 17).

These two geometries as in Pc and Lac correspond to the state energies illustrated in Figure 3.[17] The qualitative difference between the two ligand fields is the presence of the bonding orbital localized on the Sδ of the apical Met in the case of Pc. The most significant quantitative difference between the two geometries, a difference that corresponds to the removal of this ligand and the 'relaxation' to the trigonal planar geometry in *T. versicolor* Lac, is the decrease in the energy of the d_{z^2} orbital on this Cu atom. The highest energy

orbital in either case is the $d_{x^2-y^2}$ one (thus defining the ground state) whose lobes usually lie along the bonds to ligands in the xy plane. However, the two spectral and, therefore, electronic features that characterize a type 1 Cu(II) site indicate that the $d_{x^2-y^2}$ orbital is rotated in this plane such that the Cu–Sγ (Cys) bond lies between and not aligned with the $d_{x^2-y^2}$ electron density (Figure 3). The first of these spectroscopic features is the intense $S_{cys}\pi \rightarrow$ Cu $d_{x^2-y^2}$ charge-transfer band observed at ~600 nm.[3,4,10,17] The strength of this charge transfer can only be accounted for by significant overlap between the S_{cys} p-π orbital and the lobes of the Cu $d_{x^2-y^2}$ one. These lobes would have diminishing probability at the S_{cys} p-π orbital if they were oriented along and orthogonal to the Cu–S bond. Second, the π-type S_{cys}, Cu $d_{x^2-y^2}$ interaction leads to covalency in the Cu–S bond, and thus to significant transfer of unpaired spin density to the S. The result is a reduction in electron spin-orbit coupling (with the electron delocalized to the less anisotropic S-centered orbitals) and thus in the deviation of the electron's g value from that of a 'free' electron. In addition, the net unpaired spin at the Cu is reduced so as to decrease the Cu nuclear hyperfine coupling as well. Thus, type 1 Cu(II) in proteins exhibits smaller g and A values; the latter are most commonly in the range of $80-90 \times 10^{-4}\,cm^{-1}$ (Table 1).[1,3,10]

Spectrally, the type 2 Cu(II) in multicopper oxidases is typical of this class of protein copper sites in that it exhibits the very weak absorbance in the far visible due to forbidden d–d transitions (~$100\,M^{-1}\,cm^{-1}$) and the spin Hamiltonian parameters of normal, tetragonally distorted square-planar Cu(II). The relatively larger g and A values show the unpaired electron strongly localized on the copper atom. In particular, $A_{||}$ for type 2 Cu(II) is in the range of $160-200 \times 10^{-4}\,cm^{-1}$.[1,3] The larger hyperfine coupling means that the type 2 Cu(II) alone contributes to the low field region of the EPR spectrum (g value equivalent >2.3) with its $m_s = -3/2$ transition typically centered at ~2750 G (at

9.5 GHz). The spectral similarity between the type 2 Cu(II) in MCOs and in other mononuclear type 2 Cu(II) proteins is somewhat surprising since the coordination in the former is different than in the latter. While type 2 Cu(II) is most commonly characterized by a four-coordinate, tetragonally distorted square-planar ligand field (with, in some cases, some rhombic distortion also), the MCO type 1 Cu(II) is coordinated by two protein His residues and a solvent H_2O only.[1,3] The ligand field associated with this coordination is not directly obvious; that is, among other uncertainties, whether the H_2O is an equatorial or an axial ligand has not been established. In AO, the Cu–O distance is 2.02–2.03 Å,[18,19] whereas in *T. versicolor* Lac it is 2.3–2.9 Å.[20,21] The shorter distance is consistent with equatorial ligation, while the longer distances are what one might expect for an apical ligand. In both structures, the His–Cu–His bond angles are very close to 180°, however, suggesting that they could be trans ligands in a square planer ligand field.[18–21] This appears to be the case and will be considered again below.

The type 3 binuclear Cu(II) pair in an MCO is characteristic of this type of copper site in biology. First, both copper atoms are ligated by three protein side chains each; all six are His residues. Five of the imidazoles coordinate the Cu(II) atoms via the Nε2 nitrogens while the sixth His does so via Nδ1. This coordination pattern is a conserved feature of the MCO structure.[18,20–24] Second, the two Cu(II) are bridged by an oxygen atom, probably as OH^-. This bridge is the distinguishing feature of type 3 Cu(II) generally because it provides a superexchange pathway that couples the unpaired electron density on the two cupric ions rendering the type 3 site diamagnetic.[1] Another spectral signature of this coupling is a strong O → Cu CT transition at ca. 330 nm ($\varepsilon = 3{-}5000\,M^{-1}\,cm^{-1}$). The binuclear cluster exhibits a relatively strong d–d transition at ca. 750 nm as well.[1,25]

Functionally, the most significant feature of MCOs is the spatial relationship of the type 2 and type 3 copper atoms: atom-to-atom distance, they form a near isosceles triangle of ∼3.5–4.5 Å on a side.[18,20–24] Together with the relatively 'under-ligated' nature of all three copper atoms, particularly the type 2 copper, this feature provides for the docking and ligation of dioxygen to the trinuclear copper cluster, most probably bridging the type 2 and one of the type 3 copper atoms during O_2 turnover (reviewed in Reference 2). The cluster structure is illustrated in the polypeptide strand topology rendering shown in Figure 1(b).

2.2 MCO Species Distribution and Differences

The sequences listed in Figure 4 provide a fair representation of MCO homologues that are archived at www.sanger.ac.uk/Software/Pfam (keyword, 'multicopper

Figure 4 Four Cu-binding motifs in representative MCOs from Eukarya (a) and Bacteria (b)

oxidase'), the 'Pfam' web site.[26] This database of protein family alignments catalogues 534 putative MCOs; excluding a number of entries, such as blood coagulation factor VIII, that are not, in fact, MCOs, leaves >400 family members. Of these, most are distributed between eukaryotes (55%) and bacteria (40%), with the few remaining found among archea (one representative) or unclassified organisms. The single largest group identifiable in this sequence database are the laccases; among metazoa, however, the largest group includes ceruloplasmin-like proteins. In addition, MCOs are found in many eukarya that contain encoded transmembrane domains making them likely integral membrane proteins. Otherwise, as a family, MCOs are 'soluble' proteins.

As discussed in more detail below, all relevant differences among MCOs are not readily discerned from sequence database information alone. One such difference that can be deduced from sequence is the presence of a transmembrane domain, for example, thus distinguishing ceruloplasmin from hephaestin in mammalian genomes. MCO size also correlates with a recognizable difference in MCO tertiary structure; as noted below, most MCOs are proteins of ca. 600 residues with three-domain repeats, while a few – like Cp and Hp – are proteins of ca. 1200 residues with six domain repeats. However, a Blast search using a 'laccase' as the query sequence generates a list of subject sequences comparable to one generated by using AO as query, or using a fungal ferroxidase like Fet3p (although the 'Expect' values do differ to some extent). Species origin most commonly defines function: a secreted MCO in a fungus or a woody plant is presumed to be a laccase, one in a leafy plant an AO. At this point, there are not enough structural, that is, crystallographic data to provide the prediction algorithm(s) correlating MCO sequence to MCO structure and function. For example, an aromatic phenol/amine binding surface in an MCO could be predicted given sufficient structural data on a number of known laccase proteins. Such differences are known among the MCOs, but we now have only one or a few examples of three eukaryotic MCO types: one AO, one ferroxidase, and three laccases.

2.3 Bioinorganic Chemistry – MCO Models

Of specific relevance to MCOs are biomimetics that attempt to reproduce the intramolecular electron transfer between a type 1 site and a bi- or trinuclear copper cluster, or model the trinuclear cluster itself. Three recent reports exemplify these attempts. Lever and his coworkers synthesized the tetracopper assembly shown in Figure 5(a) and demonstrated that it was reduced stepwise by $3e^-$: {Cu(II)–Cu_2(II,II)–Cu(II)} → {Cu(I)–Cu_2(II,II)–Cu(II)} → {Cu(I)–Cu_2(II,II)–Cu(I)}/{Cu(I)–Cu_2(I,II)–Cu(II)} → {Cu(I)–Cu_2(I,II)–Cu(I)}.[27] Figure 5(b) illustrates the polarogram for this reduction. EPR spectra were consistent with the reduction scheme proposed and indicated that the last of these $1e^-$ electron transfers was associated with the reduction potential of −0.42 V. In summary, this complex

did appear to mimic the intramolecular electron transfer from a mono- to a binuclear copper-site characteristic of the MCOs.

Tolman and Lee constructed a type 1-like site linked to a type 2-like site and investigated the potential for intramolecular electron transfer between the two.[28] Their coordination scheme is illustrated in Figure 6(a); the structure of their complex in shown in Figure 6(b). Cyclic voltammetry showed the two Cu(II) atoms to undergo quasi-reversible, independent reduction with $E_{1/2}$ values consistent with the two copper atoms' coordination: −0.911 V for the CuSR site, −0.112 V for the CuPyr one. These studies did not address the question of intramolecular electron transfer between the two sites, however.

Chakravarty and his coworkers prepared a pseudo-trinuclear cluster mimic, pseudo because all three Cu are O-bridged (Figure 7);[29] in the trinuclear cluster found in an MCO, only the type 3 Cu(II) are oxygen-bridged (*cf* Figure 1(b)). Magnetic susceptibility measurements confirmed that all three Cu(II) in this model are exchange-coupled, albeit with a set of two J values (for example, for complex **1**, the values were −82.7 and $-73\,cm^{-1}$). The synthetic methodology employed offers some promise for fine-tuning the structural features of such complexes to provide more relevant biomimetics of the MCO bi- or trinuclear cluster. The challenge in exploiting bioinorganic approaches in MCO research will be to define precise questions about MCO

chemistry that can be productively if not uniquely examined by study of small molecule biomimetics.

3 OXIDASES: LACCASES AND ASCORBATE OXIDASE

3.1 Laccases

Three of the five crystal structures of eukaryotic MCOs archived in the PDB are of laccases: from *Coprinus cinereus* (1A65[30] and 1HFU[31]); from *Melanocarpus albomyces* (1GWO);[32] and from *T. versicolor* (1GYC[21] and 1KYA[20]). The structure of *Cc* Lac is of a type 2-depleted form (T2D, hereafter) which not only lacks the information about the ligation of this copper atom but, because of the absence of this prosthetic group, the ligation at the type 3 site is also changed. In addition to this structural information, Lac has been the most intensively studied of the MCOs, particularly by spectral techniques that can elucidate both the physical and electronic structure of copper sites in proteins: EXAFS, EPR, and MCD, in particular.

3.1.1 Structure

Of the three Lac structures, two contain the full complement of four copper atoms. Although the third – of *C. cinereus* – lacks the type 2 Cu(II), it is overall similar to the other two, and all provide a view of the canonical tripartite cupredoxin (or plastocyanin) fold that characterizes the MCOs that contain ~500–600 amino acid residues. This fold is found in all of the small blue copper electron transport proteins (*see* ***Copper Proteins with Type 1 Sites***) and is described as a member of the 'Greek-key' connectivity pattern family found in biology.[33] Greek keys are β-barrel tertiary folds, a fold which, in the case of the cupredoxin domain, consists of 8 strands and that, unlike many other Greek-key folds that are composed of exclusively antiparallel sheet, include two that form parallel H-bonds with their neighboring strands. The cupredoxin fold, typically containing 125–150 residues, is diagrammed in Figure 8(a). As noted above, the simplest MCOs are assembled from three cupredoxin domains. Thus, the MCO fold clearly arises from a gene 'triplication' in which the three folding elements, domains

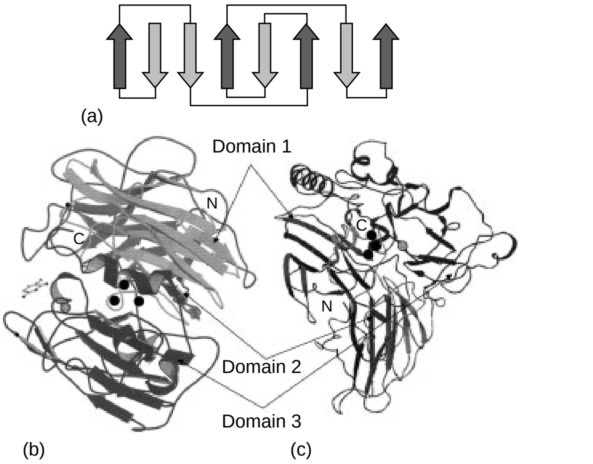

Figure 8 The connectivity of the cupredoxin fold in shown in (a); the ribbon diagrams of *Tv*[20] and *Ma*[32] Lac are shown in (b) and (c), respectively. (Reproduced by permission of Nature (Y-hotlink www.nature.com))

1, 2, and 3 (or a, b, and c) conform to the first, second and third one-third of the protein sequence. Thus, the MCOs are modular proteins as is illustrated by the ribbon diagrams for *T. versicolor* and *M. albomyces* laccases shown in Figure 8(b)[20] and (c),[32] respectively. As an indication of the conservation of the MCO fold is that the striking structural similarity between these two laccases evident in the two ribbon diagrams obtains despite the fact that as products of different fungal divisions – *Basidiomycota* and *Ascomycota*, respectively – the two laccases share less than 30% sequence identity.

The type 1 Cu in the three laccases crystallized (and in AO and hCp, also) is located in the third cupredoxin domain; as discussed above, all of the ligands to the type 1 copper are found in the carboxyl-terminal region of the MCO sequence, the region that folds into domain 3. The trinuclear cluster is composed of ligands from both the first and third regions of the primary sequence (*cf* Figure 1) and is therefore found at the interface between domains 1 and 3 in the structure (Figure 8(b) and 8(c)). This general fold in relation to the coordination fields of the three copper sites is common to all MCOs characterized structurally; sequence homology and other biophysical studies suggest strongly that it represents the 'MCO' fold in general, although there are some intriguing exceptions. Another relatively rare difference found is additional gene duplication giving rise to 6 rather than 3 cupredoxin domains as in hCp.[34] The Cp family members have >1100 residues; size appears to be a legitimate predictor of whether an encoded MCO homolog is composed of 3 or 6 cupredoxin domains as discussed below.

3.1.2 Type 1 Copper-site Coordination and Properties

In MCOs, the type 1 Cu inner coordination sphere can come with or without a Met whose thioether sulfur atom occupies the apical coordination site at this copper (below); archived Lac sequences divide roughly 50:50 in this respect. If the Met is absent, the coordination of the type 1 copper is trigonal planar in geometry as illustrated for *T. versicolor* Lac in Figure 9(a);[20] the spectral properties of *T. versicolor* Lac were summarized in Table 1. The ligand, 2,5-xylidine (a substrate analogue), is present in the structure (Figure 9(a)). The structure suggests that amino group H-bonding to the protein contributes to ligand binding and indicates that a typical aryl phenol substrate would bind similarly via the D206 carboxylate and the H458 Nε2 hydrogen. The latter interaction would provide the initial electron matrix coupling element in the intermolecular electron transfer from reducing substrate to the type 1 Cu(II). Electron transfer in MCO reactivity is discussed more fully below.

The relative specificity that laccases have for bulky aromatic (poly) phenols and amines is due not only to the H-bond Network. The type 1 site associated with these H-bonds lies at the base of a shallow cavity that is lined with nonpolar side chains, or the nonpolar aliphatic carbon skeleton of a polar one, for example, Q and K. The binding cavities of two laccases (superimposed) are shown in Figure 9(b).[20] As discussed below, those MCOs that exhibit a strong specificity for Fe^{2+} as substrate – the ferroxidases – have a substrate binding site that differs in two respects from the laccase one: the ferroxidase site is spatially more constrained and it

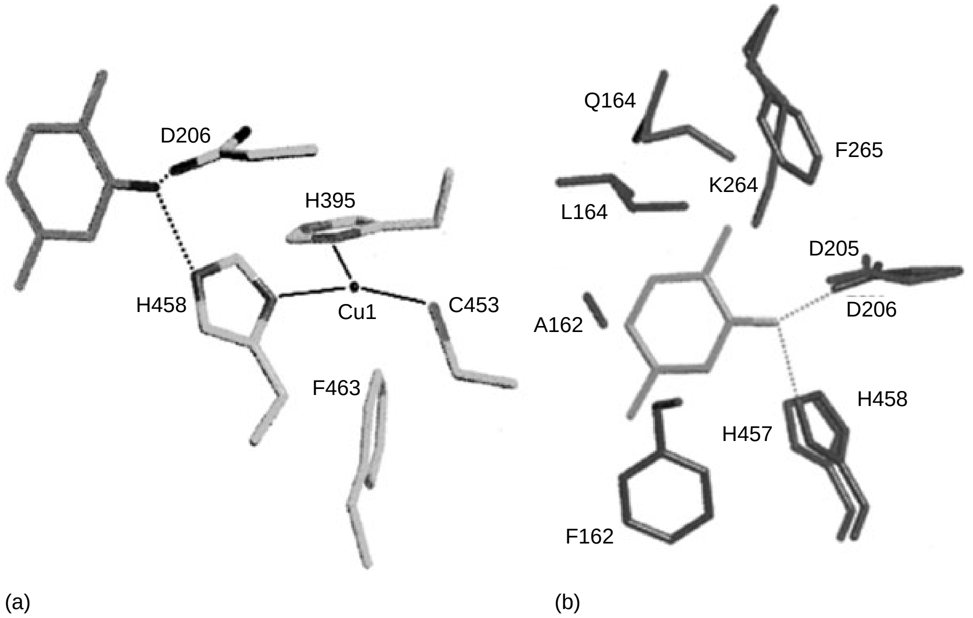

Figure 9 The T1 Cu site in *Tv* lac with H-bonding to substrate analog, 2,5-xylindine (a); the overall substrate binding cavity is illustrated in (b) for *Tv*[20] and *Ma*[32] laccases. (Reprinted with permission from Ref. 20. © 2002 American Chemical Society)

displays an overall net negative electrostatic surface rather than a nonpolar one (see below).

The redox potential of the type 1 Cu(II) in MCOs has been a subject of much examination since $E^{\circ}_{\mathrm{type1}}$ provides the driving force for oxidation of a given reducing substrate. Also, despite the fact that all type 1 sites possess a 2 His, 1 Cys ligand field, and exhibit essentially the same (quantitatively) 600 nm $S_{cys}\pi \rightarrow$ Cu $d_{x^2-y^2}$ charge-transfer band, the reduction potentials for these sites vary from 0.34 V in *Cp* ascorbate oxidase to 0.79 V in *Tv* laccase (Table 1). In comparison to the reduction potentials of type 1 sites in simple mononuclear blue copper proteins, the T1 sites in MCOs, except T1 Cu in ascorbate oxidase, are significantly higher. A major contributor to setting the reduction potential of this Cu(II) is likely to be the fourth, axial ligand. As implied above, the presence (or absence) of this ligand can be deduced from the sequence in that it is encoded five residues carboxyl-terminal to the HCHxxxH sequence that essentially defines these oxidases (*cf* Figures 1 and 4). This Met is present in many if not most of the metazoan MCOs that are likely to be ferroxidases (e.g. Cp and Hp in mammals, MCOs encoded in the *Drosophila* genome) but in none of the known or likely fungal ferroxidases. Most if not all of the bacterial MCO genes encode this Met. There is no correlation between substrate specificity (physiologic function?) and the presence of this methionine ligand.

Solomon and his coworkers have examined the relationships between type 1 site ligation, electronic structure, and reduction potential in some detail, making use of site-directed mutagenesis to test the role of the Sδ of Met as an axial ligand directly.[8,9,17] Indeed, the electronic structure of the type 1 Cu(II) in the F463M mutant of *Polyporous pinsitus* laccase (F463 in this laccase is equivalent to F463 illustrated in the structure of *T. versicolor* laccase in Figure 6) was intermediate between that of the parental wild-type laccase and plastocyanin. This relationship is evident in the absorbance and MCD envelopes centered at 15 000 cm^{-1} (600 nm) due the $S_{cys}\pi \rightarrow$ Cu $d_{x^2-y^2}$ charge transfer (Figure 10).[17] The former has been deconvoluted into seven bands that were assigned to the transitions associated with the ligand field diagram shown in Figure 3.

The relative intensities in absorbance versus MCD of bands 4 and 6 are the most informative about how axial ligation changes the electronic structure of the type 1 Cu(II). MCD depends on the magnitude of spin-orbit coupling, therefore, transitions centered on Cu(II) (greater coupling) will have greater MCD intensity. In contrast, absorbance correlates with charge transfer from ligand to metal; as noted above with respect to type 1 Cu(II) *g* values, the shift of spin density from Cu to S reduces spin-orbit coupling, and, therefore the intensity of an associated MCD transition. The 'conversion' of the laccase type 1 Cu(II) into a more plastocyanin-like one in the F463M mutant is strikingly evident in the MCD spectrum. The spectra were used to calculate the oscillator strengths of the various bands that were summed to give a total oscillator strength for the three proteins. The values ranged from 0.1046 to 0.1096 for wild-type fungal laccases, but was 0.1032 for the F463M mutant and for Pc was 0.0824. Since oscillator strength of a ligand-to-metal charge-transfer transition is directly proportional to the strength of the metal-ligand bond, the relative values indicate that axial ligation of the Met Sδ lowers the covalency of the Cu–S_{cys} bond. However, covalency alone does not determine the overall bonding and electronic structure of the MCO type 1 site since

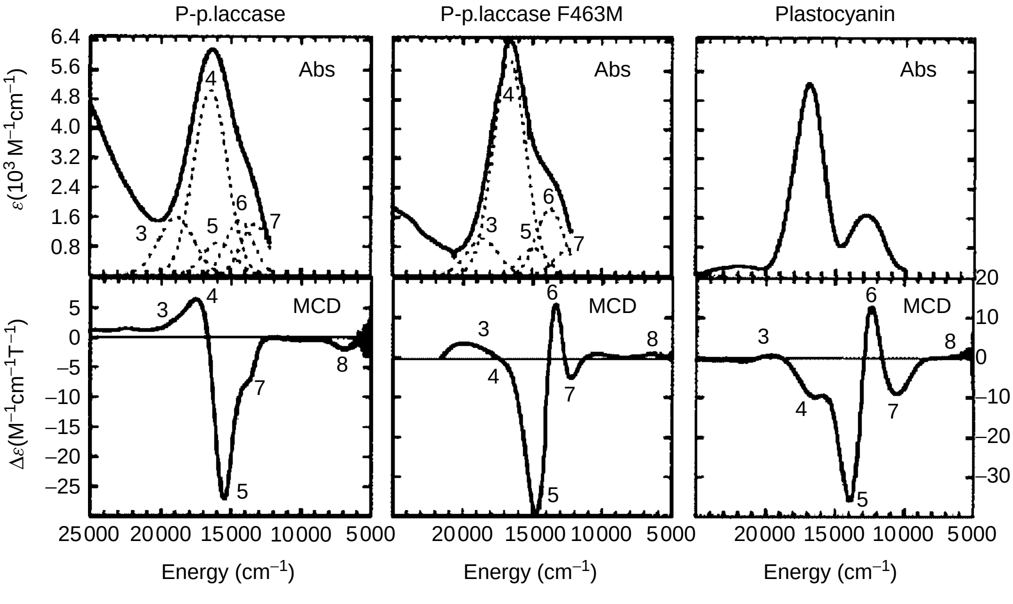

Figure 10 Absorbance and MCD spectra of three T1 Cu(II) sites with deconvolution of the absorbance spectrum into the individual transitions as indicated. (Reprinted with permission from Ref. 17. © 1999 American Chemical Society)

the type 1 Cu(II) in the F463M mutant is *not* equivalent to that in Pc. This conclusion is illustrated further by the fact that while the F463M substitution reduced the type 1 Cu(II) reduction potential from 780 to 680 mV, the E° value for the mutant remained 300 mV higher than that in Pc. Clearly, there are other factors that together, quantitatively, contribute more to the 'tuning' of type 1 Cu E° than does the absence or presence of axial ligation by Met. These additional factors have not been delineated. Note that there is a relative lack of spectral and structural information about laccases that likely have Met, thioether coordination at their type 1 sites, for example, *Rhus vernicifera* laccase, whose kinetic properties have been much studied (below).

3.1.3 Dioxygen Turnover at the Trinuclear Cluster

The mechanism of dioxygen reduction at the trinuclear cluster in MCO catalysis has been a strong focus for research on this class of copper oxidases.[1,2] Dioxygen reduction has been most thoroughly investigated in *Rhus* laccase (a plant laccase, from the Japanese lacquer tree).[35–38] The primary reason for using *Rhus* Lac is the availability of a metal-substituted form the enzyme, a T1Hg form, in which the type 1 Cu has been replaced by a redox-inert Hg^{2+} ion. T1Hg enzyme is inactive in turnover, but the fully, three-electron reduced form does react with O_2 forming a reduced oxygen, peroxy intermediate, whose properties have been well-characterized. The properties of the adduct that forms upon the binding of H_2O_2 to the fully oxidized T1Hg protein have also been thoroughly examined. In addition, the true 'native' intermediate that forms when fully reduced native laccase is mixed with O_2 has been studied by spectral and kinetic means. As a result of these several investigations, a molecular mechanism has been proposed for the reduction of O_2 to H_2O by MCOs. This mechanism is illustrated in Figure 11.[2,17]

The salient features of the proposed mechanism are as follows. First, the 'resting' fully oxidized enzyme does not appear to be a kinetically competent enzyme form during turnover since its formation from the native intermediate ($0.034\,s^{-1}$) is at most 1/30th the turnover number for laccase with a typical substrate (e.g. phenylenediamine). A 'ball-park' value for k_{cat} – $100\,s^{-1}$ – is given in Figure 11 for illustration. In any event, under pseudo-first-order conditions (e.g. mM [**S**] or more) the steady-state level of E_{ox} would be diminishingly small given the relative rates of formation and reduction of

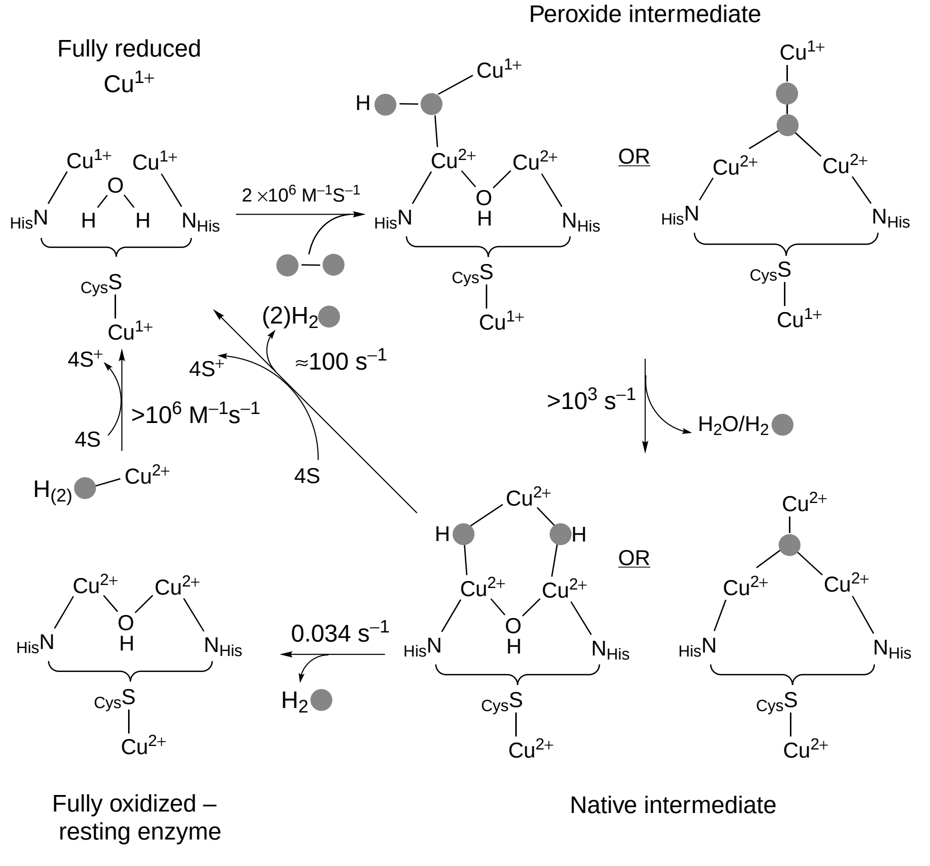

Figure 11 Reaction scheme for MCO dioxygen turnover based on spectral and kinetic data for *Rv* lac. (Reprinted with permission from Ref. 17. © 1999 American Chemical Society)

the 'resting' fully oxidized protein. Instead, the rate-limiting step in turnover is the four-electron reduction of the native intermediate. Since, as noted, the reduction per se does not represent a significant fraction of the energy barrier to this reductive turnover process, this step must involve ligand reorganization/displacement and/or proton transfers. These presumably would be associated with the protonation of the O^{2-} species tethered to the trinuclear cluster (Figure 11) and the release of H_2O. Indeed, the pH dependence of turnover and of the rate of decay of the peroxide intermediate reveal a dependence on the conjugate acid form of a group with pK_a values of 5.9 (turnover),[39] and 5.8 (intermediate decay).[37] On the other hand, whereas a kinetic solvent isotope effect (KSIE) of 2.12 was measured in turnover,[39] the KSIE for intermediate decay was 0.89.[37] A KSIE less than 1.0 represents an inverse effect and can indicate that the proton (deuteron) involved is bound more tightly in the transition state in comparison to the reactant state. Thus, although both turnover and intermediate decay exhibit the same pH dependence, the different KSIE values could indicate that the proton transfers involved in the two reactions are not precisely the same, that is, that two different free-energy surfaces are involved.

The two models for both the peroxide and native intermediates shown in Figure 11 are based on a variety of spectral evidence the most compelling of which is provided by the power-saturation behavior of the native intermediate's EPR spectrum and its EXAFS. Figure 12 compares the X-band EPR spectra of the native intermediate at 77 K (A) with that of the resting oxidized protein (B).[38] The spectra show that in the intermediate, the type 1 copper is fully oxidized, but the type 2 copper is effectively diamagnetic, either reduced or spin-coupled. The saturation behavior of this spin system at 10 °K (C and D) reveals the presence of a broad, rhombic signal centered around 4000 G, a feature apparent only as the axial T1 Cu(II) transition saturates. The saturation behavior of the rhombic signal yielded a value of $P_{1/2} > 25$ mW, nearly 100-fold greater than for the T1 Cu(II). In a magnetically isolated protein matrix, the dominant electron spin relaxation mechanism is likely to be coupling with a low-lying excited state in the spin manifold such that $\ln P_{1/2} \propto -\Delta/k_B \cdot T$, where Δ is the energy gap between the ground and the excited state in cm^{-1}. Evaluating the relaxation as a function of temperature yields Δ; based on this Orbach analysis,[40] the native intermediate has a low-lying excited state at $\sim 140\ cm^{-1}$.[38]

The origin of the excited state was inferred from EXAFS analysis that provided a structural model for the Cu atoms in the intermediate. The 'result' of any EXAFS experiment is a best-fit based on evaluation of several possible models; Figure 13 gives the best-fit.[38] The primary difference in the underlying model and all others tested was the inclusion of 1 to 1.5 Cu–Cu interactions at 3.3 Å. This corresponds to two or three bridging interactions in the trinuclear cluster, with the former possibility yielding a more favorable σ^2 value. However, the EPR data, which show that the trinuclear cluster is 'spin-frustrated', requires that the three Cu(II) must be spin-exchange coupled via a set of equivalent bridges, that is, as in the two models illustrated in Figure 11. In the first, both oxygen atoms remain as bridges (shown between the two type 3 Cu atoms and the type 2 one); in the second, one of the oxygen atoms has debound (as H_2O) with the second remaining as a single μ_3-oxo bridge. Note that decay of the peroxide to the native intermediate exhibits an oxygen isotope effect, $k(^{16}O_2)/k(^{18}O_2) = 1.11$,[37] a value that strongly

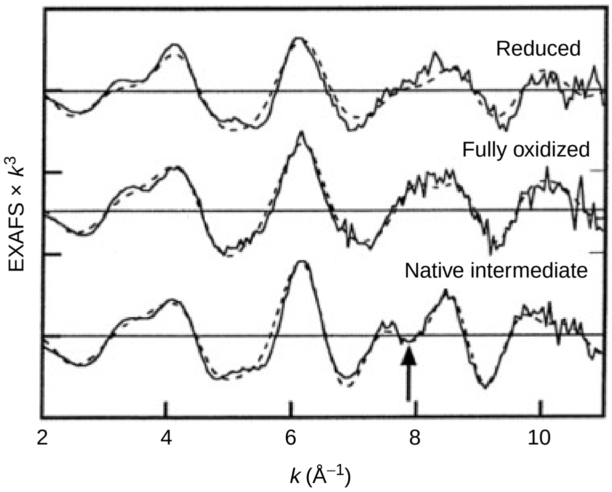

Figure 13 EXAFS of the *Rv* forms represented in Figure 12; the feature at $\sim 8\ Å^{-1}$ is assigned to a Cu–Cu interaction unique to the native intermediate. (Reprinted with permission from Ref. 38. © 2002 American Chemical Society)

indicates that in this process, the dioxygen bond is cleaved, as illustrated in Figure 11. Furthermore, the fact that all four copper atoms are in the cupric state indicates that O_2 has been converted to O^{2-} as in both suggested models.

The rate constants and the associated free-energy surfaces available to the peroxide and native intermediates deserve comment since they differ overall by nearly 10^5 (or ca. 7 kcal mol^{-1} in absolute value). Given the relatively electroneutral nature of electron transfers between the copper sites (the E° values for the three sites differ overall by only 60 mV), the differences in rate in the first instance reflect the difference in the E° value for $1e^-$ versus $2e^-$ reduction of dioxygen (leading to the peroxy intermediate) and peroxide (leading to the native intermediate). Second, the differences reflect the 'work' available from the favorable $4e^-$ reduction that drives the turnover from native intermediate to fully reduced enzyme primed, now, to react with O_2. This latter process, $k \approx 100\,s^{-1}$ (compare to $k = 0.34\,s^{-1}$ for decay of the native intermediate to fully oxidized enzyme), is functionally equivalent to the reductive release of Fe^{2+} from Fe^{3+}·transferrin catalyzed by the membrane metalloreductase, Dcytb; in both cases, the lower valent metal species is more loosely coordinating. Whereas Fe^{2+} dissociates in the latter case, in MCO turnover the bound water(s) dissociate.

The overall reaction mechanism for MCO catalysis reflects the electron stoichiometry associated with the lowest free-energy surface.[2] For dioxygen, the surface is given by $2e^{-1}$ transfers as is strikingly demonstrated by the 1 versus $2e^-$ reduction of peroxide. With $E° = 0.38$ V for the T1 and T2 copper atoms, and for the $1e^-$ reduction of H_2O_2 to $H_2O + HO\bullet$, there is no driving force for a $1e^-$ reaction. In contrast, the $E° = 1.37$ V for reduction of H_2O_2 to $2H_2O$ provides a strong driving force for the $2e^-$ process, a difference illustrated by the Morse potential energy surfaces in Figure 14.[2] The Morse potentials predict that the $\Delta\Delta G^{\ddagger}$ for the $2e^-$ versus $1e^-$ reduction of peroxide is ca. -10 kcal mol^{-1}, consistent with the kinetic data shown in (Figure 11). The argument for the $2e^-$ mechanism is basically teleologic: given all the atom rearrangements, there is a large Franck–Condon barrier between H_2O_2 and $2H_2O$; the only compensating driving force large enough to overcome this barrier is from $2e^-$ reduction.

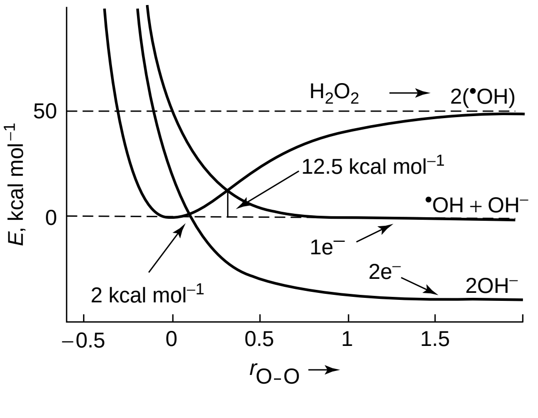

Figure 14 Morse potentials for $1e^-$ and $2e^-$ H_2O_2 reduction illustrating the ~10 kcal mol^{-1} more favorable $\Delta G^{\ddagger}$ for the latter.[2] (Reproduced by permission of Wiley-VCH)

3.2 Ascorbate Oxidase

Functionally, ascorbate oxidase is a specialized laccase in that it exhibits specificity for dihydroascorbic acid as reducing substrate whereas laccases turn over a wide range of bulky aromatic phenols and amines. Also, AO appears confined to plants whereas laccases are widely dispersed in both plants and fungi. This suggests that AO is associated with the cellular differentiation that distinguishes higher from lower eukaryotes, and/or with the development of plants specifically. However, the few studies on the expression pattern of AO in plants, for example, in cultured tobacco,[41] have not clarified AO's biological role. One hypothesis, that has not been thoroughly tested, is that the AO, de/dihydroascorbate system functions in plants to maintain cell redox balance as the glutathione reductase, GSH/GSSG system does in other eukaryotes.[42]

AO was the first of the MCOs to be crystallized and characterized by X-ray diffraction.[18,19,43] Of continuing relevance are the structures of the azide- and peroxide-bound forms of the trinuclear cluster that have informed our understanding of ligation at this MCO copper site.[19] For example, the native, oxidized trinuclear cluster is pictured in Figure 15(a); of interest here is the solvent water coordinated in what is an apparent trigonal planar geometry of the type 2 Cu(II) (the type 2 Cu is designated Cu4 in the coordinate file). However, the two protein His ligands are fully trans indicating the type 2 Cu(II) could have a square-planar geometry with one open equatorial coordination site. However, the crystal structure does not define nor determine the electronic ground state. An alternative, albeit less probable interpretation of T2 Cu(II) ligation geometry is that the H_2O is apically coordinated and that there are two open equatorial sites. The oxygen bridging the binuclear Cu atoms, Cu2, and Cu3, is also clearly defined in the electron density map. Upon reduction of the cluster (not shown) or upon peroxide binding to the cluster (Figure 15b), the bridging oxygen is lost with the peroxide bound in an end-on fashion to Cu2. The loss of the bridging oxygen (in either case) results in Cu2 and Cu3 moving apart, from 3.7 to 4.8 Å in the peroxide-bound form. The other significant change is in the relationship of the type 2 Cu(II) to the type 3 copper atoms; whereas the Cu4 ↔ Cu3 distance remains essentially unchanged at 3.7 Å, the Cu4 ↔ Cu2 distance increases to 4.5 Å, undoubtedly due to the change in the ligand field at Cu2 due to peroxide coordination. Qualitatively and quantitatively similar structural changes occur upon N_3^- binding to Cu2,

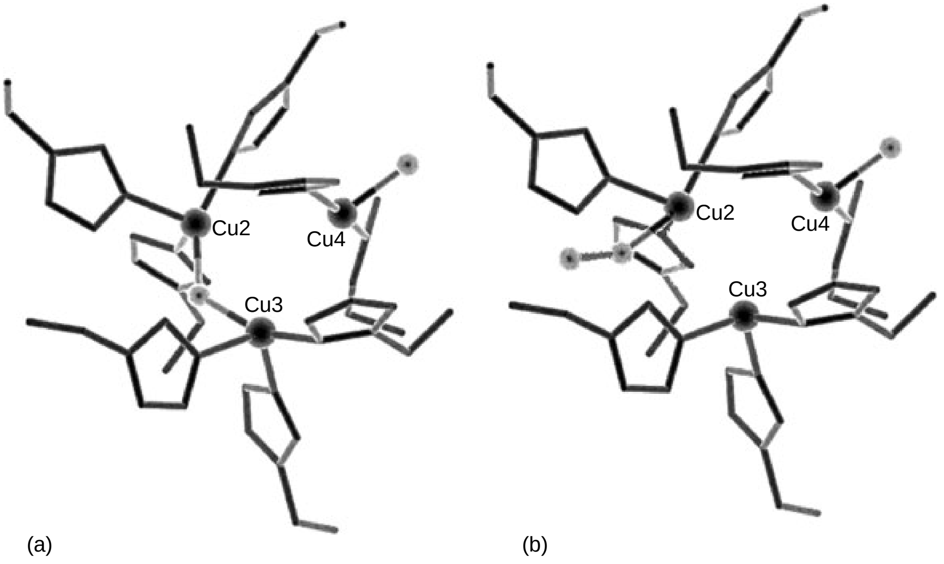

Figure 15 Trinuclear cluster in AO (a) and the AO, peroxide adduct (b)[19]

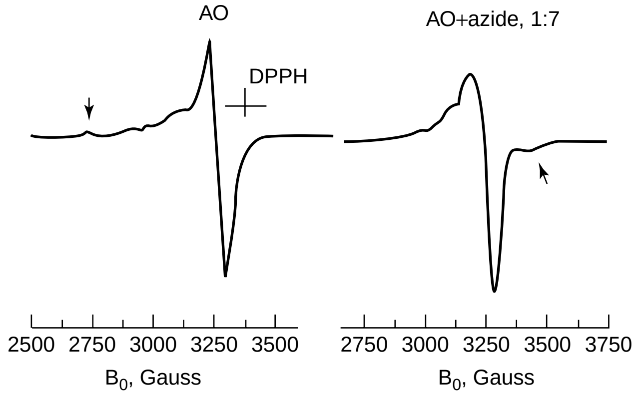

Figure 16 cwEPR spectra of AO and AO, azide adduct[44]

indicating that these structures reflect the basic coordination chemistry at the MCO trinuclear cluster.

The structural changes are reflected in electronic ones as well. The differences in the X-band cwEPR spectrum of AO and the AO-azide adduct illustrate one such change (Figure 16).[44] The spectra, recorded at 14 K, show that upon N_3^- binding, the normal T2 Cu(II) low field transition in $A_{||}$ decreases and a broad signal between 3000–3200 G appears ($g \approx 1.97$), but only below 40 K. A new T2 signal centered at 2860 G appears, also, but this signal is observed only above 40 K. The temperature and power-saturation dependence of the low g value signal suggests that it arises from an $S = 1$ spin system, likely to be a dipolar-coupled Cu(II) pair. This inference is fully consistent with the structure determined for the azide (and peroxide) AO adducts in which the two type 3 Cu(II), while not bridged (and thereby exchange-coupled), certainly could be spin-coupled through-space. That the T2 Cu(II) spin Hamiltonian in the azide adduct is perturbed is also consistent with the adduct's structure. First, the native trinuclear cluster is symmetric while in the adduct, the T3 Cu2 'moves away' from the T2 Cu4 by ca. 0.7 Å. In addition, the T3 Cu(II) atoms are no longer antiferromagnetically coupled. Both the perturbed T2 Cu(II) and the $g \approx 1.97$, $S = 1$ T3 Cu(II) spin systems exhibit an increased spin-lattice relaxation rate consistent with these structural and electronic changes. Finally, the results support the model for dioxygen reduction at the trinuclear cluster (Figure 11) in that they show that a potentially bidentate ligand binds end-on to only Cu2 in the cluster. Either form of the peroxide intermediate in Figure 11 would be compatible with this ligation scheme. What is missing, of course, from the structural and EPR studies is the mixed-valent state of the cluster suggested by kinetic and other spectral data in which the type 2 copper is present as Cu(I). Perhaps the more exchange-labile lower valent state of the T2 copper allows for the system to sample the Cu2-Cu4 bridged forms shown in the model; a ~4.5 Å spacing of Cu2 and Cu4 as in the peroxide adduct would be compatible with either the μ-1,1-hydroperoxide or μ_3 $(\eta^1)_3$ bridging modes illustrated. However, explicit correlations between static and kinetic experiments like those briefly summarized here have not been thoroughly explored.

4 FERROXIDASES: CERULOPLASMIN AND THE Fet3 PROTEIN

4.1 Background – The Copper, Iron Connection

Over fifty years ago, nutritional studies in swine and sheep demonstrated that copper deficiency correlated to the

symptoms of iron deficiency in iron-replete animals.[45] This physiological correlation was subsequently extended to a biochemical one, namely, that the apparent iron-deficient state was linked to the decline in serum oxidase activity due to a blue, copper-containing protein, ceruloplasmin.[46] In the 1960s and 70s, Earl Frieden and his coworkers established that ceruloplasmin had a strong kinetic specificity for Fe^{2+} as substrate and proposed that the physiologic dependence that normal iron metabolism had on copper status was due to the role that Cp played in the efficient trafficking of iron – as Fe^{3+} – to apotransferrin (Tf) (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***).[47,48] Hence, Cp was described as a ferroxidase, a specialized member of the MCO family.

Biochemical support for this hypothesis was difficult to obtain. For example, if Cp 'catalytically' traffics Fe^{3+} to *apo*Tf then the transfer 'catalysis' should be kinetically demonstrable. The reactions involved are complex, however:[49]

$$Fe_{(aq)}{}^{2+} \longrightarrow Fe_{(aq)}{}^{3+} + e^- \qquad (k_1)$$

$$Fe_{(aq)}{}^{3+} + apo\text{Tf} \longrightarrow \text{Tf}\cdot Fe^{3+} \qquad (k_2)$$

$$Fe_{(aq)}{}^{3+} + H_2O \longrightarrow Fe(OH)_n \qquad (k_3)$$

$$Fe_{(aq)}{}^{2+} + \text{Cp} \longrightarrow Fe_{(Cp)}{}^{3+} \qquad (k_4)$$

$$Fe_{(Cp)}{}^{3+} + apo\text{Tf} \longrightarrow \text{Tf}\cdot Fe^{3+} \qquad (k_5)$$

The first two reactions lead to formation of $\text{Tf}\cdot Fe^{3+}$ via the autooxidation of 'free' ferrous iron (k_1). However, the hydrolysis of $Fe_{(aq)}{}^{3+}$ (k_3) competes with the binding of $Fe_{(aq)}{}^{3+}$ to *apo*Tf (k_2), reducing the observed rate of formation of $\text{Tf}\cdot Fe^{3+}$. Thus, irrespective of the rate of Fe^{3+} binding to *apo*Tf, there are two barriers that rate-limit the formation of *holo*Tf: the rate of autooxidation of Fe^{2+}, and the partitioning of Fe^{3+} between binding and hydrolysis. Cp could 'catalyze' the binding reaction in two ways: 1) increasing the rate of oxidation (ferroxidation) and/or 2) by reducing or eliminating the competition from hydrolysis.

The first of these effects is easily demonstrated independent of iron trafficking to *apo*Tf. For example, given the strongly limited concentration of free oxygen in the presence of hemoglobin ($<10\,\mu$M in plasma), the pseudo-first-order rate of autooxidation of Fe^{2+} at physiologic pH is $\sim 0.1\,\text{min}^{-1}$. With a K_M for $O_2 \sim 1\,\mu$M, hCp functions close to its V_{max} for ferroxidation under physiologic conditions and can turn over 100-fold more Fe^{2+} than would autooxidization.[50] Such 'catalysis' is required given the daily iron turnover in humans of *ca* 700 µmol. The question of competition from the hydrolysis 'side reaction' is more difficult to address experimentally. Experiments in which the rate of accumulation of $\text{Tf}\cdot Fe^{3+}$ was enhanced by inclusion of Cp in the binding reaction mixture do not by themselves confirm a mechanism.[49] However, the fact that enhancement occurs only when the binding reaction is initiated with the addition of Fe^{2+} (and not when Fe^{3+} is added to Cp and *apo*Tf) suggests that Cp-generated Fe^{3+} is a 'preferred' Tf substrate ligand. Also, the combination of Cp and *apo*Tf stimulates release of ^{59}Fe from mammalian cells (with the formation of $^{59}\text{Fe}\cdot\text{Tf}$). That neither Cp alone, nor Tf alone, stimulates ^{59}Fe release suggests the two proteins function synergistically in this iron trafficking but does not indicate how they do so.[51]

However, the link between the ferroxidase activity of an MCO and iron homeostasis has been put on firm ground due to genetic studies in yeast and normal and transgenic animals over the past decade.[52,53] First, the identification of a family of fungal ferroxidases that are required for normal iron trafficking in their respective organisms – the Fet3p family of proteins – has provided a biochemical model system in which to study if not establish how a ferroxidase enzyme can 'channel' Fe^{3+} within an iron trafficking pathway, for example, as in the formation of $\text{Tf}\cdot Fe^{3+}$ from $Fe_{(aq)}{}^{2+}$ and *apo*Tf as above. In fungi, and most likely in plants also, these ferroxidases are part of an enzyme-iron permease complex that transports iron across a membrane.[53,54] Second, genetic studies in animals have revealed the presence of additional members of the mammalian ferroxidase family, one of which – hephaestin – like the Fet3 protein, is required for membrane iron transport.[55] Thus, irrespective of the role that Cp might play in iron loading of *apo*Tf, there is a superabundance of data that the iron oxidase activity of the ferroxidases is not a curiosity and that the ferroxidases are aptly named.

4.2 Ceruloplasmin

4.2.1 *Protein Properties, Synthesis, and Processing*

Human ceruloplasmin (hCp) is an encoded 1065 residue protein, calculated $M_r = 122\,205$ Da. The preprotein contains a 19-residue signal sequence that targets it to the endoplasmic reticulum during synthesis; this sequence is cleaved during processing leaving a mature protein of 1046 residues.[52] Note that all reference to residue number in this chapter is based on the encoded protein and not on the sequence of the mature protein even if this sequence is known precisely from experiment. As are all of the eukaryotic MCOs, hCp and its mammalian homo- and orthologues are glycoproteins; mature hCp is ca. 10% w/w N-linked carbohydrate. In addition to the signal sequence cleavage and glycosylation, Cp also obtains its prosthetic group copper atoms during its processing in the vesicular protein trafficking pathway. This copper addition appears to occur relatively late in this pathway, in what is commonly referred to as the trans-Golgi network that includes vesicles targeted for fusion with the plasma membrane (and in fungi, the vacuolar membrane, as well).

The copper content of this compartment is maintained by one or two P-type ATP-utilizing copper pumps. These two proteins are known by their association with two disorders of human copper metabolism, the Menkes (MNK) and Wilson (WND) proteins, and genetically as ATP7A and ATP7B, respectively (*see* ***Metal-related Diseases of Genetic***

Origin).[56,57] These pumps, in turn, are 'supplied' with copper, as Cu(I), by the cytoplasmic copper chaperone, the product of the human HAH1 gene (*see* ***Metallochaperones & Metal Ion Homeostasis***). This chaperone is also commonly known at Atox1, the product of the mouse ATX1 gene. The latter designation followed from the original isolation of this locus, in yeast, where it was given the designation *ATX1* for antioxidant protein 1.[56] The point to be made here is that the fully metallated Cp, or of any eukaryotic MCO, is the product of a true metabolic or processing pathway that involves two separate compartments and at least two copper trafficking activities. A last subtle point is that the copper 'substrate' for this trafficking is very clearly Cu^{1+}; data below will indicate that this is likely to be the state of the copper in the newly mature MCO.

4.2.2 *Structure, Specificity, and Electron-transfer Mechanism*

As noted above, hCp represents the 'duplicated' MCO family, those MCOs that contain >1000 residues and, therefore, possess a tertiary fold consisting of six cupredoxin domains.[34] What is unusual about Cp is the presence of three type 1 Cu sites; that is, whereas in the other MCOs, the first two of the three cupredoxin domains 'lost' the type 1 ligands found in the third, carboxyl-terminal one, in Cp, these motifs are retained in three of the six, in domains 2, 4 and 6. The relationship of these three type 1 Cu sites to the trinuclear center (found at the interface of domains 1 and 6, not 1 and 3 as in the three-domain MCOs) is shown in Figure 17.[24] The type 1 Cu in domain 6 is ∼13 Å from this cluster; the distance from the cluster of the other two are ∼22 (domain 2) and ∼30 Å (domain 4), respectively. On the other hand, the three putative type 1 sites form a near isosceles triangle, ∼18 Å on a side.

One of these type 1 copper atoms is redox inert and, with a reduction potential of ∼1.0 V, is in a permanently reduced site. The redox properties of this site were deduced from a combination of chemical assay for Cu(I) using biquinoline and XAS.[58] The copper K-edge XAS for Cu(I) exhibits a distinctive feature at 8983 eV; the peroxide-oxidized Cp retains ∼12% of the intensity of this edge absorption observed in the fully reduced protein. The biquinoline assay indicates that ∼20% of the total copper in this oxidized Cp is present as Cu(I). These values indicate that of the six copper atoms/molecule detected in Cp by chemical solution, one of them is present as Cu(I). Since three of the others can be accounted for as part of the trinuclear cluster, and two as 'normal' type 1 Cu(II) based on absorption at 608 nm and spin quantification by cwEPR, this reduced Cu(I) must be at one of the type 1 sites predicted by sequence (Figures 1 and 4) and confirmed crystallographically.[24,59] Kinetic analyses indicate that the two redox-active blue sites are competent in enzyme turnover of reducing agent and dioxygen. Again, note that Cp (and its paralogue, hephaestin) is the only known MCO that is a 'dimer of trimers'; that is, Cp has two of the prototypical plastocyanin 'triplets' characteristic of all MCOs.

The specificity of Cp for Fe^{2+} as substrate appears to derive from two structural features.[59] First, the cavity that rings the ferroxidase-active type 1 Cu(II) atoms noted above presents an overall negatively charged electrostatic surface to bulk solvent. Second, there appear to be two specific binding sites for Fe^{2+} and Fe^{3+} and other comparably sized and charged first-row transition metals (e.g. Co^{3+}, Cu^{2+}) that are found associated with this anionic surface. These two sites are shown in Figure 18; metal soaking and subsequent crystallographic difference analyses indicate that these sites in domains 4 and 6 only are occupied.[59] Distinct functions for the two sites are indicated in the figure. The ferroxidase site directly adjacent to the type 1 Cu(II) is where Fe^{2+} is oxidized by electron transfer to the Cu(II) via one or both the metal's two His ligands. Following metallo-oxidation, the higher valent species is suggested to migrate to the distal, 'holding' site. The fate of the Fe^{3+} product at this site has not been established, for example, whether it dissociates or is trafficked directly to transferrin. In simple turnover, it clearly equilibrates with bulk solvent.

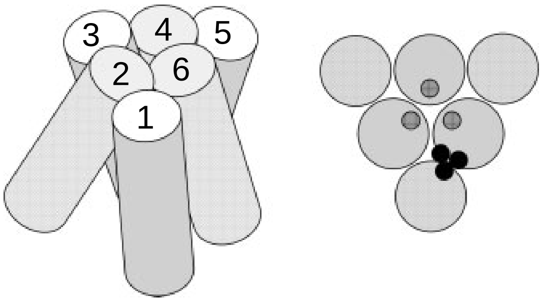

Figure 17 Domain organization in hCp illustrates the pattern for six-domain MCOs. Note the three T1 sites; the two in domains 4 and 6 are redox active, the one in domain 2 is permanently reduced

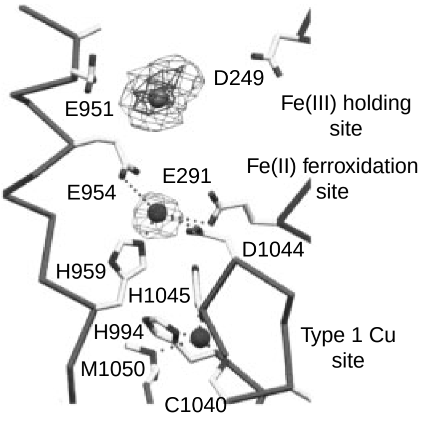

Figure 18 Fe(II) ferroxidation and Fe(III) holding sites at the T1 Cu site in hCp. (Reprinted from Ref. 59. © 1997 Society of Biological Inorganic Chemistry)

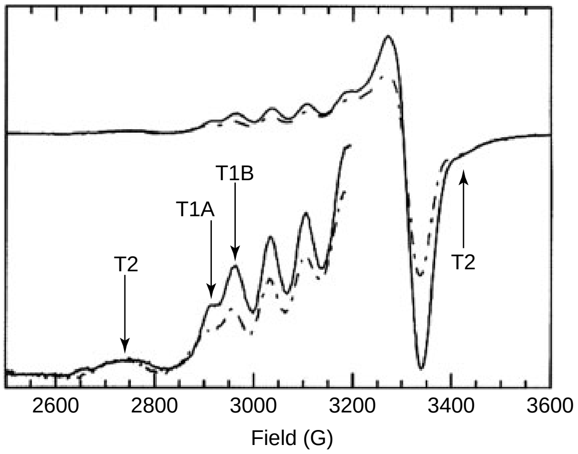

Figure 19 cwEPR spectrum of 'oxidation' product from the reaction of fully reduced hCp with O_2 showing that two T1 Cu atoms share one 'hole'. (Reprinted with permission from Ref. 60. © 2000 American Chemical Society)

The Cp system is the most thoroughly examined with regards to the intramolecular electron transfers that couple ferroxidation to dioxygen reduction. Figure 19 demonstrates several things about this redox system.[60] The solid lined spectrum is that of fully oxidized Cp in which 5 of the six copper atoms are present as Cu(II); this includes two of the three Cu at the putative type 1 sites. The spectrum shows clearly the different spin Hamiltonian parameters for these two sites; spin quantification shows that they each contain one spin-equivalent. The $m_s = -3/2$ Cu hyperfine line due to the single type 2 Cu(II) is also apparent in this oxidized sample; it, too, represents one spin-equivalent. If fully reduced protein is reoxidized by O_2, the spectrum given by the dashed line is obtained. Whereas the type 2 Cu(II) is clearly fully oxidized, the two type 1 Cu are not. Spin quantification shows that, in effect, they are sharing one 'hole', and one electron. Since fully reduced Cp has five redox-available electrons while dioxygen reduction requires only four, this leaves one electron 'on' the enzyme. The spectrum in Figure 19 demonstrates that this electron is shared by the two type 1 copper atoms.

This result indicates that the type 1 sites in domains 4 and 6 (based on the fact that metal binding is observed at these sites crystallographically) are both ferroxidase-active in turnover. The reduction-oxidation result above suggests that an electron transferred to one of these copper atoms is 'shared' with the other. Based on kinetic studies, the lower limit of this intramolecular electron transfer is $150\,s^{-1}$ but is likely to be as much as ten times this value. A calculation of this rate based on the Pathways program developed by Beratan and Onuchic[61] gives a value of $1500\,s^{-1}$. This program generates a value for the electronic coupling matrix element, H_{AB}, that in simple Marcus theory is given by the product of a single scalable factor, β, times the distance between the electron transfer

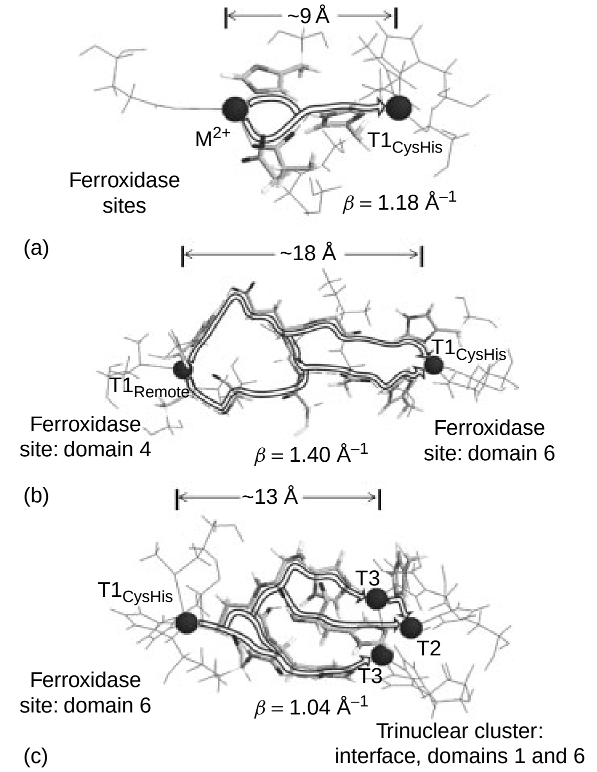

Figure 20 Intramolecular electron-transfer pathways in hCp with the coupling decay value, β, for each. (Reprinted with permission from Ref. 60. © 2000 American Chemical Society)

sites. The program assigns different 'efficiencies' to electron transfer through covalent bonds of different types, H-bonds, and through-space 'jumps'; input for this program is a protein structure coordinate file with protons added as needed to complete putative H-bonds (*see* ***Electron Transfer Reactions: Theory*** and ***Long-range Electron Transfer in Biology***). The results of this modeling are illustrated in Figure 20 for the three electron-transfer steps that kinetic analyses suggest for the Cp-catalyzed turnover of Fe^{2+} and O_2. The computed values of the coupling decay, β, are given; these give an estimate of the 'conductance' of the putative electron-transfer pathways indicated in the figure.[60]

4.2.3 The GPI-ceruloplasmin Isoform and Hephaestin

Cp is a soluble protein, secreted by mammalian cells into the plasma or interstitial space.[52] However, in some cells (neuronal, visual), alternative splicing of the nascent Cp transcript produces an mRNA that is translated into a Cp protein with a carboxyl-terminal extension that is substrate for the addition of a glycosylphosphatidylinositol (GPI) tag.[62] This tag leads to the insertion of this Cp form into the inner surface of the vesicular membrane that encloses this Cp processing pathway. Upon fusion of this vesicle with the plasma membrane, the Cp becomes tethered to the outer

surface of the cell. Metazoan genomes also encode a Cp-like protein that contains a carboxyl-terminal transmembrane domain; in mammals, this is hephaestin.[63] Like the GPI-Cp protein, Hp is found tethered to the inner surface of the vesicular membrane, or to the outside of the cell. Either enzyme is thus positioned to act on Fe^{2+} that is found in these two environments.

GPI-Cp is linked to neuronal cell homeostasis, probably by preventing the abnormal accumulation of Fe^{2+} (and, perhaps, Cu^{1+}).[64] Loss of Cp activity in neurons correlates with a variety of degenerative diseases of the nervous system with an underlying pathophysiology that involves iron deposition and oxidative damage.[52] Given the known pro-oxidant activity of low-valent metal ions like Fe^{2+} and Cu^{1+}, Cp could suppress this pathophysiology simply by lowering these ions' steady-state level, or by coupling this oxidation to the trafficking of iron out of 'harms way', for example, by catalyzing its transfer to transferrin. Cp also could work by assisting in the membrane transport of iron; this suggestion is based on the known role that hephaestin plays in iron transport in the epithelial cells in the intestine,[63] and that fungal ferroxidases play in the uptake of iron in those organisms (below). Hephaestin is expressed in the intestine, and together with a divalent metal ion transporter, Ireg1,[65] is required for the export of iron across the epithelial lining of this tissue into the circulation. The coupling of the activities of Hp and Ireg1 in this iron trafficking process is not understood, but most certainly involves the ferroxidase activity that Hp has.[66] This coupling is characteristic also of high affinity iron uptake in fungi, as discussed below.

4.3 Fungal Ferroxidases – The Fet3 Protein from *Saccharomyces cerevisiae*

4.3.1 Protein Properties, Synthesis, and Processing

All fungal genomes archived encode at least one MCO of *ca* 700 residues that contains a carboxyl-terminal transmembrane domain; this is in addition to the laccase(s) that many also produce. Most if not all of these membrane-associated MCOs are ferroxidases, and, like Cp and Hp, play an essential role in the iron metabolism of these fungi. Three of these were represented in the sequences given in Figure 4 (Fet3p, Fet5p and Fio1). Of these proteins, the most thoroughly characterized representative is the Fet3p protein from baker's yeast, *Saccharomyces cerevisiae*.[53,54]

Fet3p is produced as a 636 residue preprotein that is processed first by cleavage of a 20-residue signal sequence that targets the nascent polypeptide to the endoplasmic reticulum. The mature protein is highly glycosylated; there are as many as 13 potential N-linked glycosylation sites within the sequence. The apoprotein is metallated in what is termed the trans-Golgi network, a series of vesicular compartments that connect the Golgi apparatus to the plasma membrane, or, in yeast, to the vacuole as well. Insertion of the protein's four copper atoms requires three membrane functions in these vesicles: acidification due to a H^{+}-ATPase; Cl^{-} trafficking due to a chloride pump; and the fungal homologue to the mammalian copper pumps, ATP7A/B, the Ccc2p protein.[56] Yeast deficient in any one of these three actitivies produce only the apo form of Fet3p. These yeast mutants, like those that are mutant in the Fet3p gene itself or those that are in a copper-deficient state, exhibit a strong iron deficiency owing to a lack of high affinity iron uptake. This metabolic coupling of an MCO with normal iron trafficking was and is the most compelling data relevant to the molecular mechanism of the 'copper-iron' connection in biology (*see* ***Nutritional Aspects of Metals & Trace Elements*** and ***Metallochaperones & Metal Ion Homeostasis***).

This iron deficiency is due to the fact that Fet3p likely forms a complex with the high affinity iron permease, Ftr1p, in the yeast plasma membrane.[54] In this complex, Fet3p oxidizes Fe^{2+} produced by a plasma membrane metalloreductase (the Fre1p protein in yeast, comparable to the Dcytb protein in mammalian cells[66]) to Fe^{3+} in the ferroxidase reaction; the Fe^{3+} is substrate for iron uptake through Ftr1p. The obligatory coupling of the ferroxidation and uptake processes suggests that Fet3p-produced Fe^{3+} is trafficked directly to Ftr1p in a nondissociative ligand-exchange reaction much as Cu^{1+} traffics between copper chaperone and target protein (*see* ***Metallochaperones & Metal Ion Homeostasis***).[56,67] This direct solute transfer in a metabolic pathway is termed 'channeling' and is common when the solute transferred is likely to undergo an undesirable side reaction if it equilibrates with bulk solvent.[68] In the case of Fe^{3+}, one such reaction would be hydrolysis, as outlined above in regards to the role of Cp in Fe^{3+} transfer to transferrin.

4.3.2 Spectral Properties

The Fet3p system has been exploited to produce mutant MCO forms that lack one or more of the copper atoms so as to isolate the spectral and functional properties of the remaining sites.[53] Chemical means had been used to produce metal-substituted (T1Hg forms) and metal-deficient forms (T2 depleted) of Lac and AO. With Fet3p, site-directed mutagenesis afforded T1D, T2D and, for the first time, T1D/T2D MCO protein without the use of possibly damaging chemical treatments.[25] Figure 21 illustrates the T1 and trinuclear cluster sites in Fet3p (panels A and B, respectively) and the amino acid substitutions that were made to produce these copper-site depleted mutants (the double mutant contained both C484S and H81N substitutions). The X-band cwEPR and near UV–vis spectra for wild-type Fet3p and these mutant proteins are shown in Figure 22. The spectral values corresponding to these spectra were given in Table 1.

Both the EPR and UV–vis spectra demonstrate two features of this system. First, they show that the remaining Cu(II) sites in mutant proteins lacking either the T1 or T2 Cu(II), or both, exhibit the same spectral properties that obtain in the wild-type protein. Second, sequentially depleting the protein of Cu(II) atoms allows the direct assignment of these spectral

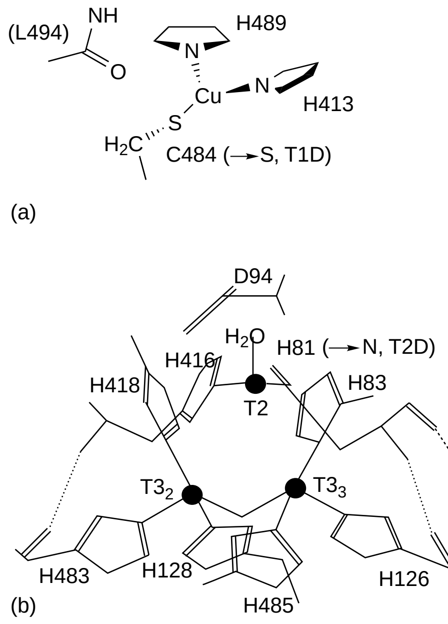

Figure 21 T1 Cu (a) and trinuclear cluster (b) of Fet3p indicating substitutions leading to site-depleted protein forms

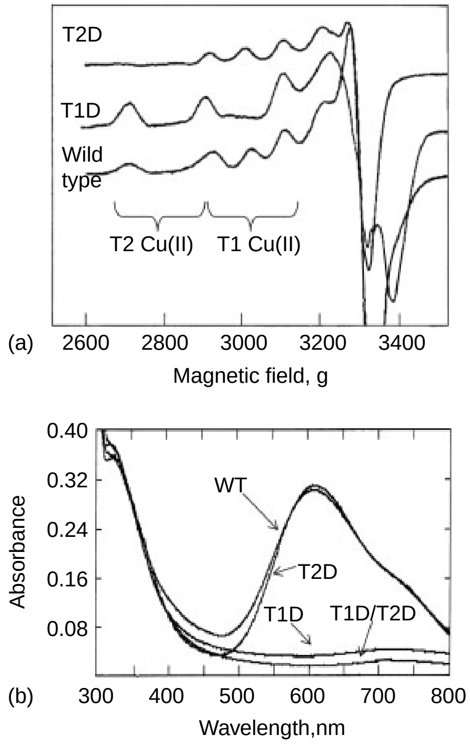

Figure 22 cwEPR (a) and absorbance spectra (b) of wild type and site-depleted forms of Fet3p.[53] (Reprinted with permission from Ref. 25. © 2000 American Chemical Society)

values to specific Cu(II) atoms. This is most obvious in the UV–vis spectra: the shoulder at 330 nm is clearly from the T3 binuclear cluster while the broad absorbance at ~720 nm persists in the T1D/T2D mutant indicating that it, too, comes from the T3 site.

The double mutant was most useful in examining the EXAFS of the binuclear cluster in an MCO, spectrally isolated for the first time in this mutant; the experimental and fitted spectra for the oxidized and reduced clusters in Fet3p(T1D/T2D) are shown in Figure 23 a and b, respectively. Some of the parameters used to construct the fits are shown in the model in Figure 23(c). The three principal insights provided by these fits, as illustrated in this model, are: 1) a bridging O is clearly distinguished in the oxidized T3 site that is absent in the reduced form: 2) upon reduction, the Cu–Cu backscatterer detected in the oxidized site is reduced or absent, likely due to the two Cu(I) moving apart; and 3) an

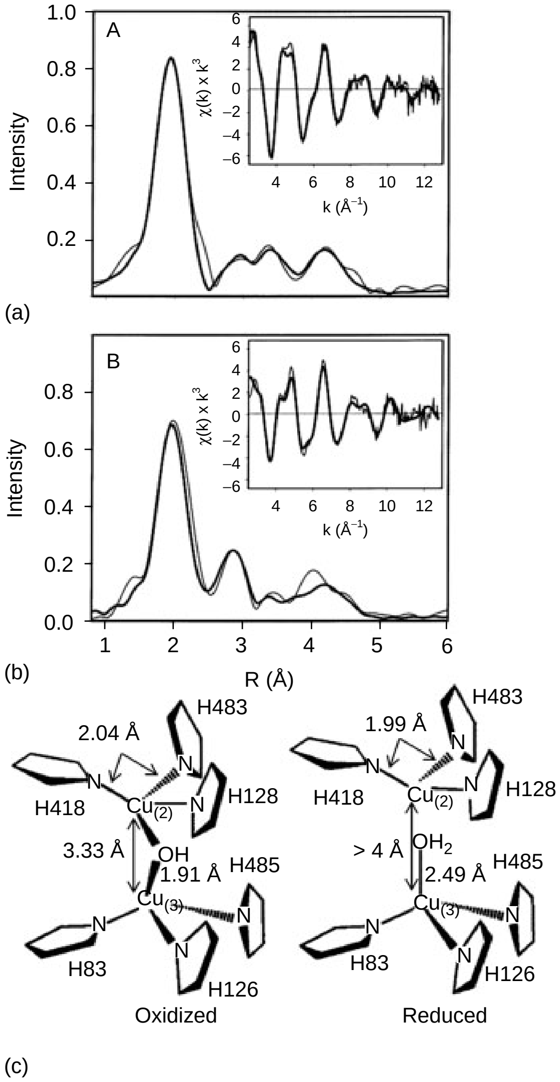

Figure 23 EXAFS of oxidized (a) and reduced (b) T3 site in Fet3p. The fits shown are illustrated by the model of the binuclear site shown in c.[53] (Reprinted with permission from Ref. 25. © 2000 American Chemical Society)

additional O/N is fit in the EXAFS of the reduced site, that, at 2.49 Å, is dissimilar to the coordinating imidazole nitrogen atoms. These changes upon reduction of the type 3 site in Fet3p deduced from the EXAFS data parallel those observed crystallographically upon reduction of AO.[19] Specifically, upon reduction, the bridging O in AO is lost and the type 3 Cu–Cu distance increases from 3.7 to 5.1 Å. Furthermore, the coordination geometry of the two Cu atoms differ, much as they do in the model of the reduced type 3 cluster in Fet3p shown in Figure 23(c). This difference could be due to the H_2O molecule apically coordinated to one of the Cu(I). This Cu atom, designated $Cu_{(3)}$, remains somewhat tetragonal because of this water coordination, while the other, $Cu_{(2)}$, becomes more trigonal planar in geometry.

4.3.3 *Structure-function Relationships*

The utility of yeast as a genetic and recombinant protein system is exemplified also by the several structure-function studies on the Fet3p protein. In addition to those studies that targeted copper-site ligands (above) are those that probed for amino acid residues required for oxidase activity or for substrate specificity, that is, specificity for Fe^{2+} as reducing substrate. Enzyme turnover involves three electron-transfer steps: to the type 1 Cu(II) from the reducing substrate; intramolecular electron transfer from the type 1 Cu(I) to the trinuclear cluster; and electron transfer from the cluster to dioxygen. In regards to the first of these electron-transfer steps, it is likely that the coupling pathway from substrate to Cu(II) is via the coordinating histidine imidazole homologous to H1045 in hCp and H489 in Fet3p (*cf* Figures 1 and 21). Depending upon the solvent exposure of this NHε2, the coupling is direct (as in the laccases) or indirect, as in hCp. This difference in solvent exposure is illustrated in Figure 24; the Connolly (water-accessible) surfaces for *C. cinereus* laccase (1A65, Figure 24a) and hCp (1KCW, Figure 24b) are shown (images generated using InsightII software from Molecular Dynamics). Whereas the NH is fully exposed to solvent in Lac, it is ~9 Å beneath the surface in hCp. One cannot directly correlate the extent of solvent accessibility of this His with electron-transfer rate since, according to the Marcus formulation, this rate depends on the driving force ($\Delta E°$) and steric and 'binding' terms (S and K_A, respectively), as well as on the electronic coupling matrix element and reorganization energy (which is likely to be roughly the same for all MCOs). However, with a large organic reductant like hydroquinone as substrate, T1 Cu(II) reduction in Lac is 500-fold faster than in hCp.[69] This difference is not due to a difference in $\Delta E°$ since the two T1 Cu(II) have essentially the same redox potential (~440 mV); thus, in this case, the rate difference could be due to a physical interaction of this substrate with Lac in comparison to the electron transfer-productive interaction with hCp. Indeed, as noted, crystallographic studies have demonstrated the Lac does have a shallow binding site for bulky aromatics where the substrate binding site is more constrained. Since this histidine coupling element is also a copper ligand, mutagenesis cannot be used to test its role in electron transfer; as outlined above, substitution at this ligand results in the production of a stable T1D protein.

However, substrate specificity at the T1 copper can be probed by site-directed mutagenesis; in particular, this approach has been used to identify residues that confer the Fe^{2+} specificity characteristic of ferroxidases. The acidic (negative) patch adjacent to the T1 copper in hCp has been noted; two of the residues implicated in this Fe^{2+} site are E954 and H959 (*cf* Figure 18). Mauk and coworkers demonstrated that the E954A/H959A hCp double mutant lost 50% of its ferroxidase activity while retaining full activity towards *o*-dianisidine.[70] Although not directly measuring the increase in K_m for Fe^{2+} that would be expected if these residues were part of the specificity site, these experiments did provide evidence in support of this model.

There is no structure of Fet3p (or of any other fungal ferroxidase) on which to base such structure-activity studies; on the other hand, the plethora of fungal Fet3p homologues

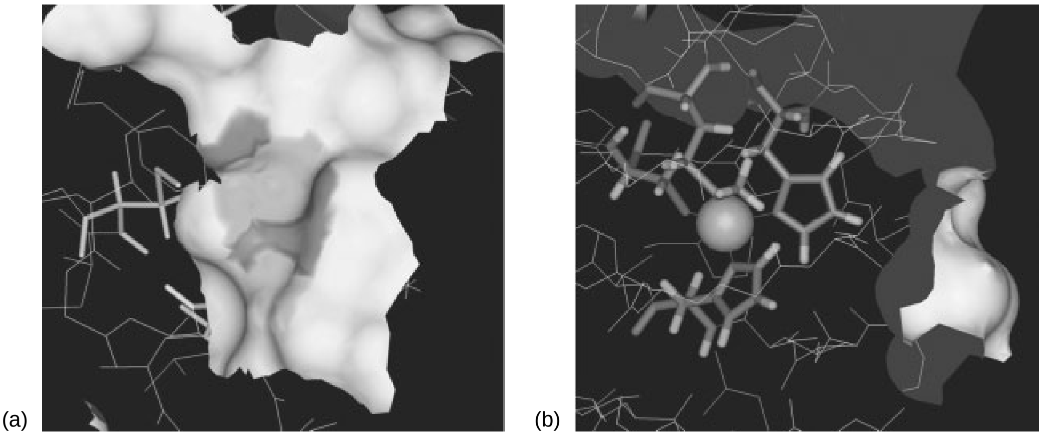

Figure 24 Connolly surfaces of *Cc* Lac (a) and hCp (b) illustrating solvent exposure of the T1 site

provides a wealth of sequence data on which to make well-educated guesses as to which sequence motifs might distinguish a ferroxidase from other fungal MCOs. Two such studies have identified E185 and Y354 as residues that contribute to the specific binding of Fe^{2+} in Fet3p turnover of O_2.[71,72] This conclusion was based on three- to tenfold increases in K_M for Fe^{2+} in E185A and Y354A mutants. A D278A mutant also exhibited a specific twofold increase in this value suggesting that this residue contributed to Fe^{2+} binding as well. All three residues are conserved among the fungal 'ferroxidases', but their specific roles in catalysis have only been tested in *S. cerevisiae* Fet3p.

The binding of Fe^{2+} at E185 has been demonstrated directly by use of low temperature (LT) MCD.[73] High spin, non-heme Fe^{2+} has a $^5T_{2g}$ ground state; spin-allowed electronic transitions are to the ^5E_g state, which is at $10\,Dq$.[74] With common biological ligands like N and O, $10\,Dq \approx 10\,000\,\mathrm{cm}^{-1}$. The splitting of these ground and excited states is sensitive to coordination number and distortion from pure octahedral symmetry; Solomon and his coworkers have correlated calculated and measured splittings with well-characterized coordination complexes, for example, octahedral, square pyramidal, and trigonal bipyramidal.[74] Octahedral complexes exhibit two overlapping transitions centered at ca. $10\,000\,\mathrm{cm}^{-1}$ whereas the latter five-coordinate geometry alone gives rise to a single Fe^{2+} LT MCD transition between 8500 and $10\,000\,\mathrm{cm}^{-1}$. The LT MCD spectrum of a 1:1 Fe^{2+}:Fet3p mixture exhibits a broad transition at $8900\,\mathrm{cm}^{-1}$ (Figure 25, WT).[73] One equivalent of Fe^{2+} experiences an equivalent ligand field in the presence of the Fet3pE185D mutant (Figure 25, E185D). In contrast, in the presence of Fet3pE185A, added Fe^{2+} experiences a ligand field equivalent to that in buffer alone, with a transition energy shifted up to $9700\,\mathrm{cm}^{-1}$ (Figure 25, E185A). Variable temperature variable field (VTVF) analyses of this MCD transition, and a comparable one observed for Fe^{2+} in the presence of hCp, indicate that the ferroxidase Fe^{2+} binding sites in both proteins are most likely distorted octahedral in geometry; irrespective of the precise geometry, however, in Fet3p, E185 is part of this coordination sphere.

Possible catalysis by protein groups of dioxygen turnover at the trinuclear cluster has been examined in Fet3p also.[75] As noted above, both turnover and intermediate decay in laccase catalysis exhibit a descending pH dependence ($\mathrm{p}K_a = 5.8$) and a KSIE that indicate an enzyme-derived H^+ is transferred during O–O bond cleavage. A similar pH dependence of intermediate decay has been determined for Fet3p(T1D) (see Figure 21(a) for structure) as shown in Figure 26. The enzyme group responsible for the acid catalysis indicated is likely the carboxylic acid group on a Asp residue adjacent to the type 2 site that is conserved in all MCOs; in Fet3p, this is D94 as shown in Figure 21(b) in a model based on the *Tv* Lac structure. The structure-activity relationship

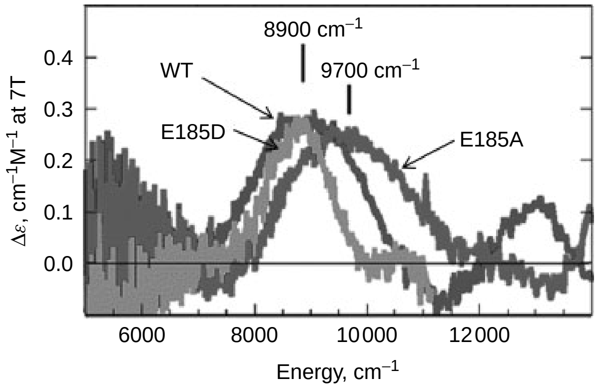

Figure 25 LT MCD spectra of wild type and E185 mutant forms of Fet3p in the presence of one equivalent of Fe^{2+}. (Reprinted with permission from Ref. 73. © 2004 American Chemical Society)

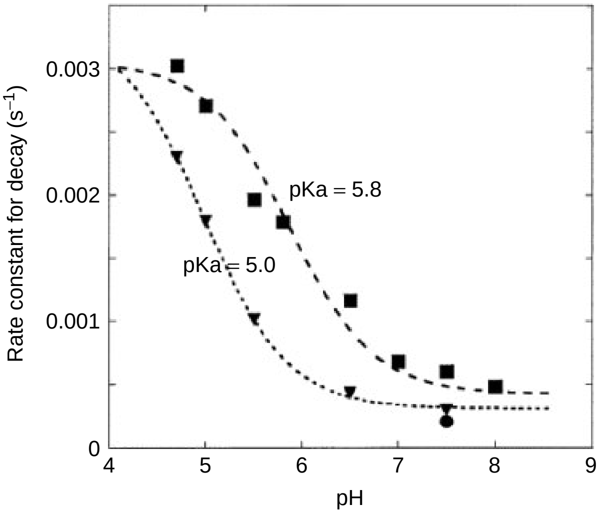

Figure 26 Acid catalysis of decay of peroxide intermediate in *Rv* Lac (squares) and Fet3p (triangles). (Reprinted with permission from Ref. 75. © 2002 American Chemical Society)

suggested by the pH and isotope studies has been tested in Fet3p by substitution of this residue by Glu, Asn, and Ala. Whereas the D94E mutant is fully wild type in activity, the other two mutants are catalytically inert. The absorbance and cwEPR properties of all three Cu(II) sites in these three mutants are quantitatively wild type consistent with the hypothesis that the D94 side chain interacts with some part of the substrate during turnover and not with any one of copper atoms in the trinuclear cluster in the free enzyme.

One unexpected finding came from these studies on Fet3p mutants. The strategy employed to produce these proteins was to 'engineer-out' the carboxyl-terminal transmembrane domain of the native protein so that following synthesis and processing, the Fet3p species produced was secreted from

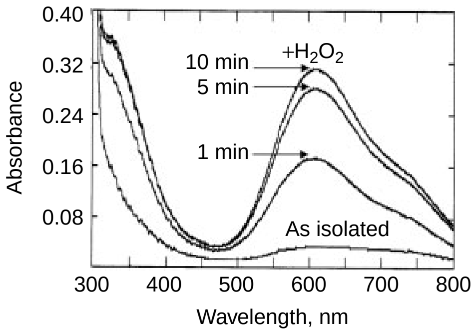

Figure 27 T2D Fet3p is fully reduced when isolated but readily reoxidizes with H_2O_2 indicating that Cu(I) is the valence of Cu trafficked to apoprotein

the cell into the growth medium; from there it was easily purified.[76] As for all MCOs, solutions (at $>100\,\mu M$) and crystals of the secreted Fet3p are azure-blue. In contrast, Fet3p forms that have oxidation-inert trinuclear clusters are colorless. These include Fet3pT2D, for example. In the protein secreted from the cell, the type 1 copper is present as Cu(I), and because electrons flow from the type 1 to the type 3 binuclear Cu pair, this cluster is also stably reduced. All three Cu are stably reduced because, lacking the type 2 Cu to supply the critical O_2-cleaving electron (in going from the peroxide to the native intermediate, Figure 11), this reduced protein cannot turn over. The reduced sites can be oxidized by peroxide or other oxidants, demonstrating, after this reaction, that these remaining sites are otherwise 'wild type'. This story is illustrated by the spectra in Figure 27. This result indicates that copper is inserted into the *apo*-Fet3p as Cu(I). This inference is fully consistent with the overall model of copper uptake and trafficking that has evolved from the study of the transporter, copper chaperone, and copper pump involved, Ctr1p, Atx1p, and Ccc2p, respectively (in yeast).[56] All three copper processing proteins handle Cu(I) in a series of transfer reactions, that, in the case of the transfer from Atx1p to Ccc2p, is a nondissociative, ligand-exchange process in which the Cu(I) does not equilibrate with bulk solvent.[56,67] The nonblue, Fet3pT2D that is secreted from the yeast cell is the end-product of this cuprous ion trafficking pathway (*see* ***Metallochaperones & Metal Ion Homeostasis***).

5 BACTERIAL OXIDASES, COPPER RESISTANCE, AND METALLO-OXIDATION

5.1 The PcoA/CueO Protein Family

Free-living organisms tend to be highly adaptable to relatively precipitous changes in their environments. In bacteria, this adaptation is often due to the acquisition of episomally encoded enzymatic activities; penicillin resistance due to β-lactamase inhibitors is a well-known example. Resistance to metal ions that at some level of exposure are toxic is another, albeit less well advertised one. In *E. coli*, this resistance is due in part to the *pco* metabolic pathway encoded on plasmid pRJ1004[77] while in *Pseudomonas syringae* the homologous *cop* system is encoded on plasmid pPT23D.[78] Among the enzymes found in this pathway is an MCO that in *E. coli* is known as the PcoA protein; an homologous CopA protein is found in *P. syringae* (not to be confused with the chromosomally encoded CopA Cu-ATPase in *E. coli*). Although the spectral and chemical properties of these proteins have not been determined, they are suggested to act to both sequester copper [perhaps as Cu(I)] and catalyze the oxidation of Cu(I) to Cu(II).[23,78,79]

Their metallo-oxidase activity is inferred from two facts. First, the bacterial chromosome also encodes an MCO that has been linked to copper resistance, also. In *E. coli*, this is the CueO protein (previously YacK), but similar MCOs have been identified in all bacterial genomes archived, including that of *Pseudomonas aeruginosa*. That these proteins are MCOs is indicated by their oxidase activity (e.g. towards aromatic phenols and amines), and, in the case of CueO, by extensive biophysical studies including X-ray crystallography.[23,80] The second fact is that PcoA can partially complement the absence of CueO in regards to the copper sensitivity of a Δ*cueO Pseudomonas* mutant strain indicating that PcoA exhibits CueO-like activity.[78] What this physiological activity is, however, has not been directly demonstrated. The hypothesis is that these proteins act as cuprous oxidases, reducing the steady-state level of the redox-active, Cu(I), a known pro-oxidant. There are no enzymatic activity data with either enzyme that support this hypothesis; their correlation with bacterial copper resistance is the only observation that does. However, one aspect of the structure of CueO that is consistent with a role in Cu(I) binding, at least, is the presence of a Met-rich region that is absent in the 'classic' MCO. This motif, that roughly starts at the beginning of the third cupredoxin domain, is shown below in its entirety although there is no evidence that this whole element is required for function.

355 <u>M</u>DPML<u>D</u> MMGMQMLMEK YGDQAMAGMD
HSQMMGHMGH GNMNHM 396

However, an equivalent Met-rich sequence is found in tens of bacterial PcoA homologues indicating that whatever this motif's function, it could be highly conserved. A related Met-rich sequence is found in the much smaller PcoC protein that a variety of spectral studies have shown binds Cu(I)[81] and Cu(II).[82]

This region is illustrated in Figure 28 that gives several views of the structure of CueO.[23,80] The significant difference in the structure of CueO in comparison to that of AO or Lac, for example, is the helix that 'covers' access to the

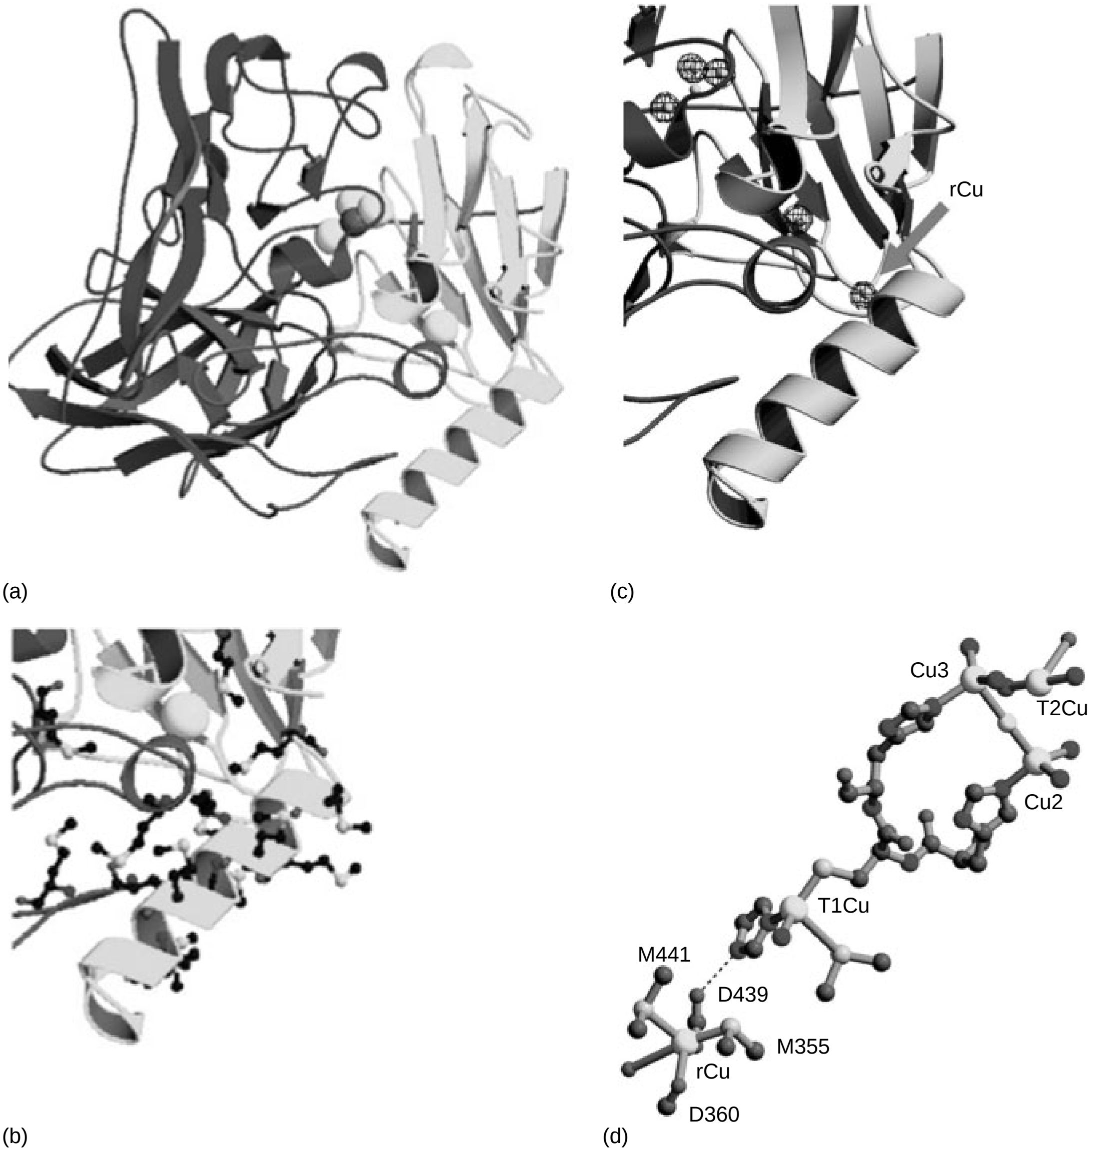

Figure 28 Views of the Met-rich, Cu-binding site adjacent to the T1 copper in CueO (S. A. Roberts, A. Weichsel, G. Grass, K. Thakali, J. T. Hazzard, G. Tollin, C. Rensing, and W. R. Montfort, Proc. Natl. Acad. Sci. USA, 2002, 99, 2766–2771. © 2002 National Academy of Sciences, USA)

T1 site (Figure 28a). An expanded view of this Met-rich helix is shown in Figure 28(b). Although copper binding to this region in CueO has not been demonstrated spectrally (e.g. by EXAFS), a 'labile' copper is observed bound in CueO crystals soaked with $CuCl_2$. The difference Fourier that identifies this Cu is shown in Figure 28(c). The binding of this Cu(II) (precisely, the redox state of the copper atom is not known, however) is specific, involving ligation to two Met thioether S atoms, and two Asp carboxylates. One of these carboxylates appears H-bonded to the (noncoordinating) NHε2 of H443 at the type 1 Cu site in CueO. This H-bonding network is shown in Figure 28(d); it provides an attractive electronic matrix coupling pathway for electron transfer into the type 1 Cu(II) although that analysis has not been reported. Note that only two of the four ligands to this labile Cu come from the Met-rich motif noted above – M355 and D360 (highlighted) – and neither of these residues is actually in the helix that restricts solvent exposure of the type 1 site (Figure 28). Furthermore, the other two ligands come from a ^{438}GDMM^{441} motif that is part of a subsequent strand of β-sheet. In other words, the structural genomics of the bacterial MCOs and their relationship to the structure-function relationships in other copper-handling proteins remain to be fully elucidated.

However, cupric ion does stimulate the oxidase activity of CueO with a kinetic K_M for this dissociable Cu(II) of 0.16 mM.[78] Structure-activity studies on CueO mutants confirm that this activation is likely due to Cu(II) binding at the Met-rich region. Substitution at any one of the Cu-binding residues seen in the structure (Figure 28d) increased the Cu(II) K_M; most striking are the 10- and 500-fold increases seen in the D360A and M355L mutants, respectively.[80] While these studies clearly demonstrate Cu-binding to this region in CueO – and likely, therefore, to the same region in the other 'Met-rich' homologues – and demonstrate the catalytic activation associated with this Cu-binding, they do not resolve the question of the physiological substrate specificity and function of these bacterial MCOs. There is some evidence that these MCOs may target phenolic siderophores such as enterobactin,[83] although the physiological outcome of that reaction remains obscure.

On the other hand, the *P. aeroginosa* MCO exhibits a molecular activity (k_{cat}) with Fe^{2+} as substrate of $\sim$10 min^{-1}, similar to the rate measured for Fet3p. In addition, deletion of the gene encoding this MCO reduced bacterial iron uptake by ca. 70%. The data suggest that this MCO is involved in iron uptake via its ferroxidase activity much as Fet3p functions in yeast. In contrast to data reported in *E. coli*, the *P. aeruginosa* MCO was not required for copper resistance.[84] Indeed, CueO does have an activity towards Fe^{2+} that is comparable to its oxidase activity,[83] so it and the other bacterial MCOs could be involved in iron acquisition as well. The significance of this possibility is the known correlation between iron availability and bacterial pathogenicity.[85] The bacterial MCO could be a critical element in this correlation. Clearly, the role of bacterial MCOs in the metabolism of copper and iron remains to be fully understood.

5.2 MCOs As Metallo-oxidases: Metabolism and Resistance

However, there is evidence that MCOs do have oxidase activity towards low-valent metal ions other than Fe^{2+}, specifically, Mn^{2+} and Cu^{1+}. Furthermore, this activity does correlate with a specific aspect of metal metabolism. In the case of phylogenetically distinct bacteria, an MCO with Mn^{2+} oxidase activity is likely involved in the remarkable resistance bacterial spores have towards environmental insults. The mnxG protein in the spore coat of *Bacillus* strains and the cumA protein in the plasma membrane of *Pseudomonas* strains oxidize environmental Mn^{2+} to form $Mn^{III/IV}$ oxides that precipitate on the cell surface, eventually encrusting the organism. This oxidation has been demonstrated histochemically (e.g. formation of the brown Mn oxides on bacterial colonies on plates or associated with MCO protein bands in acrylamide gels) but the proteins have not been characterized in vitro. However, one curious aspect of the *Bacillus* mnxG protein (but not the *Pseudomonas* cumA one) is that the cupredoxin domains are in the 'order' 2-3-1. If the chain-fold in mnxG is equivalent to that found in the 'normal' MCO, this sequence (shown below) places the trinuclear cluster between the 2nd and 3rd cupredoxin domains (rather than the 1st and 3rd ones) and the overall relationship between the copper clusters would be the mirror image of that illustrated in the several MCO structures above. The MCO from *Nitrosomonas europaea* (which, in addition, appears to have six cupredoxin domains) has a similar 'inverted' domain structure;[13] both sequences are illustrated below.

mnxG protein	*Nitrosomonas europaea* MCO
^{281}HVFHYH	^{451}HVFHLH
^{334}HCHLYPH	^{521}HCHLYPH
^{528}HIH	^{877}HIH
^{574}HDH	^{998}HDH

The Fox1 protein from the blue-green algae, *Chlamydomonas reinhardtii*, a plant homologue of the Fet3p ferroxidase involved in iron uptake, has a similarly inverted domain pattern (*cf* Figure 4).[86] None of these 'unusual' MCOs have been chemically characterized.

Although the cuprous oxidase activity proposed for the bacterial copper resistance MCOs has not been demonstrated (above), it has been for the yeast ferroxidase, Fet3p, and for the human ferroxidase, hCp.[87] The cuprous oxidase and ferroxidase activities of the two enzymes are comparable with K_M values for Cu^{1+} as substrate $\sim$35 µM in comparison to the $\sim$5 µM value with Fe^{2+} as substrate. The k_{cat} values with the two substrates are nearly the same. In yeast, this cuprous oxidase activity does correlate with copper resistance. For example, yeast deficient in Fet3p are two- to threefold more sensitive to copper added to the medium as Cu^{2+}. This sensitivity is suppressed if the plasma membrane metalloreductase, Fre1p, is also absent indicating that the toxic species is Cu^{1+}. The protection towards copper afforded by Fet3p is likely to be the maintenance of a low steady-state concentration of Cu^{1+} at the plasma membrane due to the enzyme's cuprous oxidase activity. hCp reasonably plays a similar role in mammalian cell copper homeostasis, although this inference has not been experimentally tested. Putting metal ion speciation aside, one might assume that any metal with a reduction potential low enough to provide an adequate driving force for the reduction of the type 1 Cu(II) – for most MCOs this would be $<$400 mV or so – would support MCO-catalyzed O_2 turnover. This would include Fe^{2+} and Cu^{1+} in many ligand environments, as well as Mn^{2+}. The question then becomes what other Marcus factors serve as 'specificity' elements in the substrate selectivity exhibited by an MCO. In the end, MCO substrate specificity centers on the same questions about the origin of efficient electron transfer that have engaged bioinorganic chemists for the past two decades.

Glossary

β-barrel: a roughly cylindrical arrangement of strands in a protein
Resolution (in Å): the minimum interplanar spacing of reflections used in single-crystal diffraction analyses

Abbreviations

P. aer. = *Pseudomonas aeruginosa*; *A. den.* = *Alcaligenes denitrificans*; MCD = magnetic circular dichroism; EPR = electron paramagnetic resonance; XAS = X-ray absorption spectroscopy; NMR = nuclear magnetic resonance; EXAFS = extended X-ray absorption fine structure.

1 INTRODUCTION

Type 1 or 'blue' copper proteins were among the first to be isolated and as such, they have played a long-standing and distinguished role in the development of bioinorganic chemistry. Proteins of the type 1 class are defined as containing a copper-binding site with the following properties: (1) an intense blue color in the Cu(II) oxidation state which results from a strong visible absorption near 600 nm; (2) a small hyperfine coupling constant in the EPR (electron paramagnetic resonance) spectrum, and (3) a relatively high redox potential when compared with values found for 'typical' copper complexes. The unique characteristics of type 1 copper proteins have also been a major driving force in the development of the 'entatic' or 'rack' concept in metalloproteins[1,2] (reviewed in,[3–5] *see* ***Long-range Electron Transfer in Biology***), which states that the blue copper coordination is not dictated by the presence of the metal ion *per se*, but is instead predetermined by the energetic constraints of the polypeptide that forces a geometry that effectively accommodates both Cu(I) and Cu(II) coordination states. This coordination geometry is believed to confer distinct functional advantages, particularly in long-range electron-transfer processes. Given the above, it is not surprising that extensive chemical and physical approaches have been directed toward a comprehensive understanding of the properties of the type 1 copper site over the last 35 years.

Type 1 copper sites are found in both small, single copper-containing proteins as well as in larger, multicopper-containing proteins. The latter, in addition to their blue copper sites, contain other copper atoms with different characteristics that leads to the classification of their sites as type 1, type 2, or type 3[6,7] (*see* ***Copper Proteins with Type 2 Sites***; ***Copper Proteins with Dinuclear Active Sites***; ***Copper Proteins: Oxidases***). This general review will focus primarily on the small, single polypeptide blue copper proteins that contain only type 1 copper. Their simplicity and small size have made them amenable to structural analyses as well as attractive targets for mutagenesis studies. Because they also serve as models for the blue copper sites found in the more complex multicopper proteins, the spectroscopic properties of the type 1 sites will on occasion be compared to those found in nitrite reductase or laccase. The first part of this review provides an inventory of the occurrence, distribution, and classification of blue copper proteins based on analyses of genomic and expressed sequence tag data. The second part provides information on the overall architecture of these proteins as well as an inventory of the three-dimensional structures of blue copper proteins as determined by X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy. The last part discusses the electronic, spectroscopic, and electron-transfer properties of these proteins.

A number of excellent reviews on this subject are available. Some are general, covering biological, chemical, and physical aspects[8–16] while others concentrate on structure,[17] spectroscopy,[18,19] or electron transfer.[20,21] A short, very readable review by Gray and colleagues[5] is particularly recommended to the general reader.

2 OCCURRENCE, CLASSIFICATION, AND BIOLOGICAL ROLES

2.1 Overview

Blue copper proteins have been purified and biochemically characterized from *Archaea*, *Bacteria*, and *Eukarya*. Such ubiquitous distribution suggests an important ancient role. A survey of sequence databases reveals genes encoding blue copper proteins that display characteristics often quite different from those of well-studied canonical (traditional) blue copper proteins. For example, there are modular proteins where the domains that bind type 1 copper are fused with structurally distinct and evolutionarily unrelated sequence motifs (Figure 1). While these additional domains do not usually contribute directly to the function of a blue copper protein, they do so indirectly by facilitating protein translocation to a specific cellular compartment. Together, these blue copper proteins can be combined into a large superfamily which can be subdivided into three classes as described below.

Proteins of the first class are composed of only a single type 1 copper-binding domain in their mature form. They are known as cupredoxins after the suggestion by Adman that they function analogously to the iron-containing ferredoxins.[12] These include plastocyanin, azurin, pseudoazurin, amicyanin, auracyanin, rusticyanin, halocyanin, and sulfocyanin. The second class includes multidomain blue copper proteins, which are composed exclusively of two (nitrite reductases), three (laccases and ascorbate oxidase), or six (ceruloplasmin and hephaestin) domains. The proteins of the third class display a mosaic/chimeric domain organization in which the blue copper domains are fused with structurally unrelated sequence motifs. These include plant stellacyanins, uclacyanins, and dicyanins. The proteins in the first and third classes are the focus of this review. The proteins in the second class are discussed elsewhere (*see* ***Copper Proteins: Oxidases***).

2.2 Copper-binding Site and Sequence Characteristics

The copper ion is bound to the protein via imidazole nitrogens from two His residues and a thiolate from a Cys residue, which form a pseudotrigonal plane. These three equatorial ligands are found in all naturally occurring type 1 sites. In most cases, a fourth ligand coordinates the copper ion in an axial position, pulling it out of the pseudotrigonal plane. The nature of this axial interaction is partially responsible for the subtle differences in the electronic structure of blue copper sites and for the tuning of their redox potentials, which range from +165 mV to +800 mV (see Section 5.1). The vast majority of blue copper sites have a weakly coordinated thioether from a Met residue or more rarely, a strongly coordinated oxygen from a Gln side chain. However, amino acid sequence alignments indicate that in some instances the protein does not provide any ligating residue at the axial position. In these cases, the noncoordinating amino acid is a Leu, Phe, Ile or Val.

Three of the four copper ligands, His, Cys, and the axial ligand, are located together at the C-terminus in the copper-binding loop (Figures 1 and 3). The fourth ligand, also His, is approximately 40-amino acids N-terminal of this triad. The length (determined by the number of amino acids separating ligating residues) and the composition of the copper-binding loop are important indications for the phylogenetic relationships between blue copper proteins (see Section 3.5.3).

2.3 Subcellular Localization and Function

All type 1 copper proteins, with the exception of plastocyanin, possess an ∼20-amino acid N-terminal signal peptide (Figure 1). These peptides help the proteins translocate

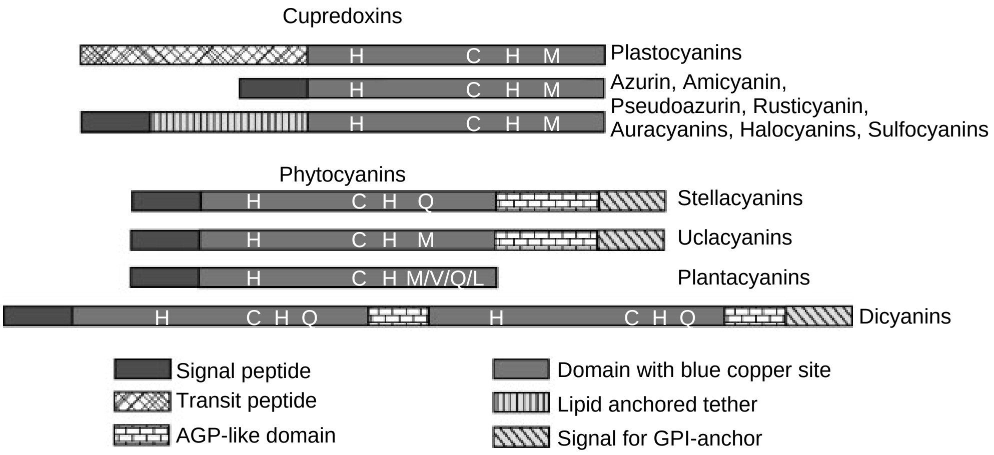

Figure 1 Domain organization of the precursors of type 1 copper proteins in the cupredoxin and phytocyanin families. Positions of copper ligands are indicated by single letter codes

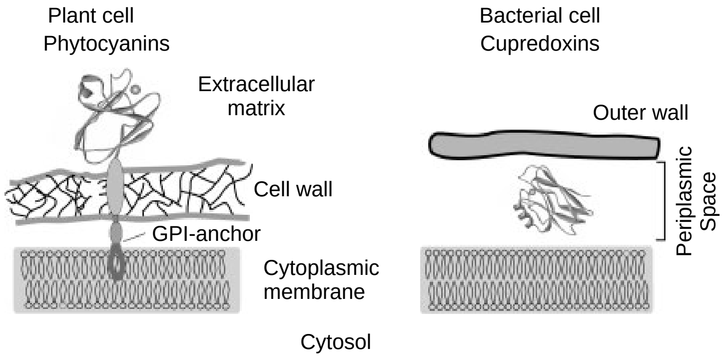

Figure 2 Localization of phytocyanins and cupredoxins in plants and bacteria

across the bacterial cytoplasmic membrane into the periplasmic space (Figure 2). In eukaryotes, the signal peptides target blue copper proteins to the endoplasmic reticulum where they enter the secretory pathway that subsequently directs them into the extracellular milieu. Plant plastocyanins are targeted to the chloroplast. Although most cupredoxins are freely diffusible, some of them are attached to the cell surface via an N-terminal lipid modified anchor. Those with an additional C-terminal hydrophobic sequence (a signal for covalent modification with a glycosylphosphatidylinositol, GPI, moiety) are also anchored to the cell surface (Figure 2).

Not surprisingly, the proteins harboring type 1 copper sites are involved in a diverse array of vital cellular processes. They are crucial components of (1) the electron-transfer chains used in bacterial energy conversion; (2) the photosynthetic apparatus in plants, cyanobacteria, and algae; and (3) the plant-defense response against attacking pathogens.

2.4 Cupredoxins

Cupredoxins are found primarily in *Bacteria* and in *Archaea*. None have been identified in vertebrates, nematodes, insects or unicellular eukaryotes, but they do exist in plants. Where their function has been established, they act as freely diffusible electron-shuttle proteins in a variety of electron-transfer chains for energy conversion.

2.4.1 Plastocyanin

Plastocyanins are the most widely studied cupredoxins. They are one of the most abundant copper proteins in plant photosynthetic tissues.[22] Plant plastocyanins have an intricate evolutionary history because of their ancient bacterial origin. It is currently well accepted that plants diverged from the main eukaryotic domain into a separate lineage when the unicellular, oxygen respiring common ancestor of the eukaryotes incorporated a prokaryotic endosymbiont, the cyanobacterial chloroplast.

Plant plastocyanins are synthesized in the cytosol as 160–170-amino acid precursor polypeptides consisting of a 60–70-residue transit peptide followed by a 97–99-amino acid mature protein.[23] The transit peptide imports the precursor plastocyanin molecule across the chloroplast envelope and thylakoid membranes to its final destination in the thylakoid lumen, where it shuttles electrons by accepting them from the membrane bound cytochrome f (cyt f) of the cyt $b6/f$ complex and donating them to the photooxidized reaction center P700+ of photosystem I. Cyanobacterial plastocyanins use an ~30-amino acid leader sequence for thylakoid membrane translocation. Currently, there are more than 100 plant and cyanobacterial plastocyanin sequences that are available either by direct protein sequencing or deduced from the nucleotide sequences of their genes.

2.4.2 Azurin

The amino acid sequence of azurin from *Pseudomonas fluorescens* was reported in 1964,[24] one of only a few dozen protein sequences available in the mid-1960s. Currently, more than thirty sequences of azurins are available. The azurin gene was one of the first cupredoxins to be cloned in 1987,[25] which led to the generation of mutant proteins. This made azurin an attractive model system for redesigning blue copper sites[15] and the information gained from these mutagenesis studies has had a significant impact on our understanding of many of their properties. Azurin has also been extensively applied as a useful model protein for characterizing long-range electron-transfer processes within a polypeptide matrix.[21] The redox partners of azurin remain largely unknown, although it has been implicated in anaerobic nitrite respiration.

2.4.3 Pseudoazurin and Amicyanin

Pseudoazurins are found in bacteria which under limited oxygen conditions are capable of using nitrate/nitrite as an energy source. They are key components of the electron-transfer chain that sequentially reduces NO_3^-/NO_2^- to

molecular nitrogen. Pseudoazurin donates electrons to another blue copper protein, nitrite reductase. However, the biological electron donor of pseudoazurin has not yet been identified.

Amicyanin is found in methylotrophic bacteria that can use methylated amines as an energy source. The inactivation of the amicyanin gene in *Paracoccus denitrificans* results in complete loss of its ability to grow on methylamine,[26] a direct indication that amicyanin is a key component of the methylamine driven electron-transfer chain. Amicyanin accepts an electron from methylamine dehydrogenase and transfers it to a *c*-type cytochrome (see Section 5.4.5). Currently, more than a dozen amicyanin and pseudoazurin sequences are available.

2.4.4 Rusticyanin

Rusticyanin is found in *Thiobacillus ferrooxidans*, an acidophilic, chemolithotrophic sulfur bacterium utilizing Fe^{2+} and reduced sulfur compounds as its sole energy source.[27] *T. ferrooxidans* does not produce rusticyanin when grown on reduced sulfur. Similar to other substrate-inducible cupredoxins, the rusticyanin gene is activated when soluble iron is present in the media. Little is known about its redox partners and it should be noted that rusticyanin itself does not carry out Fe^{2+} oxidation. Other iron-oxidizing bacteria, for example, *Leptospirillum ferrooxidans*, produce a cytochrome which substitutes rusticyanin functionally. To date *T. ferrooxidans* remains the only source for rusticyanin.

2.4.5 Halocyanin and Sulfocyanin

Halocyanin and sulfocyanin are archaebacterial cupredoxins that are attached to peripheral membranes through a lipid anchor at their N-terminus. Halocyanin was the first cupredoxin purified from an archaeon, haloalkaliphilic *Natronobacterium pharaonis*.[28] These cells live in high pH (around 10–11) and in extreme salinity (30%) environments. The presence of the blue copper protein, sulfocyanin in *Sulfolobus acidocaldarius* was first predicted from its gene sequence.[29] It has been subsequently purified as a recombinant protein and shown to bind a single copper ion with spectroscopic properties typical for a blue copper site.[30]

The sequences of halocyanin and sulfocyanin, deduced from their gene sequences, have unusually long N-terminal extensions. These extensions feature a hydrophobic signal peptide which is followed by a segment that in the case of halocyanin has an Asn-Gly doublet occurring consecutively seven times.[31] In sulfocyanin, this segment is rich in Ser residues. It is believed that these extensions are covalently modified by a lipid moiety which anchors the proteins to the cell membrane.

The function of these proteins is not known. The sulfocyanin gene is positioned in the same operon with the components of the respiratory electron-transfer chain, and it therefore has been implicated as a direct electron donor for the Cu_A-containing terminal oxidase.[32]

2.4.6 Auracyanin

Two distinct cupredoxins labeled auracyanin A and B have been characterized from the gliding thermophilic photosynthetic bacterium *Chloroflexus aurantiacus*,[33] which is only distantly related to other photosynthetic organisms and appears to have acquired its photosynthetic capabilities by lateral gene transfer. The two forms of auracyanin are distinctly different from each other with respect to their amino acid sequences and the spectroscopic properties of their blue copper sites. In addition, auracyanin B is glycosylated while auracyanin A is not.

Like halocyanin and sulfocyanin, auracyanin B has an N-terminal extension that is thought to anchor the protein to the cell membrane. In contrast to those proteins, however, this extension is rich in Pro, Ala, and Thr residues. In auracyanin A, they are Gly residues.[34]

Numerous other putative members of the cupredoxin family can be identified in the GenBank database (http://www.ncbi.nlm.nih.gov). Many of these sequences display remote similarities to other cupredoxins and they therefore cannot be attributed to any of the above described traditional groups.

2.5 Phytocyanins

Phytocyanins are plant-specific proteins distinctly different from plastocyanins, azurins, and other cupredoxins of archaeal and bacterial origin with respect to sequence, structure, and function. Phytocyanins constitute one of the largest gene families in plants. For example, rice and *Arabidopsis thaliana* house, respectively, 57 and 39 distinct phytocyanin genes. More than 300 full-length sequences of phytocyanin precursors deduced from either genomic DNA or cDNA are currently available. Phytocyanins are further classified into three subfamilies: stellacyanins, plantacyanins, and uclacyanins.[16] This classification is based (1) on their spectroscopic properties, (2) on precursor as well as mature protein domain organization, and (3) on identity or availability of residues that are involved in blue copper binding.

With the exception of the plantacyanins, phytocyanins are chimeric proteins in their mature forms. They are composed of two structurally distinct sequence motifs, a 100–109-amino acid blue copper domain followed by a domain that varies in length between 30–220 amino acids, lacks any obvious consensus sequence, but resembles heavily glycosylated arabinogalactan proteins (AGP). Where such AGP domains are present, they are followed by a hydrophobic sequence predicted to provide a signal for the attachment of a GPI moiety, which anchors the protein to the cell surface (Figure 2). This cell-surface attachment of phytocyanins

via a GPI anchor has been demonstrated experimentally.[35] Intriguingly, stellacyanin, umecyanin, and mavicyanin have also been purified from plant tissues as soluble proteins, indicating that phytocyanins may be freed from their GPI anchors and released into the extracellular matrix.

2.5.1 *Stellacyanins and Uclacyanins*

Stellacyanin from the Japanese lacquer tree *Rhus vernicifera* was one of the first blue copper proteins to be described in the literature.[36] Because of its unusual spectroscopic and sequence characteristics, it has been the subject of thorough biochemical and biophysical studies. *R. vernicifera* stellacyanin possesses a Gln residue at the position of the axial Met found in all other blue copper proteins known at that time.[37] Proteins displaying spectroscopic properties similar to those of *R. vernicifera* stellacyanin have been subsequently purified from horseradish (umecyanin),[38] zucchini (mavicyanin),[39] cucumber,[40] and spinach.[41] Their sequences also feature a Gln residue at the position of the axial ligand (Figure 1). In contrast, uclacyanins have a Met residue, which is one of the main features that differentiate them from stellacyanins. Stellacyanins and uclacyanins display identical domain organization, where in their mature form they consist of both copper-binding domain and an AGP-like domain. Both subfamilies have GPI-anchoring signals in their precursors and carry several N-linked glycosylation sites in their copper-binding domains through Asn residues, as well as numerous O-linked glycosylation sites in their AGP-like domains through hydroxyproline, Ser, and Thr residues. There are five different stellacyanin genes in *Arabidopsis*, while rice has only three. In contrast, the rice genome contains twenty-one uclacyanin genes. *Arabidopsis* has eight, one of which (UCC1), has been expressed and purified from *Escherichia coli* and is the only uclacyanin for which the copper-binding abilities and spectroscopic properties have been reported.[16]

2.5.2 *Plantacyanin*

First isolated from cucumber in 1974,[42] plantacyanins have since been characterized from various other plant species. They are single-domain proteins in their mature form and neither an AGP-like domain nor a GPI-anchoring signal are found in their precursors (Figure 1). Most plantacyanins are strongly basic proteins with an isoelectric point around 10. However, there are examples displaying neutral or extremely negative surface charge characteristics with isoelectric points ranging between 4.5 and 8. Plantacyanins demonstrate relatively high-sequence identity and similar spectroscopic properties to stellacyanins, although they generally utilize a Met residue as the axial ligand. There are several exceptions where plantacyanins have Gln, Leu, or Val residues at this position. For instance, tomato plantacyanin has a Val (see Section 3.5.2). Such diversity in isoelectric points and ligand environment in plantacyanin subfamily has been previously documented for multicopper oxidase laccases. Although plantacyanins have been purified from cucumber and spinach as nonglycosylated proteins, there are some examples with a single N-linked glycosylation site.

Plantacyanin is represented in the *Arabidopsis* genome by a single gene, while rice has nine. Multiple plantacyanin sequences can also be identified in plant species such as wheat, barley, and maize. Spinach plantacyanin is 91-amino acids long and is perhaps the smallest blue copper protein known.

Domains with high-sequence identity to phytocyanins are also found in a recently identified novel class of blue copper proteins in which two such domains are fused together into a single polypeptide. One of them, dicyanin, was identified in tomato and is composed of two stellacyanin-like domains, both of which feature a blue copper-binding site with two $(His)_2$,(Cys)(Gln) ligand sets (Figure 1). These fused domains display 45–60% sequence identity with each other as well as with stellacyanins. Similar to the known mature stellacyanin sequences, both domains are followed by a 35-amino acid AGP-like domain. The dicyanin precursor harbors an N-terminal signal peptide and contains an additional C-terminal GPI-anchoring signal, suggesting that these proteins follow the same posttranslational secretory pathway as the phytocyanins.

It is also important to note that plants house a large group of phytocyanin-related proteins (22 and 24 in *Arabidopsis* and rice, respectively) that have extensive sequence identity and identical domain architecture to the stellacyanins and uclacyanins but lack the copper-ligating amino acid residues that are crucial for the formation of the type 1 copper site.[16] These copper-free proteins, known as early nodulins, share a common ancestor with metazoan ephrins, which are involved in multiple aspects of embryonal development.[43,44]

3 STRUCTURAL BIOLOGY AND BONDING

3.1 Historical Development

Although proteins containing type 1 copper-binding sites were first discovered in the early 1960s, the three-dimensional structures of these molecules remained unknown until 1978 when the structures of both plastocyanin and azurin were first determined using single-crystal X-ray diffraction methods.[45,46] In the interim, however, multiple spectroscopic approaches were employed in an effort to delineate the nature and determinants of the blue copper site.[45,47] The intense visible absorption at ~600 nm and narrow EPR hyperfine splitting suggested a distorted tetrahedral geometry, but the exact identity of the ligand set remained somewhat controversial. Evidence suggested there was likely a highly polarizable ligand, probably the thiolate sulfur of a Cys residue. Mercurials (which are known to be thiol-specific reagents) were shown to prevent the binding of

Cu(II) to apo-plastocyanin and subsequent metal-substitution experiments strongly suggested that the ∼600-nm band in the visible spectrum comes from an $S_{thiolate} \rightarrow Cu(II)$ charge-transfer.[48,49] In addition, NMR proton exchange studies by Markley and colleagues on both copper-bound and copper-free (apo) forms of spinach plastocyanin strongly suggested the presence of two His (imidazole) ligands.[50] By the time the plastocyanin and azurin crystal structures appeared, it had become generally accepted that the type 1 copper-binding site consisted of a distorted tetrahedral arrangement of two His ligands and one Cys ligand [$(His)_2$Cys], plus an unknown fourth ligand which might be Met. The fact that sequence analysis of all plastocyanins and azurins revealed a single conserved Met along with one conserved Cys and two conserved His further supported this view.[51]

3.2 Three-dimensional Structural Analyses

At this writing, the three-dimensional structures of eight different naturally occurring type 1 copper proteins are known. These include the cupredoxins plastocyanin at 1.33 Å resolution (pdb code 1PLC), azurin at 1.8 Å (pdb code 2AZA), pseudoazurin at 1.55 Å (pdb code 1PAZ), amicyanin at 1.3 Å (pdb code 1AAC), auracyanin at 1.55 Å (pdb code 1QHQ), rusticyanin at 1.9 Å (pdb code 1RCY), and the phytocyanins cucumber basic protein at 1.8 Å (pdb code 2CBP), and stellacyanin at 1.6 Å (pdb code 1JER) Atomic coordinates for these and all other single-domain type 1 copper proteins are available from the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank (PDB) and can be accessed online at www.rcsb.org/pdb/.

A keyword search will provide access to coordinate sets from all species that are currently available as well as various site-directed mutants, type 1 copper proteins substituted with metals other than copper, and ruthenated blue copper protein derivatives. Table 1 provides a summary (with references) of the structures of blue copper-binding domains elucidated using X-ray crystallography and NMR spectroscopy.

The crystal structures of these native proteins have been refined to high resolution by macromolecular standards. They remain, however, far from the atomic resolution limits of small-molecule crystal structures. Even so, there have now been enough independent structure analyses to establish the error level in the crystallographic analyses reasonably well. Guss *et al*. were particularly attentive to the question of accuracy in their analyses of various plastocyanin structures. The error in the 1.33 Å oxidized poplar plastocyanin is estimated, from comparison of models, as 0.1 Å in atomic positions, 0.04 Å in copper–ligand bond lengths, and 2.5° in copper-bond angles.[57] Comparison of poplar and algal plastocyanin indicates an error in the latter of 0.15 Å in atomic positions and 0.07 Å in copper–ligand bond lengths.[54] With regard to azurin, both *Alcaligenes denitrificans* (*A. den.)* and *Pseudomonas aeruginosa* (*P. aer*.) crystal structures have multiple copies of the azurin molecule in the asymmetric unit. This allows comparisons of these independent copies and the derivation of an error level of 0.1–0.15 Å in atomic positions generally, 0.05–0.07 Å in copper–ligand bond lengths, and 3–5° in copper-bond angles.[77,89,103]

3.3 General Structural Organization

The type 1 copper proteins discussed here are small, single polypeptide chains of 91–155 residues. They all possess a similar topological architecture that has been described as a Greek key β-barrel or β-sandwich. The barrel or sandwich is normally composed of eight parallel or antiparallel β-strands which are divided into two β-sheets (Figure 3). Amicyanin and auracyanin have β-barrels comprised of nine β-strands, while the rusticyanin β-barrel has thirteen β-strands. The β-sheets in all structures come together to bury apolar residues at the heart of the sandwich. This simple, stable structural module has been adopted and modified by a variety of other proteins including the multicopper oxidases, ascorbate oxidase, laccase, ceruloplasmin, and Fet3p (*see* ***Copper Proteins: Oxidases***) as well as proteins that do not bind type 1 copper, including immunoglobulin variable domain and copper-zinc superoxide dismutase (*see* ***Copper Proteins with Type 2 Sites***).

Although the β-barrel structure is common to all type 1 copper proteins whose structures have been determined to date (Figure 4), the regularity of the strands, the extent of hydrogen bonding between them, and the lengths of the loops that connect them vary from one protein to another. These structural variations, together with amino acid sequence differences and the presence (or absence) of various extensions to the blue copper-binding domain, differentiate the various proteins (see Section 2 above).

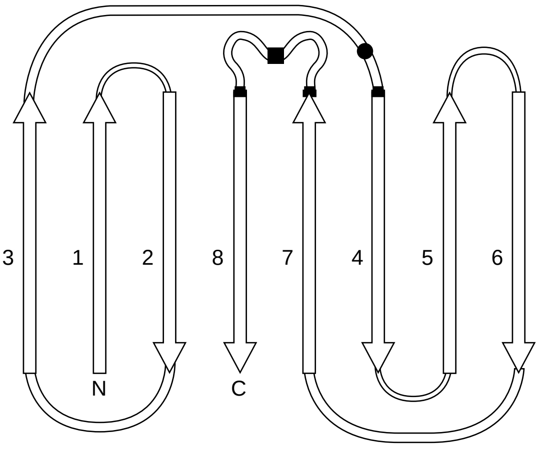

Figure 3 Topology diagram showing the connectivity of the eight extended polypeptide strands which make up the β-barrel in type 1 copper proteins. The locations of the common copper ligands and the carbonyl oxygen in azurin are shown as filled circles and squares

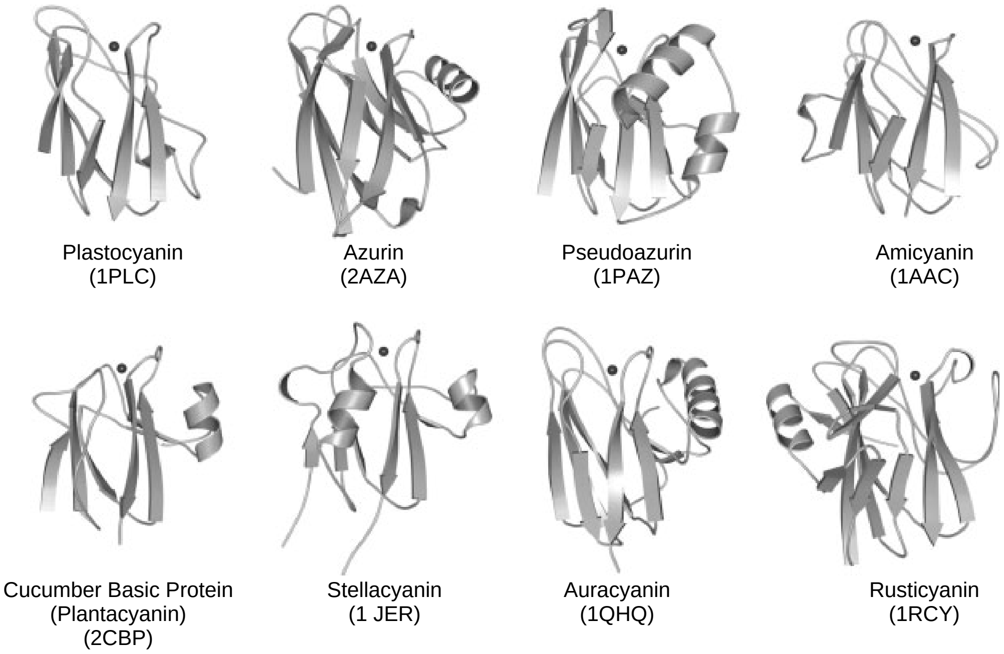

Figure 4 Polypeptide folding for eight type 1 copper proteins. In each case, the copper lies between loops at the 'northern' end of the β-barrel

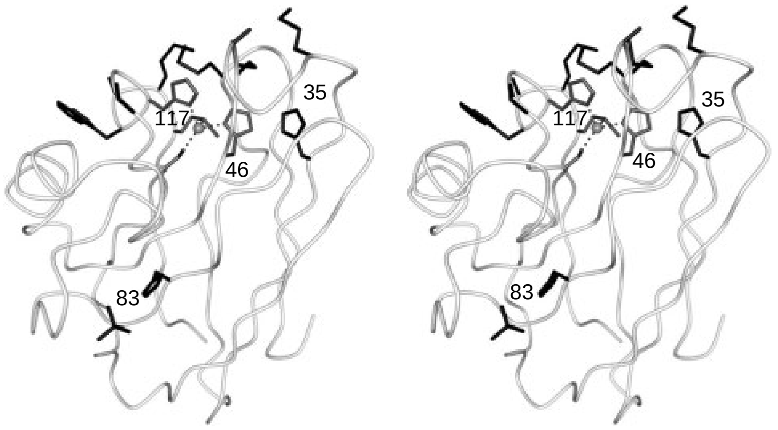

Figure 5 Stereo image of *A. den.* azurin showing (thick lines) the side chains of the hydrophobic patch (top), the His ligands 46 and 117, the conserved nonligating His residues, 35 and 83, and the bound SO_4^{2-} ion

Following the convention of Freeman and colleagues first used in the description of plastocyanin, the copper-binding site is said to be located at the 'northern' end of the molecule. Figure 4 shows that the copper ion is bound in a cavity formed by the loop elements that connect the β-strands. These loop elements and their hydrogen-bonding patterns are conserved across the family and they also provide the amino acid side chains that act as ligands to the copper ion (Figure 3). The extensive hydrogen bonding and copper–ligand interactions tend to make the northern end the most rigid part of the molecule.[77]

A feature that appears to be common to several of the proteins is a hydrophobic surface patch at the northern end (Figure 5), comprising some 5–10 apolar amino acid side chains which surround the exposed edge of one of the two copper-bound His ligands. In many other respects, however, the surfaces of the proteins are highly variable which probably reflects differing specificity in the recognition of electron-transfer partners in the different organisms.

3.4 Polypeptide Chain Variations

Plastocyanin (97–105 residues) represents the nearly minimal structural module for binding type 1 copper. The N-terminus is at the beginning of strand 1 of the barrel and the

C-terminus is at the end of strand 8. Seven of the eight strands are extended in a β-conformation (the other, strand 5, is less regular with several kinks and one α-helical turn and does not participate in the β-sheet hydrogen bonding), and the loops between strands are all relatively short.

Azurin (128–129 residues) has a more regular β-barrel than plastocyanin. All eight of the strands are extended and incorporated in the β-sheet hydrogen bonding.[77] Relative to plastocyanin, however, azurin has approximately 30 extra residues which are accommodated in two regions, the loops joining strands 3 and 4 and strands 4 and 5. The 3–4 loop is at the 'northern' end of the molecule, to one side of the copper site. The expansion of this loop by ~5 residues contributes to the somewhat more buried copper site in azurin and is probably responsible for the closer approach of a peptide carbonyl oxygen to the copper (see Section 3.5.2). The 4–5 loop in azurin contains ~15 extra amino acids compared with that in plastocyanin which creates an extra 'flap' on the azurin surface, made up of a three-turn α-helix and a series of tight turns. This 'flap' is an appendage on the surface of the barrel. It does not disturb the β-sheet structure or the copper site although it does help create a slightly larger hydrophobic patch at the northern end of the protein and it covers a region which forms an acidic patch in plastocyanin (see Section 5.4.3).

Pseudoazurin (123–124 residues) closely resembles plastocyanin in many respects. It has a minimal β-barrel with short connecting loops. Strand 5 contains fewer residues than the equivalent strand in plastocyanin, however, as it has a regular, extended β-structure without the extra kinks and loops of plastocyanin. The major difference is the presence of an extra 25 residues at the C-terminal end of the polypeptide chain; these form two α-helices which pack on the surface of the β-barrel in a location adjacent to but structurally distinct from the 'flap' in azurin.

The structure of amicyanin (99–106 residues) also more closely resembles that of plastocyanin than azurin as shown by both sequence comparisons[128] and the crystal-structure data.[113,115] It has short connecting loops and no 'flap'. Strand 5 is shorter and more regular than that in plastocyanin. Amicyanin, however, has an extension at the N-terminal end of the polypeptide chain (rather than the C-terminus as in pseudoazurin); the extra ~20 amino acids form a ninth β-strand which extends the β-barrel by hydrogen bonding to the exposed edge of one of the two β-sheets (i.e. to strand 6 in Figure 3).

Plantacyanins, such as cucumber basic protein (96 residues) and the plantacyanins from spinach (91 residues) and tomato (95 residues), have a somewhat less regular β-barrel, but with no external appendages. Part of strand 1 and all of strand 2 have irregular conformations with kinks and turns, and strands 4 and 5 are twisted out from the general orientation of the β-barrel; thus the structure, although it consists of eight strands, more closely resembles two 3-strand β-sheets packed together. This twisted barrel conformation is stabilized by a disulfide bond at the northern end of the molecule between Cys residues of the 4–5 and 7–8 loops. The presence of this disulfide bond is one of the factors that distinguishes phytocyanins from other blue copper proteins.

Cucumber stellacyanin (110 residues in soluble form) is much more similar to plantacyanins than any of the other blue copper proteins described above. It possesses a 5-residue insertion that creates a larger 1–2 loop as well as a two-turn α-helix that is absent in CBP. Unlike the soluble blue copper-binding domains described above, however, mature cucumber stellacyanin contains a C-terminal AGP-like domain that may help the protein to be integrated into the cell wall. TheN- and C-terminii are both longer than those found in plantacyanins like CBP (Figure 4). Thus, its function may be different than those freely diffusible proteins thought to be involved in long-range electron-transfer reactions.

Auracyanin (140 residues) is much more similar to azurin structurally than the other blue copper proteins except that it has an additional N-terminal β-strand that hydrogen bonds to strand 6, giving the barrel a total of nine strands. The positions of the 'flaps' are also similar in azurin and auracyanin, although the position of the α-helix differs slightly.

Rusticyanin (155 residues) has a similar topology to azurin except that the core of the molecule is a β-sandwich of two mixed β-sheets, one of six and one of seven strands. Rusticyanin contains a substantial N-terminal extension relative to azurin that includes a β-strand followed by an α-helix followed by two β-strands that are connected by a β-hairpin. Thus, the fourth β-strand in rusticyanin corresponds to the first in azurin. The 'flap' in rusticyanin is in a structurally analogous position to that in azurin, except that it does not contain an α-helix.

3.5 The Type 1 Copper Site

High-resolution crystallographic studies of type 1 copper proteins supplemented by EXAFS (extended X-ray absorption fine structure) data and analyses of sequence conservation show that the archetypal type 1 copper site has certain constant features. There exist several excellent reviews.[16,17,19] For reference, the copper sites in plastocyanin, azurin, tomato plantacyanin, and cucumber stellacyanin are shown in Figure 6.

3.5.1 The Basic Trigonal N_2S^- Ligand Set

The copper atom is coordinated to three equatorial ligands, two imidazole nitrogens and one thiolate sulfur, in an approximate trigonal planar arrangement. Bond lengths are 1.9–2.2 Å (Table 2A) and bond angles irregular, ranging from ~97° to 138° (Table 2B). The three ligands are His 37, Cys 84, and His 87 in poplar plastocyanin; His 46, Cys 112, and His 117 in *P. aer*. azurin; His 39, Cys 79, and His 84 in tomato plantacyanin; and His 46, Cys 89, and His 94 in cucumber stellacyanin (Figure 6). The same equatorial N_2S^- ligand set is found in all type 1 copper proteins characterized

[a]Ligands identified as in Figure 6.

to date. The geometry is highly conserved. The Cu–N bond lengths at ∼2.0 Å are normal for imidazole ligands, but the Cu–S(thiolate) bond is short, at 2.07–2.26 Å. This short Cu–S bond is a key feature of the blue copper site. The bond angles within the pseudotrigonal plane average 101°, 117°, and 134° in the eight oxidized structures (plastocyanin, azurin, pseudoazurin, amicyanin, cucumber basic protein, cucumber stellacyanin, auracyanin, and rusticyanin), determined at resolutions better than 2.0 Å, with rms deviations of 2.5°, 4.1°, and 2.8°. The thiolate sulfur geometry is also highly conserved; the Cu–Sγ–Cβ–Cα and Sγ–Cβ–Cα–N dihedral angles are always near 180°, so that the Cu–Sγ bond is coplanar with the Cys side chain atoms and part of the polypeptide backbone.[129]

3.5.2 *Axial Interactions*

In addition to the equatorial ligating interactions, longer axial interactions with the copper are made by other groups which can vary among different type 1 copper proteins. In poplar plastocyanin, Met 92 provides a fourth ligand, through its thioether sulfur, although at a much longer distance (2.82 Å) than the other three ligands. It thus completes an N_2SS^- ligand set with a distorted tetrahedral or trigonal pyramidal geometry, in which the copper atom is displaced 0.36 Å from the N_2S^- plane towards the thioether S ligand (Figure 6a). (Note that the displacement in a regular tetrahedron would be ∼0.7 Å.).

In *P. aer.* azurin there are two long axial approaches, one from the thioether sulfur of Met 121, equivalent to Met 92 in poplar plastocyanin, and the other from the peptide carbonyl oxygen of Gly 45 (Figure 6b). Their distances from the copper are 3.3 and 2.6 Å, respectively. In this Cu–O interaction, the oxygen is buried in a nonpolar environment with no other possible partner for polar interactions and the geometry is right for interaction with an oxygen lone pair.[77] Thus, the azurin geometry may best be described as distorted trigonal bipyramidal. The copper accordingly lies almost directly in the trigonal N_2S^- plane.

Cucumber basic protein, amicyanin, auracyanin, and rusticyanin more closely resemble plastocyanin than azurin in their copper sites. The axial Cu–S(Met) distances are all similar to that seen in plastocyanin (CBP has the shortest Cu–S(Met) distance at ∼2.6 Å); the copper atom is displaced ∼0.2–0.4 Å out of the N_2S^- plane towards the S(Met) ligand, giving a distorted tetrahedral or trigonal pyramidal geometry, and the carbonyl oxygen equivalent to that in azurin is much farther away (∼3.8 Å). The lack of a Cu–O interaction in these proteins and in plastocyanin may result from a shortened 3–4 loop. Tomato plantacyanin contains a Val residue at the axial ligand position and thus possesses only the N_2S^- ligand set (Figure 6c).

Stellacyanin contains no Met and before its structure was known, it was speculated that sulfur from a disulfide bond binds to copper in place of the Met ligand.[130] Sequence alignments (Figure 1), model building based on the highly homologous cucumber basic protein structure, and physicochemical arguments all suggested, however, that the amide group of a Gln side chain takes the

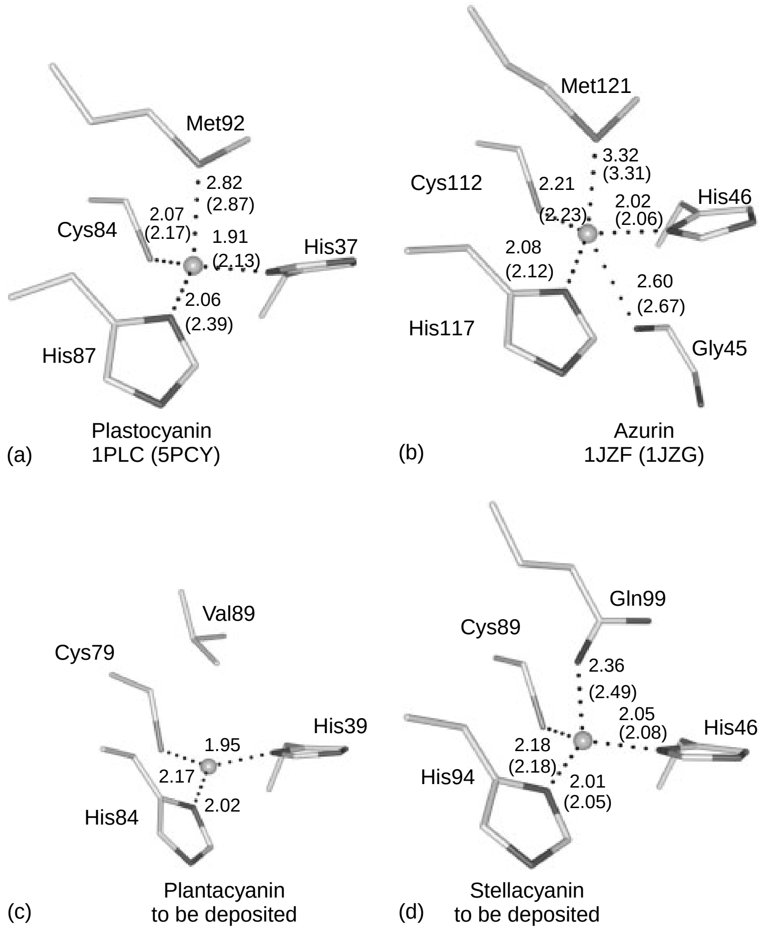

Figure 6 Copper sites in (a) poplar plastocyanin, (b) *A. den.* azurin, (c) tomato plantacyanin, and (d) cucumber stellacyanin. Distances are for the oxidized form, with those for the reduced form in parentheses

place of Met in the coordination sphere.[131] This is indeed the case, as was observed in the crystal structure of cucumber stellacyanin[120] which is found to have a short Cu–O–(Gln) bond of 2.21 Å in the 1.6 Å structure and 2.36 Å in the newly refined 1.2 Å structure. This bond lengthens to 2.5 Å in the structure of the reduced protein at 1.45 Å resolution (Figure 6d). The spectroscopic properties of cucumber stellacyanin are nearly identical to that of the protein from *Rhus vernicifera*.[132]

3.5.3 Copper-binding Loops

The copper ligands are contributed by two loops of polypeptide chain (Figure 3). The first His ligand and the peptide carbonyl oxygen (where this is close enough to be considered a ligand) are at the end of the loop joining β-strands, 3 and 4 (or the structurally analogous strands in amicyanin, auracyanin, and rusticyanin); in fact the His can be considered the first residue of strand 4. The three remaining ligands belong to the loop joining strands 7 and 8 (or their structural analogs). The Cys is the last residue of strand 7, the second His is in the middle of the loop, and the Met (Gln) is the first residue of strand 8. The 7–8 loop also plays a critical part in forming one wall of the copper-binding cleft and in contributing side chains to the hydrophobic patch surrounding the second His. Many of the functional variations between different type 1 copper proteins can be traced to variations in this loop.

The 3–4 loop is clearly shorter in plastocyanin, pseudoazurin, and amicyanin than in azurin, auracyanin, and rusticyanin, and shorter still in cucumber basic protein, tomato plantacyanin, and cucumber stellacyanin. The azurin, auracyanin, and rusticyanin copper sites are correspondingly the most buried and cucumber basic protein, spinach plantacyanin, tomato plantacyanin, and cucumber stellacyanin are the most exposed. Azurin may also be the only one with a fifth, carbonyl oxygen, although this atom in auracyanin resides ∼3.5 Å from the copper ion. The number of residues between the Cys and His, and His and Met ligands in the 7–8 loop varies from two to four; amicyanin has the minimal

number, with two sets of two, which may increase the exposure of its copper site. All, with the exception of cucumber stellacyanin, have a Pro somewhere between the Cys and His ligands, which may lend some rigidity; the location of this residue, however, affects the interactions with the thiolate sulfur (see below).

3.5.4 Thiolate Geometry

A notable feature of the Cys ligand is that its thiolate sulfur is involved in hydrogen bonding, just as the sulfur ligands are in the iron–sulfur proteins (*see* ***Iron–Sulfur Proteins***). In azurin, cucumber stellacyanin, auracyanin, and rusticyanin, the thiolate sulfur has four bonds in an almost perfect tetrahedral arrangement (Figure 7): two covalent bonds and two N–H–S hydrogen bonds (the latter unequivocally establish the sulfur as thiolate). The two N–H–S interactions at ~3.5 Å come from the peptide NH groups adjacent to the first His ligand, and from NH groups found in the 7–8 loop. The latter interaction, in which the sulfur receives a hydrogen bond from the NH of the next-but-one residue (S_n–HN_{n+2}) is of a type particularly common in the iron–sulfur proteins. Such an interaction does not occur in plastocyanin as Pro 86, two removed from Cys 84, has no NH. Pseudoazurin and amicyanin also have only one N–H–S bond for the same reason. Cucumber basic protein is somewhat of an outlier, having only very weak N–H–S interactions at distances of 3.7–3.8 Å.

The strong conservation of the short Cu–S bond and the dihedral angles involving the thiolate sulfur (see Section 3.5.1) are also key features with important implications for the spectroscopic properties of the type 1 copper site.

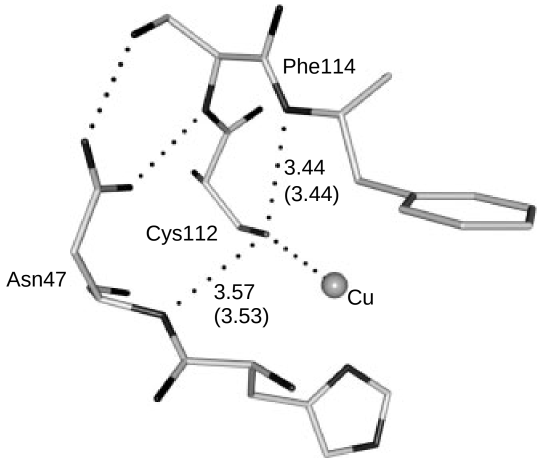

Figure 7 Cysteine ligand environment in *A. den.* azurin showing the two N–H–S hydrogen bonds. Distances are for the oxidized protein, with those for the reduced form in parentheses. Also shown are the hydrogen bonds made by the conserved Asn 47, which help constrain the copper site

3.5.5 Constraints on the Copper Site

The copper site is highly constrained by the surrounding protein structure. The Cys ligand is hydrogen-bonded as described above and the first His ligand binds to copper through Nδ1 and is hydrogen-bonded to a main-chain carbonyl oxygen through Nε2. In amicyanin, this His is hydrogen-bonded to the side chain of Glu 49; in rusticyanin, to the side chain of Asn 80; in the phytocyanins it is hydrogen-bonded to a water molecule. The second His is not hydrogen-bonded to any protein atom, but packs against other residues of the hydrophobic patch and is also hydrogen-bonded to a water molecule; the latter is further hydrogen-bonded to other protein atoms and is probably present in solution as well as in the crystal.[133] The Met (Gln) ligand always packs against an aromatic side chain (Phe, Tyr, or Trp). The orientation of the carbonyl oxygen in azurin is controlled by the secondary structure and by its packing against Phe 114. In cucumber stellacyanin, the orientation of the Gln side chain can be inferred by its proximity to Trp 13, where the nonligating atom points into the negatively charged 'hole' formed by the π electrons of the Trp 13 ring. A Trp 13/ε-oxygen ring face interaction would be electrostatically unfavorable and therefore it was suggested that the ε-oxygen was coordinated to the copper ion.[120]

Outside the immediate copper ligands there are further constraints on the site. In particular, the Asn residue which immediately follows the first His (Asn 38 in plastocyanin, Asn 47 in azurin) makes multiple hydrogen bonds, two of them to the residue which follows the Cys ligand (85 in plastocyanin, 113 in azurin); the latter is generally conserved as Ser or Thr. Thus the Asn side chain, which is conserved in most type 1 copper proteins (rusticyanin has a serine), helps to tie the two copper-binding loops together. The mutation of the Asn side chain to a Leu, which has no hydrogen-bonding capability, drastically lowers stability.[134]

These and other hydrogen bonds and hydrophobic interactions at the 'northern' end of the molecule around the copper site make this the most rigid part of the molecule.[77] This particularly applies to azurin, auracyanin, and rusticyanin, with the most buried copper sites and least to the phytocyanins, where the sites are much more exposed.

3.6 EXAFS Studies

Both protein crystallography and EXAFS data have been important in obtaining insight into the changes which occur upon reduction of the blue copper site. As noted below, while providing very limited angular information, EXAFS has the advantage of providing much more accurate metal–ligand distances. Studies on the oxidized and reduced forms of plastocyanins and azurins show that on average, the Cu–N(His) and Cu–S(Cys) bond lengths increase by ~0.06 Å and ~0.08 Å upon reduction (Table 3, adapted from[19] and references therein). Note that these changes are based on

Table 3 Summary of published EXAFS data for oxidized and reduced plastocyanins and azurins[19]

	Poplar plastocyanin		*P. vulgaris* plastocyanin		*S. oleracea* plastocyanin		*P. aer.* azurin	
Oxidation state	ox	red	ox	red	ox	red	ox	red
pH	6.0	7.0	–	–	5.5	5.5	5.5	5.5
2 Cu–N (His)	1.98	1.96/2.01	1.97	2.05	1.94/2.02	1.96/2.11	1.95	2.00
1 Cu–S (Cys)	2.08	2.19	2.11	2.22	2.09	2.15	2.14	2.21
1 Cu–S (Met)	2.76	2.86	2.66	–	2.90	–	–	–

EXAFS studies of plastocyanin at pH 6.0–7.0 and therefore do not reflect the more dramatic changes which occur in plastocyanin at low pH. The small changes in distance are consistent with the results obtained by protein crystallography. In addition, protein crystallography indicates that only limited angular changes occur upon reduction of the blue site. These small changes in the active site structure upon reduction are important in maintaining a low reorganization energy, which is critical to the electron-transfer function of these sites (*see* ***Long-range Electron Transfer in Biology***).

EXAFS results also provided the first measure of the short Cu–S(thiolate) distance in blue copper proteins[135] and have been used extensively to measure structural changes under varied conditions.[136–140] It has also been an important technique for examining systematic changes upon point mutation of the protein,[140–143] and is of particular utility when the proteins cannot be crystallized or when the changes that occur are within the error limits of protein crystallography. It should be noted that EXAFS results have historically not been able to determine contributions from the long Cu–S(Met).[144] Even the short axial Cu–O(Gln) bond in stellacyanin has proven questionable to determine by EXAFS due to correlated parameters;[137] however, it should be noted that conflicting reports exist.[136,139,145] These differences have been attributed to the method of analysis, in particular whether multiple scattering contributions from the His rings, which would occur at a similar distance, were included in the analyses.[19]

3.7 Effects of Copper Removal

A fundamental premise of the entatic state concept is that the metal simply fits into a site that is preformed by the protein and determined by the many interactions which stabilize the protein structure. This idea has been tested by crystallographic studies of apo-forms of azurin, plastocyanin, pseudoazurin and amicyanin.

The structure of apo-plastocyanin was the first to demonstrate that the geometry of the copper site is indeed created by the polypeptide.[59] The polypeptide conformation itself is essentially unchanged by copper removal, the rms deviation between oxidized and apo structures, for all main-chain atoms, being only 0.12 Å. Only minor changes occur in the copper-binding site; His 37, Cys 84, and Met 92 all move inward slightly (0.1–0.3 Å) and the largest change is a rotation of the imidazole ring of His 87. This led to the suggestion of a ‘rotating-door’ mechanism for the incorporation of copper, in which the metal binds to Nδ1 of His 87 in its ‘out’ conformer, after which the imidazole ring rotates to carry the bound copper in.[59] As with plastocyanin, the structures of apo-pseudoazurin and apo-amicyanin are practically identical to the metal-loaded forms.[113,146]

For apo-azurin different results have been obtained for the *A. den.* and *P. aer.* proteins. For *A. den.* apo-azurin, both the polypeptide structure and the copper site remain unchanged.[80] The ligand residues simply move very slightly (0.1–0.2 Å) inwards toward the site vacated by copper. In the *P. aer.* apo-azurin crystal structure,[90] there are four independent molecules in the asymmetric unit, and these show two different conformations. Two molecules are unchanged as for *A. den.* azurin, but the other two show a local rearrangement at the copper site. The second His ligand, His 117, moves outwards by ~1.6 Å and an accompanying movement of His 46 by ~0.6 Å allows the incorporation of a water molecule near the position vacated by copper. The movement suggests that a slightly different mechanism of copper insertion/removal may be operative for azurin: instead of a rotation of the imidazole ring, which is inhibited by the tighter packing of neighboring side chains compared with plastocyanin, a twist of the polypeptide backbone carries the His 117 side chain outwards. These results suggest that in solution an equilibrium exists between the two structural forms of the apoprotein.[90]

3.8 Metal Substitution

The substitution of other metal ions for copper has played an important role in spectroscopic studies of the type 1 copper proteins. For example, Mn(II), Co(II), and Ni(II) derivatives proved useful in analyzing their electronic absorption spectra[9,48] and Cd(II) substitution has been used to examine the metal binding sites through ^{113}Cd NMR spectroscopy.[148]

Five crystallographic analyses have provided direct information on the effects of metal substitution, with replacement of Cu(II) by Hg(II) in plastocyanin, and by Zn(II), Cd(II), and Co(II) in azurin (Table 4). In each case, the metal does occupy the Cu(II) site and changes in the overall protein structure are minimal. There are, however, differences that appear to depend on the type of

Table 4 Bond length (Å) in metal-substituted type 1 proteins

	PCY[a]		*A. den* AZ[b]		*P. aer.* AZ[c]

[a]1PCY; [b]2AZA; [c]4AZU (average distances, multiple molecules in asymmetric unit); [d]3PCY [e]1AIZ; [f,g]from reference (5) (average distances, multiple molecules in asymmetric unit); [h]1VLX from reference (5) (average distances, multiple molecules in asymmetric unit).

site provided by each protein and the particular metal ion chosen. In Hg(II)-substituted plastocyanin the coordination is essentially unchanged, with small protein movements allowing the three strong bonds to be lengthened to ∼2.35 Å, typical for Hg(II).[60] In Cd(II)-substituted azurin,[149] the polypeptide structure is again unchanged but the interaction of Cd(II) with the carbonyl–oxygen ligand is strengthened compared with Cu(II); the decrease of 0.4 Å in the M–O bond length is achieved by small movements, both of the metal towards the oxygen and of the oxygen towards the metal. The latter occurs through a slight twist of the Gly 45–His 46 peptide unit. In Zn(II), Ni(II), and Co(II)-azurin,[5,91] this process is continued further such that the Zn, Ni, and Co atoms make a strong bond with the oxygen ligand and the geometry is now best described as flattened tetrahedral.

The implications are that the binding site has limited flexibility. Very little movement of the three principal equatorial ligands occurs, but small displacements of the metal atom and the weaker axial ligands can occur. This is particularly the case in azurin where involvement of a peptide carbonyl oxygen in the binding site allows some movement by local twisting of a single peptide unit. The five-coordinate site may also allow more variation than the four-coordinate site in plastocyanin. Coordination preferences of the metal also have some influence, as the changes in Zn and Co azurins presumably represent a preference for tetrahedral coordination over trigonal bipyramidal, and for bonding to a carbonyl oxygen over a thioether sulfur.

3.9 The Type 1 Copper Site and the Entatic State Concept

The structural results described above give strong support for the ideas implicit in the entatic state concept of Vallee and Williams[2] and the related concept of 'rack-induced bonding' (*see* ***Long-range Electron Transfer in Biology***).[150] As applied to electron-transfer proteins, this proposes that the metal center has a geometry which is a compromise between the normal preferences of the two valence states, in this case Cu(I) and Cu(II). This geometry is stabilized by the constraints imposed by the secondary and tertiary structures of the protein.

In all the type 1 copper proteins examined crystallographically to date, the same approximately trigonal arrangement of three strongly bound ligands, two His and one Cys, is found. This is responsible for the strong conservation of the 'unusual' physicochemical properties of the blue copper site (see Section 4). With two minor qualifications, the geometrical arrangement remains the same in the absence of the metal or when a different metal is substituted for copper. The minor qualifications are that a mechanism must exist for incorporation of copper into the apoprotein (one His ligand can move to achieve this), and that substitution of a different metal, for example, Zn(II) or Cd(II) in azurin, can lead to small movements in the more weakly bound axial ligands.

Description of the site in terms of a classic coordination geometry is difficult and can be misleading. In most of the proteins, the coordination geometry could be described as distorted tetrahedral or trigonal pyramidal, but in azurin distorted trigonal bipyramidal or trigonal seems more appropriate, while stellacyanin and tomato plantacyanin have copper coordination geometries that are best described by tetrahedral and trigonal planar, respectively. On balance, the description as a distorted trigonal site with weaker axial interactions is to be preferred. The site can thus be seen as a compromise between the coordination preferences of Cu(I) and Cu(II) in terms of both ligands (mixture of S and N) and geometry [intermediate between trigonal, common for Cu(I), and trigonal bipyramidal, appropriate for Cu(II)], with a bias toward Cu(I) which explains the relatively high redox potential. The functional implications are seen in the minimal structural change accompanying the change of oxidation state, implying that the native type 1 site is optimized for rapid electron transfer by providing a very low-activation energy barrier.

4 SPECTROSCOPY AND ELECTRONIC STRUCTURE

The active sites of oxidized blue copper proteins are characterized by unique features relative to those of normal Cu(II) complexes. These features include an intense absorption

Table 5 EPR and resonance Raman parameters for blue copper sites

	EPR parameters		Resonance Raman ⟨Cu–S⟩ (cm^{-1})
	$g_{\parallel}$	$A_{\parallel}$ ($\times 10^{-4}\,cm^{-1}$)

at ~600 nm ($\varepsilon \approx 5000\,cm^{-1}\,M^{-1}$), an unusually small $A_{\parallel}$ value in the EPR spectrum ($A_{\parallel} \leq 100 \times 10^{-4}$ cm^{-1}, Table 5), and a high-reduction potential (E° > 150 mV vs. NHE (normal hydrogen electrode), Table 6). Efforts to obtain a detailed understanding of these unique characteristics and their relation to function have resulted in numerous experimental and theoretical studies. Reviews are available.[3,19,52,151–155] Insight into the electronic structure of blue copper proteins has been obtained through a combination of optical spectroscopy, EPR, resonance Raman, X-ray absorption spectroscopy (XAS), and density functional calculations. In this section, the spectroscopic results and theoretical calculations are discussed in relation to the 'classic' blue copper sites found in plastocyanins and azurins, and then extended to the 'perturbed' blue copper sites. For the purpose of discussing the spectroscopy, the perturbed sites are divided into 3 main classes:[19] (1) those sites having the same S(Met), S(Cys), $N(His)_2$ ligand set as plastocyanin and azurin, but exhibiting a tetragonal distortion of the ligand field (e.g. cucumber basic protein[118] and nitrite reductase[156] (*see* ***Copper Enzymes in Denitrification***)); (2) sites in which the axial S(Met) is replaced by a stronger field ligand (e.g. O(Gln) in stellacyanin);[120] and (3) sites in which the S(Met) is replaced by a Leu, Phe, Ile or Val as in the plant and fungal laccases[16,157] (*see* ***Copper Proteins: Oxidases***) and tomato plantacyanin,[16] and hence no axial ligand is provided by the protein. It should be noted that laccases and nitrite reductases are not single-domain mononuclear blue copper proteins. However, a discussion of their spectroscopic features is included in order to cover the full range of perturbations within blue copper sites. The correlations between the electronic structure and the function of blue copper sites are discussed in Section 5.

4.1 Electronic Absorption Spectroscopy

Possibly the most striking feature of oxidized blue copper proteins is the intense absorption band at ~600 nm which gives rise to the deep blue color (Figure 8). It is now well-established that this absorption band results from a ligand-to-metal charge transfer (LMCT) from the S(Cys)π → Cu $3d_{x^2-y^2}$ orbital, while a weak feature to slightly higher energy (~530 nm) corresponds to the S(Cys)σ → Cu $3d_{x^2-y^2}$ transition.[19,153,158,159] This assignment is inverted relative to that of normal Cu(II) complexes, which exhibit weak π charge transfer (CT) transitions and intense σ CT transitions. This assignment was first made by Solomon and coworkers on the basis of a combination of low-temperature absorption and magnetic circular dichroism (MCD) data.[159] Examination of the low-temperature MCD (LT-MCD) to absorption ratios allows for the assignment of bands as either CT (which will be intense in the absorption spectrum, but weak in the MCD spectrum) or d → d bands (which will be weak in the absorption spectrum, but intense in the MCD spectrum). Using this methodology, the absorption bands at ~430 nm and 465 nm were assigned as S(Met) → Cu and N(His) → Cu CT bands, respectively. The four absorption bands between 650–1050 nm were assigned as ligand field (LF, or d → d) transitions. A detailed description of this analysis is available.[159]

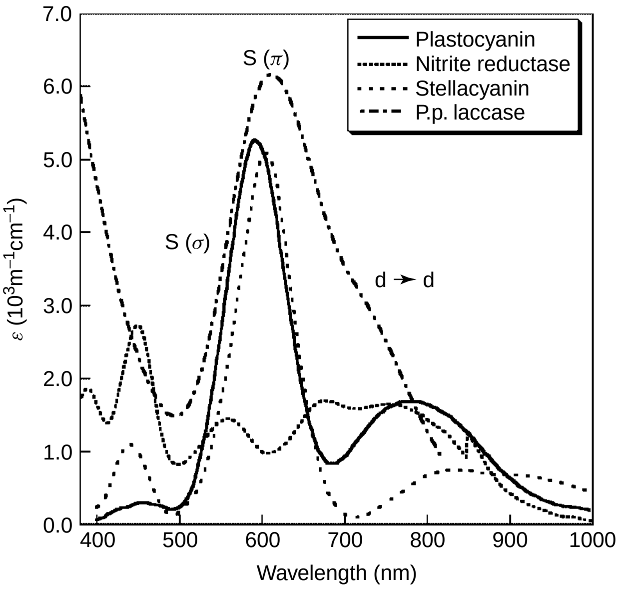

Figure 8 Low-temperature absorption spectra of plastocyanin, nitrite reductase, cucumber stellacyanin, and P. p. laccase

With a more detailed understanding of the electronic spectra of classic blue copper proteins, the analysis can then be extended to the perturbed blue copper sites. First, it is useful to examine the absorption spectra of cucumber basic protein and R.s. nitrite reductase, which have the same ligand set as plastocyanin, but exhibit altered spectral features.[160] Both of these proteins exhibit an increase in the ratio of the σ:π CT bands (with a greater change for nitrite reductase than for cucumber basic protein, data for R.s. nitrite reductase are shown in Figure 8) indicating that $3d_{x^2-y^2}$ orbital is rotating from a π to a more σ bonding interaction with the highest-occupied molecular orbital (HOMO).[161] In addition LT-MCD data show that the LF transitions have shifted to higher energy, indicating that this spectral change reflects a tetragonal distortion of the site, which is consistent with the changes observed by protein crystallography. It is also important to note that going from plastocyanin to cucumber basic protein to nitrite reductase, the Cu–S(Met) bond length decreases while the Cu–S(Cys) bond length increases, which together result in a tetragonal distortion of the site. The correlated geometric and electronic perturbation of these sites has been termed '*the coupled distortion*'.[19] In contrast, for sites with no axial ligand, the ratio of the σ:π CT bands is similar to that in plastocyanin indicating that the site remains trigonal, while the d $\rightarrow$ d bands shifts to higher energy, indicating an increase in the LF[141,162,163] (Figure 8). For the blue copper site in stellacyanin, the absorption pattern remains weak σ /intense π (Figure 8), again indicating that the site is not tetragonally distorted.[164] The LF transitions decrease in energy, consistent with a slightly more tetrahedral site relative to plastocyanin.

4.2 EPR

Like normal tetragonal Cu(II) complexes, blue copper sites show $g_\parallel > g_\perp > 2.0023$, indicating $3d_{x^2-y^2}$ ground state. However, the EPR spectra of blue copper sites are characterized by an extremely small $A_\parallel$ values ($A_\parallel \leq 100 \times 10^{-4}\,\text{cm}^{-1}$, Table 5) relative to those of 'normal' copper complexes. This small hyperfine was originally attributed to either covalency,[165] which would decrease the hyperfine coupling through delocalization of the unpaired copper electron spin onto the sulfur and thus decrease the interaction of the unpaired electron with the copper nuclear spin; or to $4p_z$ mixing into the $3d_{x^2-y^2}$ orbital,[166–168] which, due to the opposition of the $4p_z$ spin dipolar contribution with the $3d_{x^2-y^2}$ orbital, would also reduce the coupling between the unpaired electron and the copper nuclear spin. Through an elegant polarized Cu K-edge XAS study, it was demonstrated that the origin of the small $A_\parallel$ hyperfine coupling was in fact due to the highly covalent Cu–S(Cys) bond.[169] In a Cu K-edge, the intense edge jump is due to an electric dipole allowed 1s $\rightarrow$ 4p transition. At a lower energy of ~8979 eV is a pre-edge feature that is due to a 1s $\rightarrow$ 3d transition. An s $\rightarrow$ d transition is formally electric dipole forbidden, and hence the primary mechanism for pre-edge intensity is mixing of 4p character into the 3d orbitals giving this transition electric dipole allowed character. Solution data of plastocyanin shows a pre-edge peak, indicating that there is 4p mixing into the $3d_{x^2-y^2}$ orbital, although it does not show whether this originates from $4p_z$ or $4p_{x,y}$ mixing. By orienting a single crystal of plastocyanin along the electronic z-axis, it was shown that there was no intensity in the pre-edge feature, indicating no $4p_z$ mixing. In contrast, the y-polarized data demonstrated pre-edge intensity, indicating that this feature in solution plastocyanin is due to $4p_{x,y}$ mixing into the $3d_{x^2-y^2}$ orbital. Hence, these results provided experimental evidence that the small $A_\parallel$ hyperfine coupling in the EPR spectra of blue copper proteins is due to the highly covalent nature of this site.

The classic blue copper sites in plastocyanin and azurin exhibit essentially identical EPR spectra, with approximately axial ($g_x \approx g_y$) EPR signals.[160] This argues that the long ~3.0 Cu–O Å carbonyl oxygen makes little contribution to the electronic structure of azurin, consistent with other spectroscopy and the fact that the relatively compact O 2p orbitals would be expected to have little contribution to bonding at this distance.[154] On the basis of EPR, the perturbed blue copper sites can be divided into 2 classes: (1) those which exhibit a rhombic EPR signal (i.e. $\Delta g_\perp = g_x - g_y > 0.01$, as in cucumber basic protein, nitrite reductase and stellacyanin, Figure 9)[159,160] and (2) those which are perturbed, but still exhibit an axial EPR signal, for example, the T1 site in fungal laccase (Figure 9) (*see* ***Copper Proteins: Oxidases***) and tomato plantacyanin. It has been shown that the rhombic distortions are linked to stronger interactions by the axial ligand, as originally proposed by Gewirth[170] and later confirmed by subsequent structural data.[53,120,156] In cases where no axial ligand is provided by the protein (e.g. tomato plantacyanin and the T1 site in fungal laccase), a rhombic distortion does not occur.[162]

4.3 Resonance Raman

Resonance Raman spectroscopy has been used extensively as a method to probe the Cu–S(Cys) stretching frequency in blue copper proteins.[160,171–173] Laser excitation into the S(Cys) $\rightarrow$ Cu(II) CT band leads to enhancement of vibrational bands associated with the Cu–S(Cys) moiety. These bands also show a large S- and Cu- isotope shift, a high-resonance Raman intensity, and are associated with the generation of combination bands. For the classic blue copper sites found in plastocyanin, the effective Cu–S stretching frequency is $403\,\text{cm}^{-1}$ (Figure 10, Table 5).[173] In contrast, the perturbed blue copper sites in cucumber basic protein and nitrite reductase have effective Cu–S stretching frequencies of $\sim 394\,\text{cm}^{-1}$ and $383\,\text{cm}^{-1}$,[147,160] respectively, indicating a significant weakening of the Cu–S(Cys) bond (Figure 10, Table 5). The effective Cu–S stretching frequency of stellacyanin also similarly decreases to $\sim 386\,\text{cm}^{-1}$.[141] In contrast, the effective Cu–S stretching frequency for

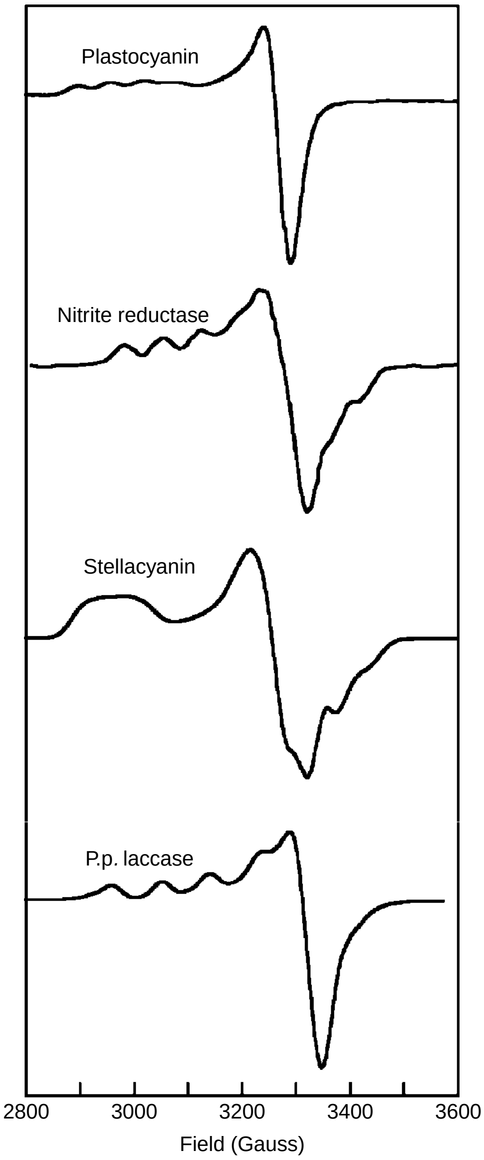

Figure 9 EPR spectra of plastocyanin, nitrite reductase, cucumber stellacyanin, and P. p. laccase

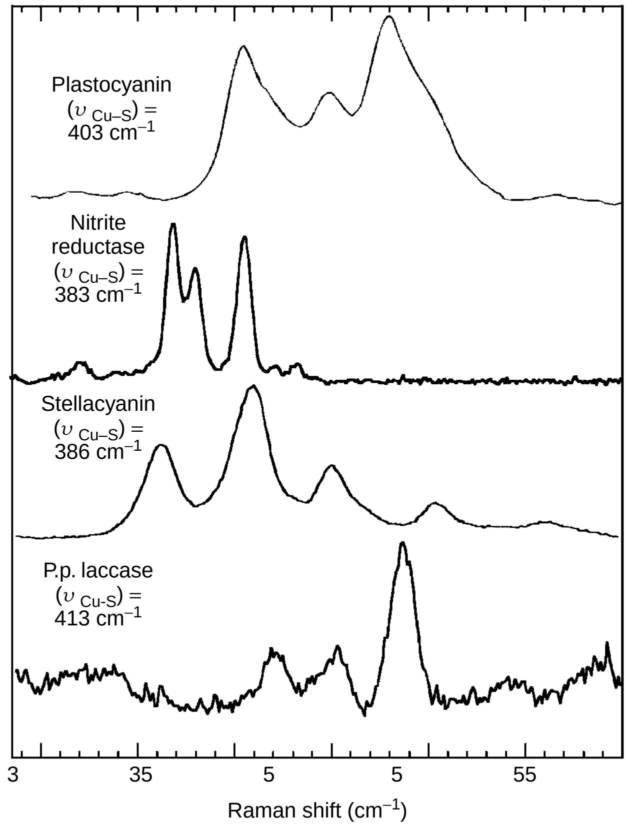

Figure 10 Resonance Raman spectra of plastocyanin, nitrite reductase, cucumber stellacyanin, and P. p. laccase

the T1 sites in fungal laccases (*see* ***Copper Proteins: Oxidases***) increase,[162] indicating a stronger Cu–S(Cys) bond. By using the intensity-weighted average of the Cu–S stretching frequencies, and applying Badger's rule, resonance Raman can be used as a sensitive indicator of the relative Cu–S(Cys) bond lengths. These data have been successfully correlated with the results of EXAFS and provide experimental evidence that the strength of the axial ligand inversely effects the strength of the Cu–S(thiolate) bond.[141]

In addition to providing a sensitive probe of Cu–S bonding, resonance Raman data have also been used to obtain an experimental measure of the reorganization energy in plastocyanin and azurin. Through an excited distortion analysis, Loppnow and coworkers have obtained a measure of the inner-sphere reorganization energies of 0.26 and 0.19 eV for plastocyanin and azurin, respectively.[174,175] The relation of these values to the electron-transfer function of these sites is discussed further in Section 5 (*also see* ***Long-range Electron Transfer in Biology***).

4.4 Copper L-edge and Sulfur K-edge XAS

Combined X-ray absorption spectroscopic studies at the copper L-edge and the sulfur K-edge (S K-edge) have been important in experimentally defining the electronic structure of the classic blue copper site in plastocyanin.[169,176] The Cu L-edge results from an electric dipole allowed Cu 2p → Cu $3d_{x^2-y^2}$ transition. Since the transition is localized on the Cu, the resultant intensity reflects the amount of Cu character in the HOMO. By using D_{4h}-$CuCl_4$ as a well-defined reference with 61% Cu character, the Cu 3d character in the HOMO of plastocyanin was determined to be ~41%. The S K-edge provides complementary information to the Cu L-edge. A S K-edge corresponds to a transition from the S 1s → S 4p orbital. When sulfur is bound to an open-shell metal (such as Cu(II)), a pre-edge feature will occur, which corresponds to a S 1s transition to the orbital formed by interaction of the Cu $3d_{x^2-y^2}$ and the S 3p orbitals. The intensity of this pre-edge is

dependent on the strength of the covalent interaction between the S and the Cu. Using these methods, the S 3p character in the $3d_{x^2-y^2}$ orbital of plastocyanin was found to be ~38%. However, it should be noted that more recent S K-edge XAS studies on azurin indicate ~45% S 3p character.[141]

It should also be noted that S K-edge studies have been extended to perturbed blue copper sites. Analysis of the S K-edge pre-edge intensity for nitrite reductase is similar to that determined for plastocyanin.[161] However, this is believed to reflect a contribution from both the S(Cys) and the S(Met) due to the tetragonal distortion of the site (note, in plastocyanin, only the S(Cys) has overlap with the $3d_{x^2-y^2}$ orbital and therefore the S(Met) does not contribute to pre-edge intensity). Systematic studies on a series of stellacyanin axial mutants show the effect of the axial ligand on the second and third class of perturbed blue copper sites;[141] upon strengthening the axial ligand, the Cu–S(Cys) covalency decreases and upon weakening the axial ligand, the Cu–S(Cys) covalency increases.

4.5 Electronic Structure Calculations

Calculations have provided general insight into the electronic structure of blue copper sites. Early studies using self-consistent field Xα calculations[159,160] overestimated the ground-state covalency of plastocyanin; hence, the Xα atomic sphere radii were adjusted to fit the experimental EPR g-values. The resulting calculational wave function was in good agreement with spectroscopic results, including the very covalent Cu–S(thiolate) bond, the Cu 3d character in the HOMO, and the orientation of the Cu $3d_{x^2-y^2}$ orbital. More recent calculations have shown qualitatively similar descriptions of plastocyanin, reproducing the Cu–S(thiolate) π bonding interaction in the HOMO, however, the sulfur 3p character in the HOMO shows a large dependence on the functional used.[19,177–180] Here it should be emphasized that spectroscopic results have provided a very detailed description of the electronic structure of blue copper sites, which have been important for the calibration of electronic-structure calculations.[19,181]

5 CORRELATIONS TO FUNCTION

Blue copper proteins are involved in electron transfer (ET) reactions in organisms ranging from bacteria to humans. In order to understand the contribution of the electronic structure to the ET function of these sites, it is useful to examine the three primary terms that contribute to the rate of ET, as described by the semi-classical Marcus equation (1) (*see also* ***Long-range Electron Transfer in Biology***).

$$k_{ET} = \left(\frac{\pi}{\hbar^2 \lambda k_B T}\right)^{1/2} (H_{AB})^2 \exp\left[\frac{-(\Delta E^\circ + \lambda)^2}{4\lambda k_B T}\right] \quad (1)$$

Here ΔE° is the difference in reduction potential between the donor and acceptor sites (i.e. the driving force), H_{AB} is the donor–acceptor electron coupling, and λ is the reorganization energy required for electron transfer. The rate is maximized when H_{AB} is large and λ is small. The reduction potential of the site is dictated by the biological function and therefore must be within the range of the donor and acceptors.[5]

5.1 Reduction Potentials (E°)

The reduction potentials for classic blue sites (165–800 mV) span a wide range, but are all higher than that of an aqueous Cu(I)/Cu(II) couple (~150 mV). The reduction potential results from both the protein environment and the geometric and electronic structure of the blue site. In order to obtain an estimate of the contribution from the protein environment, it is useful to compare geometrically and electronically similar blue copper sites within different protein environments. Table 6 ([19] and references therein) shows that S(Met) axially ligated blue proteins have reduction potentials that span a range of 250–680 mV; blue sites with an axial O(Gln) span a range of 165–563 mV; and blue sites with nonligating axial amino acids have reduction potentials in the 354–800 mV range.

This indicates that factors such as local dipoles, hydrogen bonding, and solvent exposure can make significant contributions to the reduction potential. By examining mutants in which the axial ligand is systematically varied within an otherwise fixed protein environment (as shown in Table 6), the contribution of the axial ligand to the reduction potential can be assessed. On the basis of systematic point mutations within numerous blue copper proteins, it is estimated that a O(Gln) to S(Met) or S(Met) to Phe/Leu/Thr mutation contributes ~+100 mV to the redox potential. Hence, the axial ligand can provide a means of tuning the potential of the blue copper site to a biologically relevant range.

5.2 Electron Matrix Coupling Element (H_{AB})

The rate of electron transfer through a protein is dependent on the electron coupling matrix element, $H_{AB} \cdot H_{AB}$ is dependent on the distance an electron must travel between the donor and acceptor sites (the shorter the distance, the better the coupling and the larger the value of H_{AB}) and on the covalency of ligand–metal bonds (the higher the covalency, the larger the value of H_{AB}).[182–184] In plastocyanin, there are two ET sites on the surface of the protein; one located ~5 Å from the copper and the other located ~13 Å from the copper. Despite the large difference in the length of these ET pathways, the ET rates are similar.[185] This is attributed to the increase in covalent coupling in the longer pathway, which goes through the Cu–S(Cys) bond.[183] Figure 11 shows that the shorter pathway goes through the Cu–N(His) bond, which is an order of magnitude less covalent than the Cu–S(Cys) bond.[169,186] This

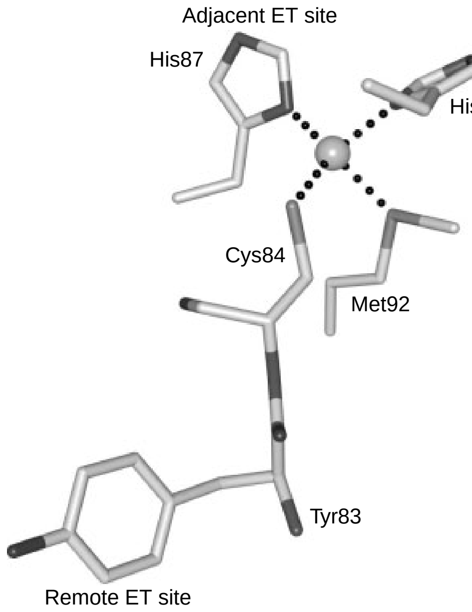

Figure 11 Proposed electron-transfer pathways to the remote and adjacent electron-transfer sites in plastocyanin. Structure from PDB, 1PLC

clearly demonstrates the importance of the highly covalent Cu–S(Cys) bond to the ET function of these sites.

5.3 Reorganization Energy (λ)

In addition to good donor–acceptor coupling, it is also important to minimize the reorganization energy (λ), in order to maximize the rate of ET. For aqueous Cu(II)/Cu(I) redox couples, λ is large owing to significant structural changes that typically occur between different redox states of copper-model complexes. For example, $[Cu(phen)_2]^{2+/+}$ has a λ_{total} of 2.4 eV.[187] In contrast, studies on ruthenium modified azurins and plastocyanins have shown λ_{total} is ∼0.7–1.2 eV.[188–190] This decrease in reorganization energy is generally attributed to protein-enforced constraints and will have contribution from both inner- and outer-sphere reorganization energies. Estimates of the inner-sphere reorganization energy have been obtained from differences in oxidized and reduced crystal structures (0.6–0.8 eV),[191] resonance Raman distortion data (0.2–0.5 eV),[174,175] and calculations (0.6–0.7 eV).[192] In all cases, the values are lower than that obtained for a copper-tetramine complex, where λ_{inner} has been calculated as ∼1.4 eV.[193] The decrease in λ_{inner} in blue copper proteins has been attributed to the lack of a Jahn–Teller distorting force, which eliminates a large angular change upon oxidation.[19]

5.4 Electron Transfer With Other Proteins

The type 1 copper proteins participate in electron-transfer reactions with a wide variety of partners, including inorganic complexes such as $[Fe(CN)_6]^{3-}$ and $[Co(phen)_3]^{3+}$, small molecules such as flavins and ascorbate, and redox proteins such as cytochromes, oxidases, and reductases. They also participate in electron self-exchange reactions. Much of the experimental data relates to plastocyanin, whose physiological electron-transfer partners, cyt *f* and P700, are clearly established. This work has been reviewed.[20] In other studies, the type 1 copper proteins have been used as models to address the mechanisms of long-range electron transfer in proteins generally (*see* ***Long-range Electron Transfer in Biology***).[98,194]

5.4.1 General Considerations

The rates of electron transfer fall within the stopped-flow range for both inorganic and protein redox agents.[20] In some cases, for example, in the reaction of $[Co(phen)_3]^{3+}$ with plastocyanin, saturation kinetics are observed, implying the formation of a stable precursor complex; an equilibrium constant of 340 has been estimated at pH 7.5.[20] This is attributed to the electrostatic interaction of the highly positive Co(III) complex with the negative patch of plastocyanin (see below). Positively charged redox inactive complexes also bind at this site. In contrast, negatively charged complexes do not show saturation behavior with plastocyanin nor do most redox reagents with the other type 1 copper proteins. Although encounter complexes must be formed, their association is generally weak; the equilibrium constant for the formation of the complex between azurin and cytochrome *c*-551, for example, is 6.7 in 0.01 M phosphate, pH 7.0 at 293 K.[195] Under these conditions the kinetics can be analyzed in terms of Marcus theory.[99,195]

Electron self-exchange rates are rapid, for example, $\sim 10^6\ M^{-1}\ s^{-1}$ for azurin and $\sim 10^5\ M^{-1}\ s^{-1}$ for amicyanin, but substantially lower for plastocyanin ($<3 \times 10^3\ M^{-1}\ s^{-1}$).[13] The lower value for plastocyanin probably reflects repulsion owing to its high negative charge. These self-exchange rates compare with the very much lower value of $\sim 10^{-5}\ M^{-1}\ s^{-1}$ estimated for the aqueous Cu(I)/Cu(II) couple.[13] The difference presumably arises from the high reorganization energy of the latter, where the two species have very different geometries compared with the minimal structural change in the proteins (see Section 3.6).

Both rate constants and equilibrium constants tend to be influenced by pH and ionic strength, depending on the importance of electrostatic interactions. For French bean plastocyanin, no saturation behavior is seen for $[Co(phen)_3]^{3+}$ at high ionic strength, but stronger association develops in low salt. These effects and competition behavior with highly charged redox inactive complexes[20] give clues to the nature of the binding sites used by different reactants.

5.4.2 Binding Sites and Electron-transfer Pathways

Many of the type 1 copper proteins appear to have a common surface feature, that is, a hydrophobic patch at the

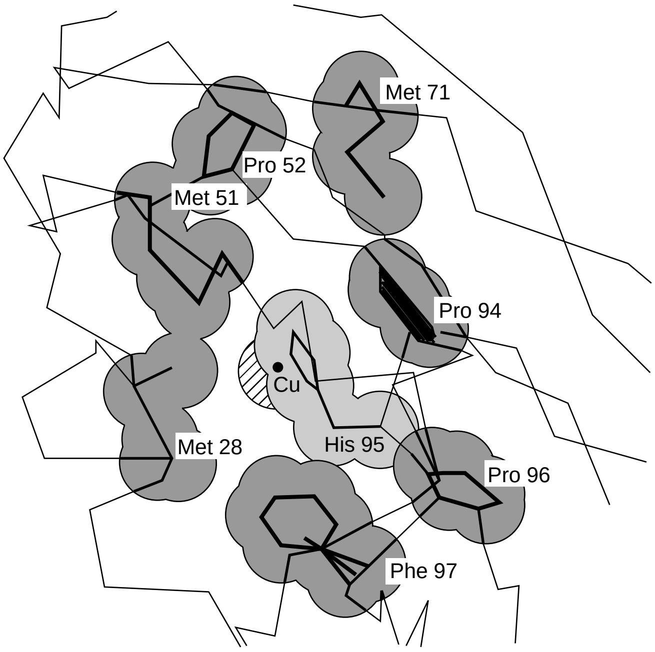

Figure 12 Hydrophobic patch surrounding the exposed edge of the His ligand, His 95, in amicyanin. (Reprinted with permission from Ref. 115. © 1992 American Chemical Society)

Figure 13 Location of the acidic patch (A) in plastocyanin around Tyr 83 (B). The copper atom and the second His ligand (C), which is located in the center of the hydrophobic patch, are also shown. (Ref. 20. Reproduced by permission of Springer-Verlag)

'northern' end of the molecule, surrounding the exposed edge of the imidazole ring of the second His ligand (Figure 12). The extent of the hydrophobic patch and the exposure of the His ligand vary somewhat from one protein to another, with azurin, auracyanin, and rusticyanin the least exposed, most hydrophobic and the phytocyanins the most exposed, least hydrophobic. While the hydrophobic patch is one clear candidate for a redox binding site, the rest of the surface varies considerably from one protein to another and binding sites are thus also likely to vary.

5.4.3 *Plastocyanin*

The 3D structure of plastocyanin reveals two potential binding sites on the molecular surface (Figure 13). The closest to the copper is the hydrophobic patch around His 87; the copper atom lies ~6 Å below this patch. The second potential binding site is the so-called *acidic patch*. This comprises two groups of acidic residues, 42–45 and 59–61, on either side of the surface-exposed side chain of Tyr 83; the latter is invariant in most all plastocyanins (some algal plastocyanins have Phe and plastocyanin from *Gleobacter violaceus* has Asn) and appeals as a likely participant in an electron-transfer pathway. This site is on the side of the β-barrel structure, some 15–20 Å from the copper site. It is a feature which appears to be shared by the plastocyanins and cucumber stellacyanin, and only universally by the plant plastocyanins, since the equivalent residues on the algal protein from *Anabaena variabilis* are no longer acidic.

NMR line broadening has been used to identify the binding sites for inorganic complexes, with the acidic patch implicated as the binding site for positively charged reagents and the hydrophobic patch and His 87 as the preferred site for neutral and negatively charged species.[14,20] Chemical modifications at the acidic patch inhibit the reaction of plastocyanin with cyt *f*, but not that with P700, implying that the acidic patch and Tyr 83 form the binding site for cyt *f*, and another site, presumably the hydrophobic patch, binds with P700 of the photosynthetic reaction center.[14] Conclusive evidence seems to have finally come from mutagenesis experiments, in which mutants of pea plastocyanin have shown that the side chain of Tyr 83, at the center of the acidic patch, is directly involved in binding to cyt *f*, and forms part of the main route of electron transfer to the copper.[196] Likewise, mutation of Leu 12 in the hydrophobic patch implicates this region in binding to Photosystem I.[197] Additional studies support these observations.[198–201] The crystal structure for cyt *f*[202] has led to a suggested model for the plastocyanin–cyt *f* interaction which has been further modeled by paramagnetic NMR and restrained rigid-body molecular dynamics.[203] The optimal orientation of the two proteins demonstrates the interaction of oppositely charged residues in plastocyanin and cyt *f*, but also showed hydrophobic interactions at the copper and heme sites necessary for electron transfer. The suggestion is that long-range electrostatic forces guide the proteins to an initial encounter complex followed by rearrangement to form a complex optimal for electron transfer and stabilized by short-range interactions.

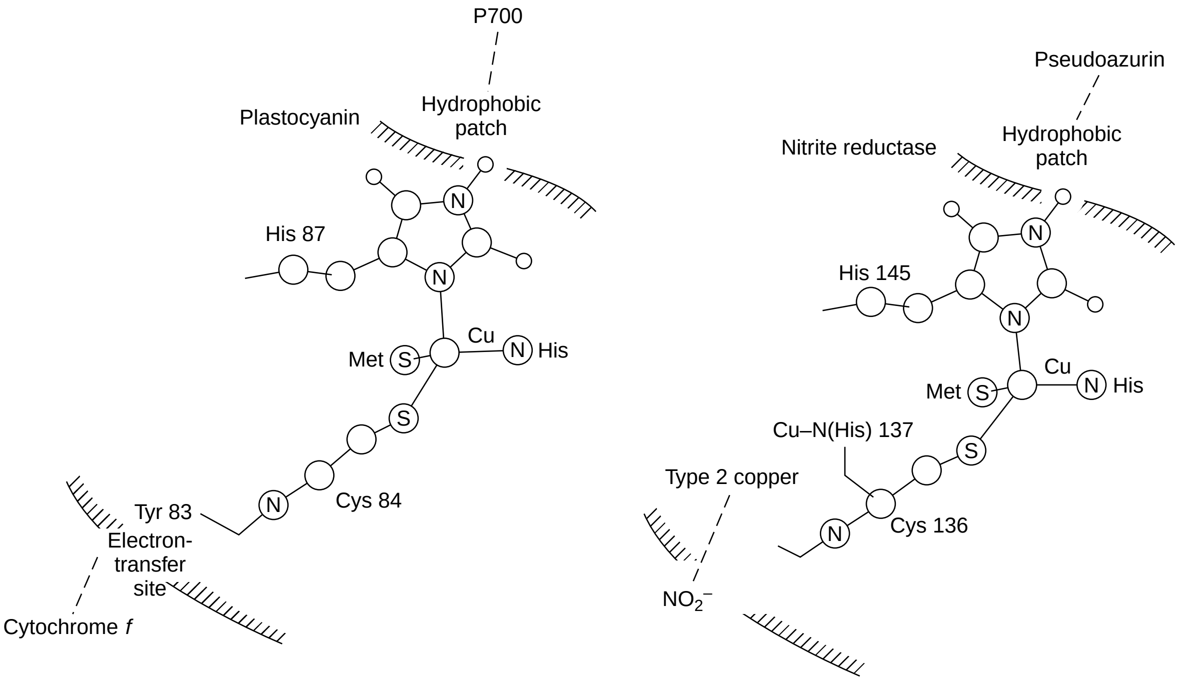

Figure 14 Similarity between the putative electron-transfer routes to and from the type 1 copper sites in plastocyanin and nitrite reductase. (Reproduced with permission of Chapman and Hall from J. Sanders–Loehr, in 'Bioinorganic Chemistry of Copper', ed. K.D. Karlin and Z. Tyeklar, 1993, p. 51)[172]

One intriguing feature of the Tyr 83 site is its similarity to the electron-transfer route in ascorbate oxidase (*see* ***Copper Proteins: Oxidases***) and nitrite reductase. In both of the latter, a His ligand belonging to the type 2 site immediately precedes the Cys ligand of the type 1 site, while in plastocyanin, Tyr 83 immediately precedes Cys 84, the Cys ligand of its type 1 copper site. This suggests the possibility of a common through-bond mechanism (Figure 14).

5.4.4 Azurin

The physiological electron-transfer partners for azurin are less well proven, although they are believed to be a small *c*-type cytochrome (cytochrome *c*-551 (*see* ***Iron: Heme Proteins & Electron Transport***) for *P. aer*. azurin) and a nitrite reductase. As in the plastocyanin case, numerous studies with inorganic redox agents have been carried out in attempts to identify binding sites and electron-transfer pathways.[12] Two conserved His residues, 35 and 83, have been implicated[10] but the evidence is not conclusive and relevance to the physiological (protein) electron-transfer partners is not established. The 3-D structure of *A. den*. azurin shows a SO_4^{2-} ion bound to His 83[77] (Figure 5) suggesting it as a possible binding site for anionic redox reagents. His 83 sits in a shallow depression between the 'flap' (which buries the region equivalent to the acidic patch in plastocyanin) and the main body of the molecule; its location is thus somewhat analogous to the acidic patch.

More attention has been focused on His 35 because of the pH-dependent conformational change which perturbs this residue and apparently influences redox activity by *P. aer*. azurin,[12] and because a nearby region becomes labeled with Cr(III) following the reduction of azurin with Cr(II).[204] These experiments suggested the 'His 35 patch' as a possible redox site. The 3-D structure of azurin shows no obvious binding region near His 35, however,[77] and mutagenesis of this residue in *P. aer*. azurin indicates that it is not involved in electron transfer with either cytochrome *c*-551 or nitrite reductase. Instead, these proteins apparently use the same mechanism and presumably the same site as is involved in the electron self-exchange reaction.[195]

There is now conclusive evidence that it is the hydrophobic patch which is the site of the electron self-exchange reaction in azurin.[195] Mutation of Met 44 in the hydrophobic patch of *P. aer*. azurin to Lys does not change the 3-D structure or spectral properties significantly but does drastically affect electron transfer. At pH 5, where Lys is protonated, the electron self-exchange rate is reduced more than 1000-fold, whereas at higher pH, as Lys becomes deprotonated and more hydrophobic, the rate approaches the native rate of $\sim 10^6\,M^{-1}\,s^{-1}$. The crystal structures of azurin, in fact, provides a model for protein–protein complexes utilizing the hydrophobic patch. In both *A. den*. azurin[77] and *P. aer*. azurin,[103] pairs of molecules dock together through their hydrophobic patches (Figure 15) in such a way that the outer edges of the two His 117 side chains are ~ 7 Å apart. This

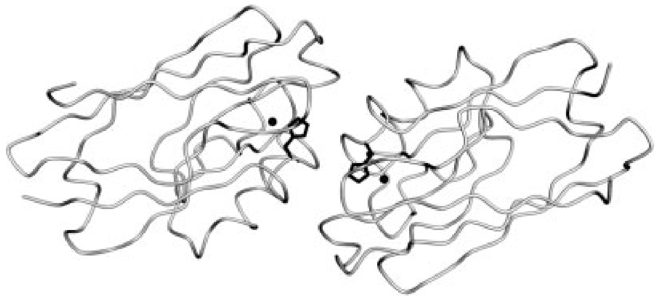

Figure 15 Interaction between two azurin molecules in crystals of *A. den.* azurin. The hydrophobic patches are docked with the two His 117 ligands (thick lines) ~7 Å apart

distance is compatible with the observed rates of electron self-exchange assuming the electron is transferred from one Cu to the other via the two-coordinated imidazole rings. In *P. aer.* azurin, there is the added suggestion that a pair of water molecules, one hydrogen-bonded to each His side chain, may further facilitate the process.[103] With respect to the cytochrome *c*-551 and nitrite reductase from *P. aer.*, the 3-D structure of the latter is not known, but cytochrome *c*-551 does have a hydrophobic patch surrounding the heme edge through which association with the hydrophobic patch of azurin could occur.[195]

5.4.5 An Electron-transfer Complex of Amicyanin

The most spectacular illustration of the importance of the hydrophobic patch in the type 1 copper proteins is provided by the crystal structure of a complex between amicyanin and its electron-transfer partners methylamine dehydrogenase (MADH) and cytochrome *c*-551.[205] As in the other type 1 proteins, amicyanin has a hydrophobic patch comprising some 7 hydrophobic side chains surrounding the exposed edge of the copper-bound His 95 (analogous to His 87 in plastocyanin and His 117 in azurin) (Figure 16). In the complex, this docks with a hydrophobic surface on MADH containing about 12 nonpolar or neutral side chains, including Trp 108, which is part of the tryptophan tryptophylquinone (TTQ) cofactor. The indole ring of Trp 108 approaches within 5.4 Å of the imidazole ring of His 95, such that electron transfer from the *o*-quinone ring of Trp 57 in the TTQ cofactor, through Trp 107, to His 95 in amicyanin, and then to the copper can be readily envisaged.

5.4.6 Electron Transfer in Modified Type 1 Proteins

Ruthenium, osmium, and rhenium complexes have been used to define electron-transfer rates over defined distances and pathways (*see* ***Iron: Heme Proteins & Electron Transport***; ***Long-range Electron Transfer in Biology***).[98,194] They can be attached to external His residues by displacement of its

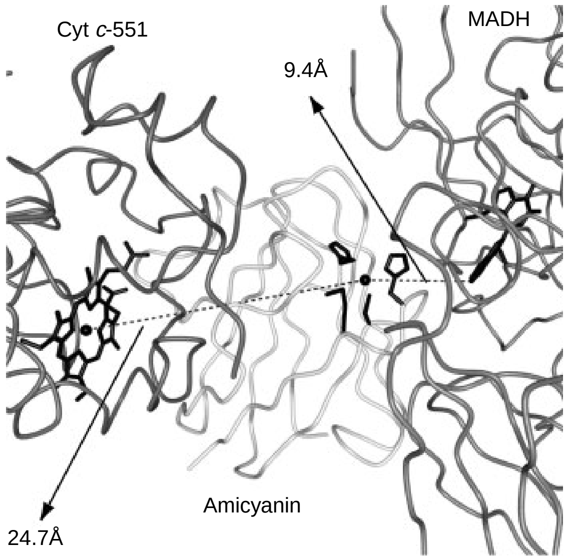

Figure 16 Structure of the ternary electron-transfer complex of MADH, amicyanin, and cytochrome *c*-551 (pdb code 2MTA). The copper atom of amicyanin is ~9.4 Å from the edge of Trp 108 in the electron donor MADH and ~24.7 Å from the electron acceptor iron atom in cytochrome *c*-551

aqua ligand, and are particularly useful because of their redox potentials and inertness to substitution. For azurin, His 83, 11.8 Å from the copper, is an ideal site for derivatization with these reagents. Rates of reduction of Os(III), Ru(III) and Re(I)* by Cu(I) in His 83-modified *P. aer.* azurin have been measured in single crystals where the protein conformation and surface solvation are defined by high-resolution X-ray crystallography. The time constants for electron tunneling in crystals are roughly what they are in solution suggesting very similar protein structures in the two states. The high-resolution structures of the oxidized (1.5 Å) and reduced (1.4 Å) states confirm that there are only very small changes in copper coordination accompany reduction. Both the driving force and temperature effects on Cu(I) → Ru(III), Os(III), and Re(I)* electron-transfer rates were examined. The reorganization energy for the electron transfer falls in the range of 0.6–0.8 eV, which agrees with that determined experimentally in solution. This work suggests that outer-sphere protein reorganization is the dominant component required for electron tunneling.

1 INTRODUCTION

The cyanide ion, CN^-, is one of the most common and longest-known ligands (*see Ligand*) in coordination chemistry. The first coordination compound to be synthesized was the cyano metal complex was Prussian blue, $[Fe_4\{Fe(CN)_6\}_3]$ (*see Prussian Blue*), made by the Berlin painter Diesbach in 1704. Much of our understanding of coordination chemistry can be attributed to research on cyano metal complexes (*see* ***Coordination & Organometallic Chemistry: Principles***).

Cyanide complexes are often compared to metal carbonyls (*see Metal Carbonyls*), and both cyanide and carbon monoxide, CO, can function as π-acid ligands (*see π-Acid Ligand*). Unlike CO, however, the cyanide ion possesses a negative charge, and can form very strong σ-bonds (*see σ-Bond*) with metal ions. This characteristic, along with other behavior such as the formation of a hydracid (HCN) and a dimer (cyanogen, $(CN)_2$), is reminiscent of halogen ligands; the cyanide ion has accordingly been described as a pseudohalide (*see Pseudohalide*). Cyano metal complexes in fact display some similarities to metal halide complexes, which has often led to their being classified as inorganic compounds. However, with very few exceptions, all cyanide complexes display metal-carbon interactions, a characteristic of organometallic compounds (*see Organometallic Complexes*). Comprehensive coverage of early cyano metal chemistry can be found in the classic monograph by Sharpe;[1] more recent reviews are available.[2–5]

2 THE CYANIDE ION

2.1 Properties of the Cyanide Ion

The cyanide ion is isoelectronic (*see Isoelectronic*) with CO, N_2 and NO^+, with an electronic configuration of $(1\sigma)^2(2\sigma)^2(3\sigma)^2(4\sigma)^2(1\pi)^4(5\sigma)^2$; this corresponds to a triple bond (one σ-bond (*see σ-Bond*) and two π-bonds (*see π-Bond*)) between the carbon and nitrogen atoms. A lone pair (*see Lone Pair*) of electrons is present on both atoms in CN^-. Calculations have indicated that the negative charge of the cyanide ion is shared approximately equally between the two atoms.[6] The carbon-nitrogen triple bond distance is 1.16 Å in the free cyanide ion; the fundamental vibrational frequency of the C≡N bond (aqueous solution) is 2080 cm^{-1}. The effective *Crystallographic Radius* of CN^-, as determined in cubic alkali metal cyanides, is 1.92 Å; this value is intermediate between those of chloride and bromide.

2.2 Cyanide Ion as a Ligand

When the cyanide ion binds to metal atoms through the lone pair (*see Lone Pair*) of electrons on the carbon atom (see Section 2.3), the resulting M–CN σ-bond (*see σ-Bond*)

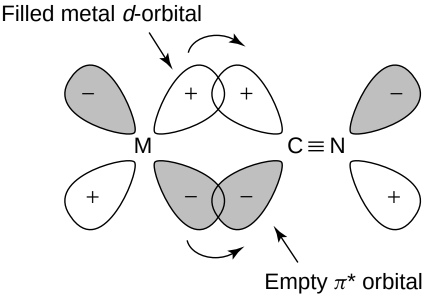

Figure 1 π-backbonding in the metal-cyanide bond

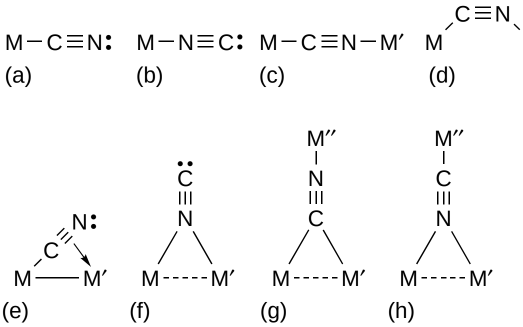

Figure 2 Metal-ligand binding modes found in cyanide complexes

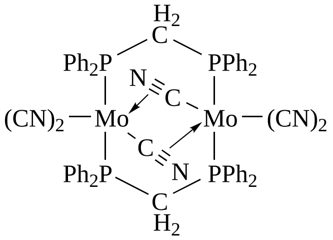
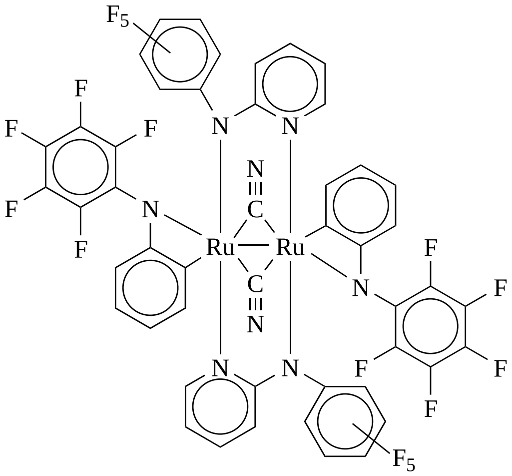
is one of the strongest metal-ligand bonds known (*see Bond Dissociation Energy*). The σ-donor (*see σ-Donor*) capacity of CN^- allows it to stabilize transition metals (*see Transition Metals*) with high oxidation numbers (*see Oxidation Number*). However, the cyanide ion also can function as a π-acid ligand (*see π-Acid Ligand*) (Figure 1), by accepting electron density from a filled metal d orbital (*see d-Orbitals*) into an empty antibonding orbital of the carbon-nitrogen bond. This allows CN^- to stabilize transition metals with low oxidation numbers (*see Oxidation Number*) as well; hence, cyano complexes can often be formed for several different oxidation states of a given metal. It should be stressed, however, that owing to the repulsive effect of its negative charge, the π-bonding (*see π-Bond*) capability of CN^- is considerably less than that of either CO or NO^+.

The bonding properties of CN^- make it a very strong-field ligand; it is one the highest in the spectrochemical series (*see Spectrochemical Series*). The strong-field character of CN^- is exemplified by its ability to form a low-spin (*see High-spin & Low-spin Compounds*) octahedral (*see Octahedral*) Fe^{II} complex, $[Fe(CN)_6]^{4-}$, and in its stabilization of a square-planar (*see Square Planar*) Co^{II} complex, $(PPN)_2[Co(CN)]_4$, with a d^7 configuration (*see Electron Configuration*).[7] The cyanide ion also exhibits a strong *trans* effect (*see Trans Effect*) and a large nephelauxetic effect (*see Nephelauxetic Effect*), indicative of the high degree of covalency in the metal-cyanide bond.



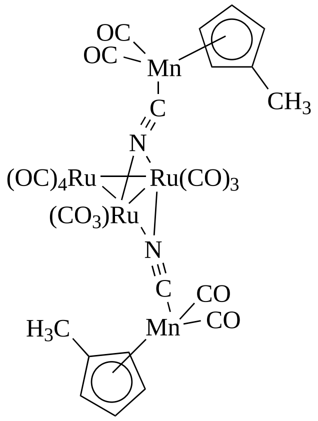
(**1**)



(**2**)

2.3 Binding Modes

Monodentate (*see Monodentate Ligand*) cyanide ligands almost always bind to the metal center through the carbon atom as in Figure 2(a); monodentate isocyano linkages 2(b) are known only in a few gas-phase species.[8] Cyanide also can act as a bridging, bidentate ligand (*see Bidentate Ligand*) through binding of the lone pair (*see Lone Pair*) of electrons on the nitrogen atom to another metal center. Usually, the cyanide ion bridges two metals in a linear fashion 2(c); this type of bridging cyanide is present in Prussian blue and several other polymeric (*see Polynuclear Complexes*) metal cyanides. Other CN^- bridging modes, although much less common, are known 2(d–h). Cyanide is capable of acting as a σ-π bridging ligand, as in 2(e); in complexes of this type, for example, (**1**), the bridging bond is formed by metal coordination to the π-bond (*see π-Bond*) of the cyanide.[9] Cyanide also can bond to metals with a single-atom bridging structure analogous to that seen in metal carbonyls, 2(f) and 2(g). In $Ru_2(F_5ap)_4(\mu\text{-}CN)_2$ (F_5ap) = 2-(2,3,4,5,6-pentafluoroanilino)pyridinate (**2**),[10] the carbon atoms of the cyanides bridge two Ru atoms, whereas in $[Ru_3(CO)_{10}\{(\mu\text{-}NC)MnCp(CO)_2\}]_2$ (**3**), the nitrogen atoms are bridging.[11]



(**3**)

3 SYNTHESIS

3.1 Cyanide Substitution

Cyano metal complexes are commonly formed by the addition of an excess of cyanide ion (usually as an alkali metal salt) to a transition metal complex in water or a polar organic solvent (equation 1).[1] The completely cyanide-substituted metal complex is usually isolated from these reactions, although one or more steps in the reaction may be relatively slow. In certain cases, cyanide substitution is not complete, resulting in partially substituted cyano metal complexes; an example is the addition of CN^- to Pt^{II} alkyl compounds, from which $[PtR(CN)_3]^{2-}$ species are isolated.[12]

$$ML_n{}^{x+} + CN^-(\text{excess}) \xrightarrow{H_2O} [M(CN)_m]^{x-} + nL \qquad (1)$$

External oxidizing or reducing reagents are often used during CN^- substitution reactions to change the oxidation state of the metal in the cyano complex. Cyanide itself can act as a reducing agent in these reactions, as it is easily oxidized to cyanogen, $(CN)_2$, or cyanate, CNO^-.[1] Liquid ammonia is used as a solvent for the synthesis of hydrolytically unstable cyano complexes, such as those of Ti^{III} and the f-block metals (*see f-Block Metals*),[13] or to provide added solubility in the synthesis of Ag^I and Au^I cyanides.[14] In the case of the square-planar (*see Square Planar*) $[Pt(CN)_4]^{2-}$ complexes, partial oxidation with halogens produces the one-dimensional conducting salts $[Pt(CN)_4]X_{0.3}{\cdot}3H_2O$ (see Section 6.1).

3.2 Oxidative Addition

Cyano metal complexes can be formed by the oxidative addition (*see Oxidative Addition*) of cyanogen to a transition metal complex (equation 2).[15] The oxidative addition of $(CN)_2$ usually requires a low-valent, electron-rich metal center such as Ni^0, Pt^0, or Rh^I, and leads to *trans*-dicyanide complexes, unless steric crowding at the metal center enforces a *cis* geometry on the incoming cyanide ligands. HCN and cyanogen halides, XCN, have also been shown to add oxidatively to metal centers to give cyano metal complexes;[15] the oxidative addition of HCN to a metal center is believed to be a key step in the transition metal-catalyzed hydrocyanation (*see Hydrocyanation*) of alkenes (*see* ***Hydrocyanation by Homogeneous Catalysis***).

$$[Ni(CO)_2(PPh_3)_2] + (CN)_2 \longrightarrow [Ni(CN)_2(PPh_3)_2] + 2CO \qquad (2)$$

3.3 Indirect Synthesis of the Cyanide Ligand

There are cases in which a cyanide ligand is generated during a reaction to give a cyano metal complex. The addition of PMe_3 to an alkylruthenium nitrosyl complex results in a Ru-bound cyanide formed from the NO^+ and methyl ligands (equation 3).[16] Pyrazine and nitric acid are found to react in the presence of CuO to give a polymeric Cu^I cyanide complex; the coordinated cyanide is evidently generated by acid-catalyzed decomposition of the pyrazine (equation 4).[17] The reductive cleavage of the nitrogen-alkyl bond in isocyanide ligands (*see Isocyanide Ligands*), –C≡NR, is another indirect route to cyano metal complexes. The reaction of ruthenium carbonyl with *tert*-butylisocyanide under CO pressure produces a 1:1 mixture of *cis*- and *trans*-$[Ru(CN)_2(CN^tBu)_4]$; formally the isocyanide is converted into a cyano ligand, isobutene, and a proton; the latter is subsequently reduced to dihydrogen (equation 5).[18]

$$Cp^*Ru(NO)(CH_3)_2 + 2PMe_3 \xrightarrow[C_6H_6]{150\,^\circ C} Cp^*Ru(PMe_3)_2CN + CH_4 + H_2O \qquad (3)$$

$$CuO + pyz + HNO_3 \xrightarrow[2\text{ days}]{200\,^\circ C} Cu(CN)(pyz) + Cu(NO_2)_2(pyz) \qquad (4)$$

$$2Ru_3(CO)_{12} + 36^tBuNC \xrightarrow[-24\,CO]{} cis\text{-}[Ru(CN)_2(CN^tBu)_4] + trans\text{-}[Ru(CN)_2(CN^tBu)_4] + 12(H_3C)_2C \equiv CH_2 + 6H_2 \qquad (5)$$

4 REACTIONS

4.1 Electrochemistry

Cyano metal complexes undergo a variety of oxidation-reduction reactions. One of the most studied is the fast self-exchange reaction of the $[Fe(CN)_4]^{3/4-}$ anions; information from this research was instrumental in establishing the outer-sphere mechanism (*see Outer-sphere Reaction*) for transition metal oxidation-reduction reactions (*see* ***Electrochemistry: Applications in Inorganic Chemistry***). The nature

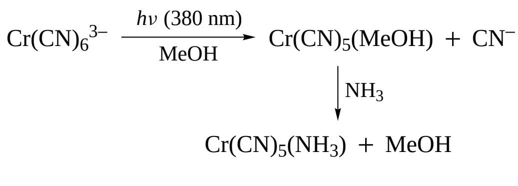
of the solvent has a pronounced effect on the oxidation of $[Fe(CN)_6]^{4-}$; its rate of oxidation by O_2 is dramatically enhanced in electron-donor solvents. Conversely, the reduction of $[Et_4N]_3[Fe(CN)_4]$ becomes much more favorable on increasing the electron acceptor properties of the solvent.[19] Cyano metal complexes also can undergo inner-sphere redox reactions (*see Inner-sphere Reaction*); a classic illustration of the ligand interaction involved in such reactions is provided by the cyanide-bridged bimetallic complex $[(NC)_5Co^{III}(\mu\text{-NC})Fe^{II}(CN)_5]^{6-}$, which can be isolated from the redox reaction of $[Co^{II}(CN)_5]^{3-}$ and $[Fe^{III}(CN)_6]^{3-}$.

In certain cases, a bound cyanide ligand can participate in an oxidation-reduction reaction. For example, the electroreduction of the complex *trans*-[Mo(CN)Cl(dppe)$_2$] in the presence of phenol reduces the cyanide ligand to the simplest aminocarbyne ligand, $\equiv CNH_2$, and gives *trans*-[(Mo≡CNH$_2$)Cl(dppe)$_2$]. The reduction of the cyanide is reversible, as oxidation of the aminocarbyne complex regenerates *trans*-[Mo(CN)Cl(dppe)$_2$].[20]

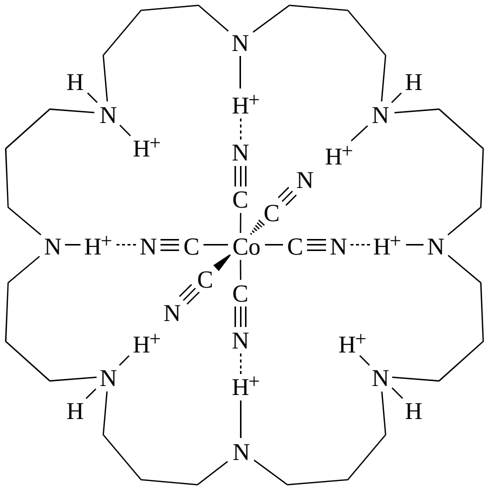
4.2 Substitution of Coordinated Cyanide

Owing to the strong σ-donor (*see σ-Donor*) properties of CN^-, only a few ligands are capable of directly replacing metal-bound cyanide: these include strong π-acids such as CO or NO^+, or aromatic N-donor chelating ligands (*see Chelating Ligands*) such as 2,2′-bipyridine or 1,10-phenanthroline.[21] For most substitution reactions of cyano metal complexes, photochemically induced dissociation of one or more of the CN^- ligands is needed (*see* ***Photochemistry of Transition Metal Complexes***). A substituted cyanide complex obtained in this manner is $[Cr(CN)_5(NH_3)]^{2-}$, synthesized by the irradiation of $[Cr(CN)_6]^{3-}$ in methanol, followed by addition of ammonia (Scheme 1).[22] Although they do not generally affect the absorption spectra of cyano metal complexes, the *Second Sphere Coordination* of polyammonium macrocyclic ligands can markedly suppress photochemically induced substitution reactions. This is exemplified in the decreased *Quantum Yield* of 0.10 mol/einstein for the photosolvation of the supramolecular polyammonium complex of $[Co(CN)_6]^{3-}$ (**4**), compared to a quantum yield of 0.30 for free $[Co(CN)_6]^{3-}$.[23] Hydrogen bonding (*see Hydrogen Bonding*) interactions with the cyanide ligands prevent their dissociation upon irradiation.

Protonation of a cyanide ligand (see Section 4.3) also can lead to enhanced rates of cyanide substitution, since this



Scheme 1 Photochemically induced CN^- substitution reaction



(**4**)

weakens the M–CN σ-bond. This is especially true for *trans* substituted cyano complexes, where the strong *trans* effect (*see Trans Effect*) of the cyanide ligands renders them more susceptible to protonation than in *cis* cyano complexes. As a result, *trans*-$[Cr(NH_3)_4(CN)_2]^+$, for example, undergoes a substitution reaction in acidic solution to give *trans*-$[Cr(NH_3)_4(H_2O)_2]^{3+}$ at a rate approximately 1000 times that of *cis*-$[Cr(H_2O)_4(CN)_2]^+$.[24]

4.3 Addition to Coordinated Cyanide

The lone pair (*see Lone Pair*) of electrons on the nitrogen atom of bound cyanide can react with Lewis acids (*see Lewis Acids & Bases*) to form adducts of the type M–C ≡N: → L. Often, strong Lewis acids such as BF_3 are used to generate complexes of this type (equation 6),[25] although weaker Lewis acids, such as Ph_3SnCl, also can form cyanide adducts (equation 7).[26] The binding of sterically bulky Lewis acids, such as BPh_3, to coordinated cyanide ligands is used to control regioselectivity (*see Regioselectivity*) in transition metal-catalyzed hydrocyanation (*see Hydrocyanation*) of alkenes.

$$\mathrm{Tp'(CO)(CN)W(PhC{\equiv}CMe) + BF_3{\bullet}Et_2O \xrightarrow{CH_2Cl_2} Tp'(CO)(CN{\cdot}BF_3)W(PhC{\equiv}CMe) + Et_2O} \qquad (6)$$

$$\mathrm{3Ph_3SnCl(in\ CH_3CN) + K_3[Fe(CN)_6]}(aq) \longrightarrow \mathrm{[(Ph_3Sn_3)Fe(CN)_6{\bullet}H_2O{\bullet}2CH_3CN]}_n + \mathrm{3KCl} \qquad (7)$$

Addition of an electrophile (*see Electrophile*) to metal-bound cyanides will often form an isocyanide ligand (*see Electrophile*), –C≡N–R. For example, the compound $[Fe\{P(OMe)_3\}(NO)_2(\eta^3\text{-}C_3H_4R)]$, which is a source of the allyl cation $(\eta^3\text{-}C_3H_4R)^+$, reacts with *trans*-[Mn(CN)(CO)(dppm)$_2$] to alkylate the cyanide, giving an allyl isocyanide ligand (equation 8).[2] The tungsten alkyne

complexes $Tp'(CO)(CN)W(RC{\equiv}CR')$ (R = H, Ph; R′ = H, ^{n}Bu, Ph, Me) react with triflic acid or methyl triflate to form the corresponding hydrogen or methyl isocyanide complexes $[Tp'(CO)(CN(H,Me))W(RC{\equiv}CR')][O_3SCF_3]$ (equation 9).[25] Fluoroboric acid is exceptional in this regard, as the same tungsten complexes react with HBF_4 in CH_2Cl_2 solution to produce BF_3 adducts (equation 10), rather than the anticipated hydrogen isocyanide complexes.

$$\textit{trans}\text{-}[Mn(CN)(CO)(dppm)_2] + [Fe\{P(OMe)_3\}(NO)_2(\eta^3\text{-}C_3H_4R)][PF_6] \xrightarrow{\text{THF}} \textit{trans}\text{-}[Mn(CO)(CNCH_2CH{=}CHR)(dppm)_2][PF_6]\cdot thf \quad (8)$$

$$Tp'(CO)(CN)W(RC{\equiv}CR') \xrightarrow[CH_2Cl_2]{[Me][O_3SCF_3]} [Tp'(CO)(CNMe)W(RC{\equiv}CR')][O_3SCF_3] \quad (9)$$

$$Tp'(CO)(CN)W(RC{\equiv}CR') \xrightarrow[CH_2Cl_2]{HBF_4,\ 0\,^{\circ}C} [Tp'(CO)(CNBF_3)W(RC{\equiv}CR')][O_3SCF_3] \quad (10)$$

5 PHYSICAL METHODS OF CHARACTERIZATION

5.1 Vibrational Spectroscopy

The characteristic absorption band in the vibrational spectroscopy of cyano metal complexes is the C≡N bond stretch, which occurs in the frequency range of approximately 1950 to 2250 cm^{-1}. Most other bands, notably the M–C bond stretch, occur at much lower wavenumbers (<600 cm^{-1}). Variations in the frequency of the C≡N bond stretching band have been used to probe the extent of metal−cyanide π-bonding; increased M–CN π-bonding decreases the strength of the C≡N bond, and therefore decreases ν(CN). For example, the C≡N stretching vibration in $Fe[(CN)_6]^{3-}$ occurs at 2135 cm^{-1}, whereas in $[Fe(CN)_6]^{4-}$, the same band is at 2098 cm^{-1}, indicative of stronger metal-cyanide π-bonding in the latter complex. Similarly, the increase in ν(CN) observed upon increasing the oxidation state of the metal (and thus decreasing the number of d electrons) has been attributed to a decrease in metal-cyanide π-bonding. It should be noted, however, that the shifts in ν(CN) due to varying degrees of π-bonding in cyano metal complexes are much smaller than the analogous shifts seen in metal carbonyls, since metal-cyanide π-bonding is weaker.

The CN^- nitrogen lone pair (*see Lone Pair*) resides in a mostly C–N antibonding (*see Antibonding*) orbital; therefore, the involvement of the nitrogen lone pair of electrons in bonding increases the strength of the carbon-nitrogen bond, which results in an increase in ν(CN) for bridging cyanides. This is illustrated by the binding of BF_3 to the cyanide in $Tp'(CO)(CN)W(PhC{\equiv}CMe)$ (equation 6, Section 4.3), which shifts the C≡N bond stretching frequency from 2110 to 2185 cm^{-1}.[25]

5.2 Diffraction Methods

X-ray diffraction has proven to be an invaluable tool for the determination of the solid-state structures of cyano metal complexes (*see* ***Diffraction Methods in Inorganic Chemistry***). Accurate data on bond distances and angles obtained from X-ray structural determinations have provided information on the bonding in cyano complexes, although interactions in the solid state can complicate interpretation of bond lengths. For example, the finding that in the solid state the Fe–C bond is shorter in the Fe^{II} complex $Cs_2Mg[Fe(CN)_6]$ (1.90 Å) than in the *Isomorphous* Fe^{III} complex $Cs_2Li[Fe(CN)_6]$ (1.93 Å) was taken as evidence of stronger metal-cyanide π-bonding in the $[Fe^{II}(CN)_6]^{4-}$ ion.[1] However, the ferricyanide and ferrocyanide ions have been studied in solution with Extended X-Ray Absorption Fine Structure (EXAFS) spectroscopy (*see Extended X-ray Absorption Fine Structure*), and the Fe–C bond distance is found to increase by 0.03 Å on electroreduction of Fe^{III} to Fe^{II}.[27] High precision charge-density X-ray diffraction and spin-polarized neutron diffraction (*see* ***Diffraction Methods in Inorganic Chemistry***) experiments on $Cs_2K[Fe(CN)_6]$ were used to determine quantitatively the electron orbital populations of the Fe–CN bonds.[28]

A common problem encountered in X-ray structural studies of oligomeric cyano metal compounds is the inability to distinguish between the carbon and nitrogen atoms in linearly bridging cyanide ligands. This problem stems from the similar electron densities and metal bond distances for both the carbon and nitrogen atoms in a bridging cyanide ligand, although in certain cases, the symmetry of the lattice forces the cyanide to be crystallographically disordered over both bridging configurations.

5.3 NMR Spectroscopy

NMR spectroscopy (^{13}C and ^{15}N) is routinely used in the characterization of cyano metal complexes. The free CN^- ion exhibits a ^{13}C NMR shift of δ 166.2, but the ^{13}C NMR shift in complexes is almost always upfield of this value; the ^{15}N shift is correspondingly downfield. Information on the rates of reactions for cyano metal complexes can be obtained from NMR studies; the self-exchange rates for electron transfer in the $[Fe(CN)_6]^{3-/4}$, $[Ru(CN)_6]^{3-/4-}$, $[Os(CN)_6]^{3-/4-}$, and $[W(CN)_8]^{3-/4-}$ couples have been determined by ^{13}C or ^{15}N NMR line-broadening techniques, but cation-catalyzed pathways dominate the observed rate constants. Experiments using sequestered K^+ (by either 18-crown-6 or crypt-2.2.2) found an exchange constant for $[Fe(CN)_6]^{3-/4-}$ of 2.4×10^2 L mol^{-1} s^{-1} (25 °C, ionic strength 0.2 mol L^{-1}); this is two orders of magnitude less than

the frequently quoted value of 1.9×10^4 L mol^{-1} s^{-1}.[29] NMR measurements on the metal nucleus in cyanide complexes also can yield useful information. For example, variable temperature ^{95}Mo NMR studies indicate that the $[Mo(CN)_8]^{4-}$ ion, which exhibits several different geometries in the solid state (see Section 6.1), is dodecahedral (*see Dodecahedral*) in aqueous solution.[30] Additionally, solid-state ^{113}Cd NMR has proven useful in determining the orientation of bridging CN^- ligands in polymeric cadmium cyanide complexes in cases where X-ray structural data could not accomplish this.[31]

5.4 Other Methods

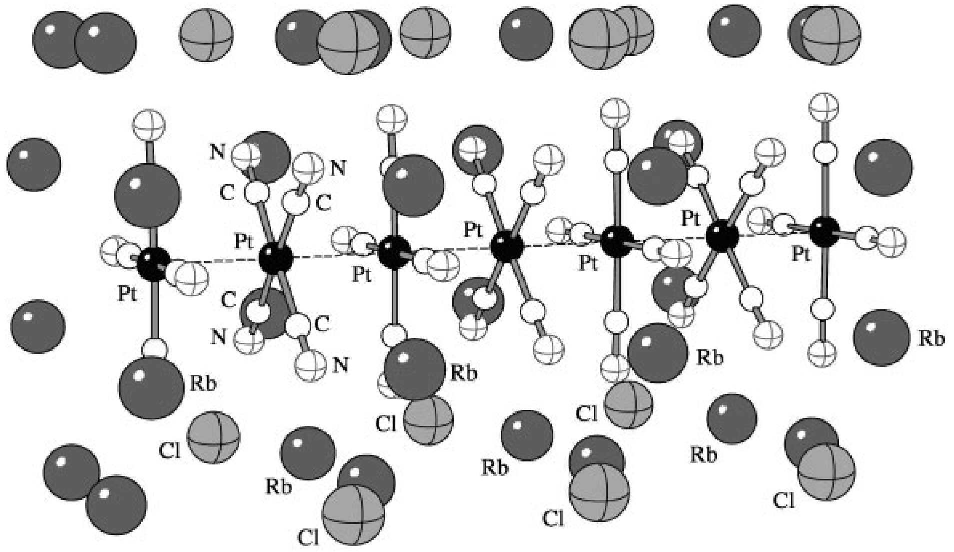
The energies of d-d electronic and metal-to-ligand charge transfer (*see Charge Transfer*) transitions that occur in transition metal-cyanide complexes can be determined by electronic spectroscopy (*see Electronic Spectroscopy*); this technique has also been used to measure reaction rates and to detect intermediates in reactions. *Mössbauer spectroscopy* has been used to determine the relative contribution of Fe–L σ- and π-bonding in a series of $[Fe(CN)_5L]^{n-}$ complexes, on the basis of the observed changes in *Isomer Shifts* and quadrupolar (*see Quadrupolar*) splitting.[32] The use of secondary-ion mass spectrometry (*see Mass Spectrometry*) has enabled the qualitative determination of the proton affinity and π-acceptor ability of CN^- in substituted cyanoruthenium complexes. Nitrogen-14 *Nuclear Quadrupole Resonance Spectroscopy* (NQR) has been used to determine the charge distribution in metal cyano complexes,[33] and to identify the binding mode (terminal vs. bridging) for CN^- by the evaluation of the *Nuclear Quadrupole Coupling Constant* for the nitrogen atom.[34]

6 STRUCTURES

6.1 Monomeric Cyano Metal Complexes

In most instances, rationalization of the geometries exhibited by monomeric cyano metal complexes is straightforward (*see* ***Coordination & Organometallic Chemistry: Principles***). All known six-coordinate metal-cyanide complexes have the expected octahedral geometry. Cyano metal complexes with the d^{10} metal centers Au^{I} and Ag^{I} are two-coordinate, that is, $[Au(CN)_2]^-$ and $[Ag(CN)_2]^-$, and have linear geometries. Four-coordinate cyano complexes are either tetrahedral (*see Tetrahedral*), when the metal center has a d^{10} configuration, or square-planar (*see Square Planar*) in complexes containing d^8 ions such as Ni^{2+}, Pd^{2+}, and Pt^{2+}. Often, the individual square-planar tetracyano metal ions stack so that the metal ions form one-dimensional infinite chains with metal–metal interactions; this is especially well-studied for the tetracyanoplatinate anion $[Pt(CN)_4]^{2-}$ and its derivatives. These chains can be straight, helical or zigzag in shape, and can possess uniform or staggered (short-long) intermolecular metal–metal distances. Partially oxidized tetracyanoplatinate chains, such as those found in the series of Krogmann salts (e.g., $Rb_2[Pt(CN)_4]Cl_{0.3}\cdot 3H_2O$, (**5**)), are examples of one-dimensional metallic conductors.[35]

For certain coordination numbers, the structures of cyano metal complexes show a surprising degree of variability. The complex $[Cr(en)_3][Ni(CN)_5]\cdot 1.5H_2O$ contains both square-pyramidal (*see Square Pyramidal*) and trigonal bipyramidal (*see Trigonal Bipyramidal*) $[Ni(CN)_5]^{3-}$ ions; desolvating the compound converts all the anions to the square-pyramidal geometry. The $[Mo(CN)_8]^{3-}$ and $[Mo(CN)_8]^{4-}$ anions have variable geometries in the solid state depending on the specific counterion present. The structure of the anions ranges from dodecahedral

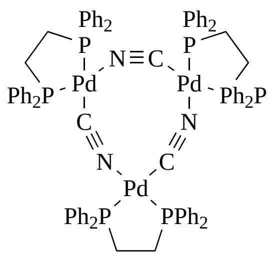


(**5**)

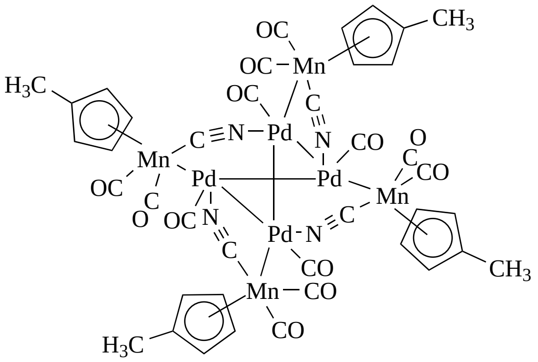
(*see Dodecahedral*) in $K_4[Mo(CN)_8]\cdot 2H_2O$, to square antiprismatic (*see Square Antiprism*) in $Na_3[Mo(CN)_8]\cdot 4H_2O$, to approximately bicapped-trigonal-prismatic (*see Trigonal Prism*) in $Cs_3[Mo(CN)_8]\cdot 2H_2O$.

6.2 Bridging Cyano Metal Complexes

One of the most distinctive features of the cyanide ligand is its ability to form a bridging M–CN–M′ bond between two metal centers. Consequently, cyanide has been increasingly used as a bridging ligand in the synthesis of discrete, molecular bi- and trimetallic mixed valence compounds (*see Mixed Valence Compounds, Classification*). A nine-membered ring is present in the trimeric compound $[Pd(dppe)(\mu\text{-}CN)]_3[ClO_4]_3$ (**6**),[36] and an unusual cyclic cluster, $[(CO)Pd(\mu\text{-}CN)Mn(Cp')(CO)_2]_4$ (**7**), was obtained by the reaction of the 'cyanometallate ligand' $[(CpMe)Mn(CO)_2(CN)]^-$ with a tetrameric palladium acetate cluster;[37] this ligand was used in the synthesis of the nitrogen-bridging CN^- compound (**3**) described in Section 2.3.

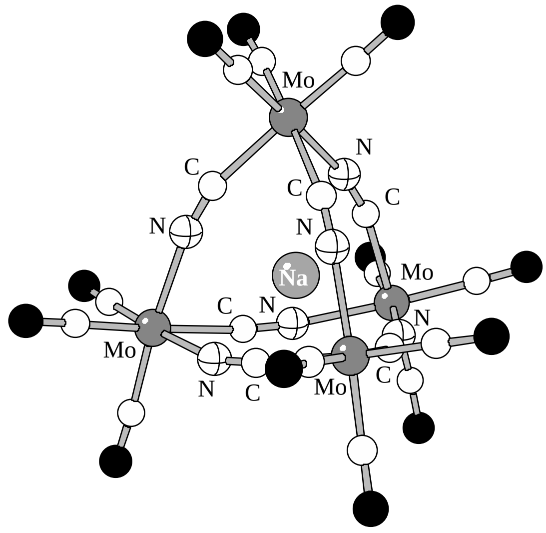


(**6**)

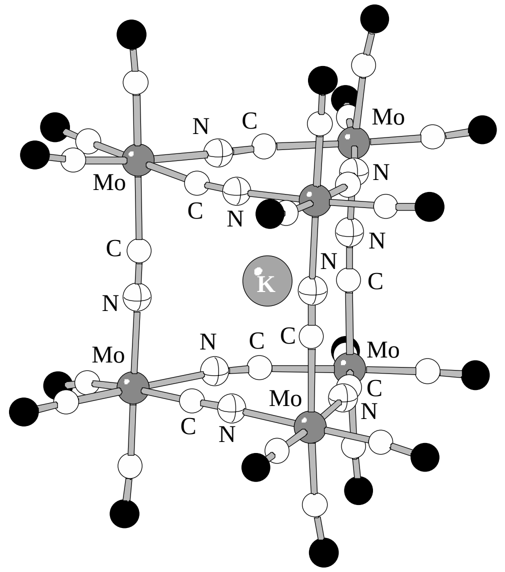


(**7**)

In some instances, the presence of templating ions strongly affects the nature of cage structures formed by bridging CN^- ligands. For example, reaction of $[Mo(Mes)(CO)_3]$ with $(Et_4N)CN$ in a 1:1 ratio generates $(Et_4N)_3[Mo_4(\mu\text{-}CN)_4(CO)_{12}(MeCN)_4]$, which contains a square 12-membered ring;[38] with excess cyanide in the presence of lithium or sodium as templating ions, the tetrahedral (*see Tetrahedral*) cyanometallates $(Et_4N)_5[(Li,Na)\{Mo_4(\mu\text{-}CN)_6(CO)_{12}\}]$ are formed (**8**).[39] Furthermore, addition of Cs^+ will convert the tetrahedral species into the cesium analogue of the less strained, trigonal-prismatic (*see Trigonal Prism*) cage $(Et_4N)_8K[Mo_6(\mu\text{-}CN)_9(CO)_{18}]$. The same trigonal-prismatic cage (**9**) will be formed if K^+ ion is used instead of Li^+ or Na^+ in the original reaction.[38] A boxlike aggregate forms from $[Cp^*Rh(CN)_3]^-$ and $[Mo(Mes)(CO)_3]$ in the presence of K^+ or Cs^+ (**10**).

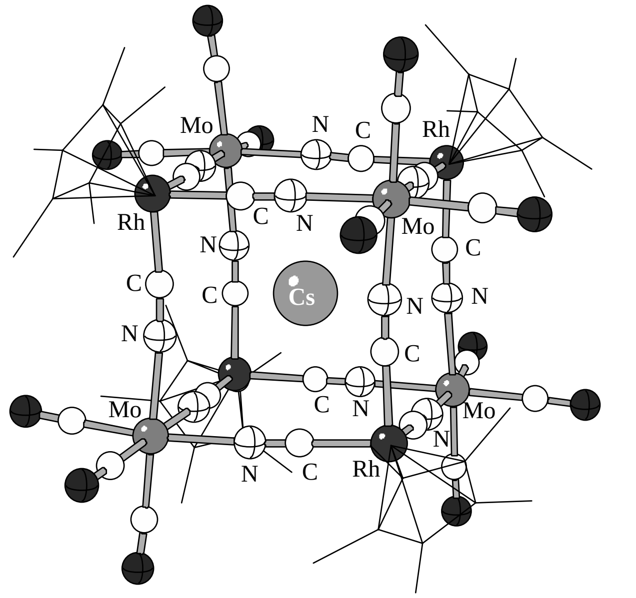


(**8**)

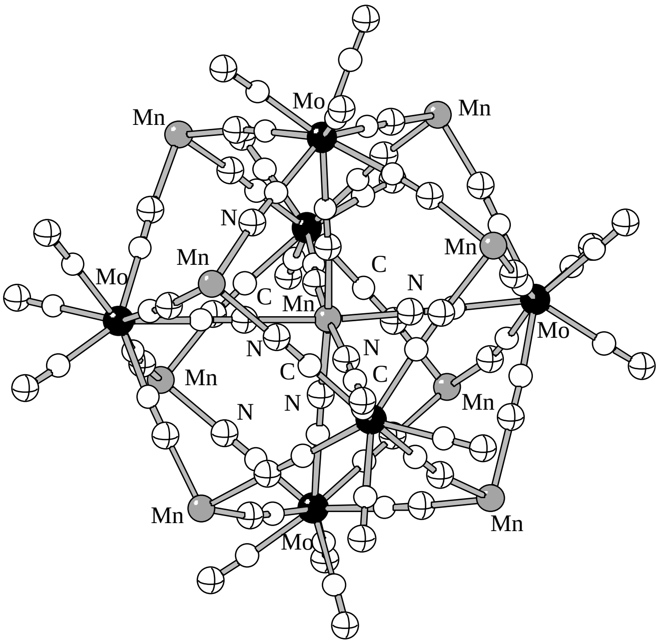


(**9**)

Even larger aggregates are known, such as $[Mn^{II}\{Mn^{II}(MeOH)_3\}_8(\mu\text{-}CN)_{30}\{Mo^{V}(CN)_3\}_6]\cdot 5MeOH\cdot 2H_2O$ (**11**), in which six Mo^V ions surround a central Mn^{II} ion, and the faces of the octahedron are capped by eight additional Mn^{II} ions, producing an approximate *Rhombododecahedron*.[40] The molecule has 51 unpaired electrons, and ferromagnetic coupling leads to an $S = 51/2$



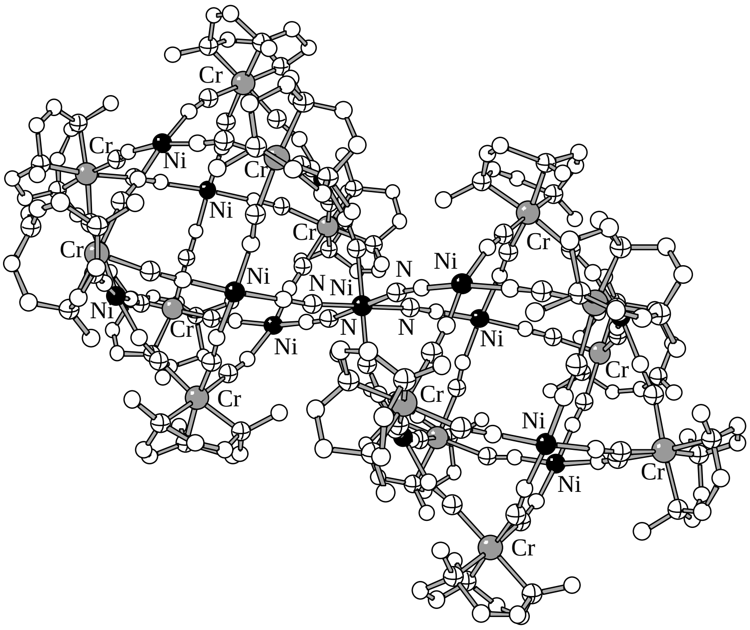
(**10**)



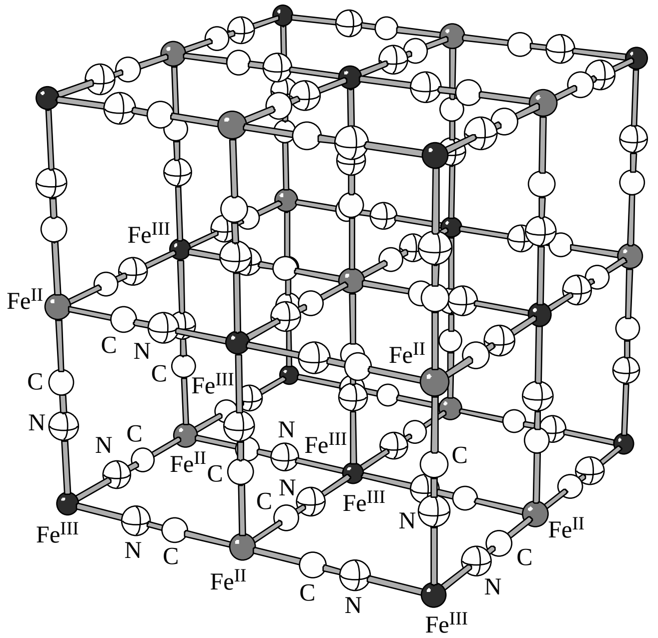
(**11**)

ground state. A double face-centered cubic aggregate, $[(Me_3tacn)_{14}Cr_{14}Ni_{13}(CN)_{48}]^{20+}$ (**12**), has been isolated from the reaction of $[(Me_3tacn)Cr(CN)_3]$ and NiI_2 in water.[41]

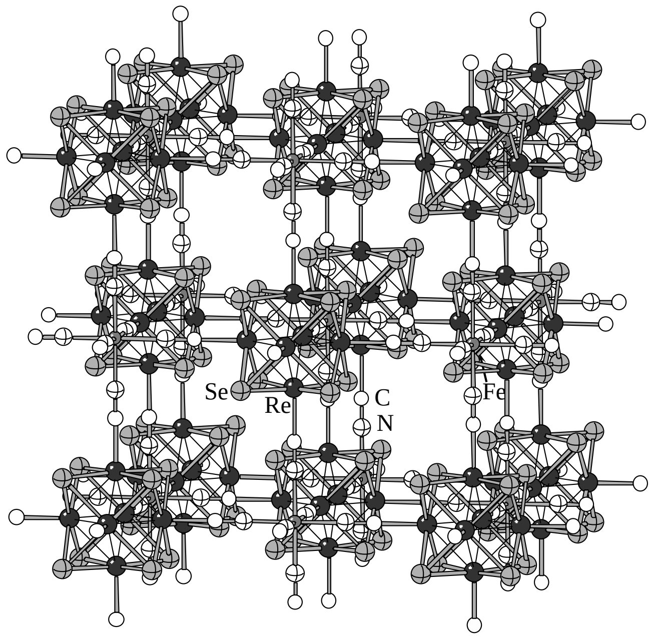
Unlike the discrete molecular complexes described above, many compounds with bridging cyanide ligands are three-dimensional coordination polymers. The classic example of this type of compound is Prussian blue, $[Fe_4\{Fe(CN)_6\}_3]\cdot xH_2O$ (**13**), whose intense color arises from an intervalence transfer transition (*see Intervalence Transfer Transition*) from low-spin Fe^{2+} to high-spin Fe^{3+} at 680 nm. Although long in dispute because of various amounts of water and/or potassium ions in different samples (potassium ions are present in 'soluble' Prussian blue, which is actually a colloidal dispersion), the generally accepted structure has a cubic face-centered lattice, with CN^- ligands on the edges of the cube bridging the iron cations. The iron centers have octahedral geometries with the Fe^{2+} ions ligated by six C-bonded cyanides and the Fe^{3+} ions by six N-bonded cyanides.[3] To achieve the 4:3 ratio of the iron atoms, one-fourth of the $[Fe(CN)_6]^{4-}$



(**12**)



(**13**)



(**14**)

groups are absent from the lattice; the vacancies left by the cyanide ligands are occupied by coordinated water molecules.

A wide variety of other structural types is known for polymeric cyano complexes, some with high degrees of void space (>50%). These range from 'expanded' Prussian blues, in which octahedral $[Fe(CN)_6]^{4-}$ units are replaced with larger aggregates such as $[Re_6Se_8(CN)_6]^{4-}$ (**14**),[42] to the interpenetrating diamond-like frameworks of $[Cd(CN)_2]_n$, to the PtS-related structure of $[NMe_4][CuPt(CN)_4]$, which has large hexagonal and square channels.[43] Often, the structures of polymeric cyano complexes can be related to the structures of silicates and zeolites (*see* ***Zeolites***); in fact, complexes such as $Mg_3[Co(CN)_6]_2$ and $Zn[Fe(CN)_5NO]$ have been shown to be effective molecular sieves.[44] Cyano metal complexes also form an immense variety of clathrates (*see Clathrate*), examples being the so-called Hofmann-type clathrates $M(NH_3)_2M'(CN)_4\cdot(guest)_2$ (M = Mn, Fe, Co, Ni, Cu, Zn, Cd; M′ = Ni, Pd, Pt; guest = C_4H_5N, C_4H_4S, C_6H_6, $C_6H_5NH_2$), and '*Mineralomimetic*' compounds with a β-cristobalite $Cd(CN)_2$ framework; the latter can be crystallized with a variety of hydrocarbon, chlorocarbon, and chlorofluorocarbon molecules in their structural cavities.[45]

7 APPLICATIONS

Historically, the major application of cyano metal complexes was Prussian blue's use as a pigment in the painting, printing, and dyeing industries. Since the 1970s, however, organic pigments such as phthalocyanine blue have supplanted Prussian blue for some of these purposes. Prussian blue has been used as an oral drug to increase fecal excretion of cesium and thallium, and has been used to remediate nuclear wastes containing ^{137}Cs.

Prussian blue has been deposited in thin films on chemically modified electrodes. Such electrodes have been used for ion detection and for promoting electrocatalytic reactions. There has also been exploratory use of Prussian blue in batteries and photoelectrochemical cells.

Photoinduced electron transfer has been described in 'antenna-sensitizer' molecules, such as $[\{Ru(bpy)_2(CN)_2\}_2$-$Ru(bpyCOO)_2]^{2-}$, in which peripheral substituents absorb light energy and transfer it to a central component (**15**). Such molecules serve as sensitizers for TiO_2 in photovoltaic cells; some have been constructed that display promisingly high levels of solar energy collection and conversion.[46]

The ability of some porous cyanide complexes to serve as hosts for organic molecules has been noted above (see Section 6.2). A series of platinum compounds containing alternating anions ($[Pt(CN)_4]^{2-}$) and cations ($[Pt(CNR)_4]^{2+}$; R = *i*Pr, *c*-$C_{12}H_{23}$, *p*-$(C_2H_5)C_6H_4$) has been developed. These compounds undergo striking color changes on absorption of volatile organic compounds, and are being examined as chemical sensing agents.[47]

1 INTRODUCTION

In bacterial and eukaryotic (mitochondrial) cell respiration, strongly reducing electrons (~ -0.35 V) that derive from the oxidation of catabolically processed foodstuffs are transferred through a series of membrane-bound electron transfer proteins ultimately to dioxygen, reducing it to water (*see* ***Long-range Electron Transfer in Biology***; ***Iron: Heme Proteins & Electron Transport***). The redox cofactors that are involved in maintaining this current include flavins, iron-sulfur centers, quinones, copper centers, and heme groups (Figure 1). The redox potentials of these centers increase sequentially as electron transfer proceeds, leaving gaps of ca. 0.2–0.5 V, at which points the exergonic redox reaction is coupled to effective translocation of protons across the membrane. The net result of cell respiration is, therefore, the buildup and maintenance of an electrochemical proton gradient, which is subsequently used to synthesize adenosine triphosphate (ATP) from adenosine 5′-diphosphate (ADP) and inorganic phosphate (P_i), catalyzed by the proton-translocating ATP synthase complex in the same membrane[1] (Figure 2). Cell respiration is an efficient and chemically sophisticated mechanism for coupling exergonic redox chemistry, through the intermediacy of a proton gradient, to the energy-conserving formation of ATP (equation 1).

$$\text{Redox reactions} \longrightarrow \text{proton electrochemical gradient} \longrightarrow \text{ATP} \quad (1)$$

This sequence has been termed *the central dogma of bioenergetics* by analogy to the universal sequence of biological information transfer, DNA → RNA → proteins. Hydrolysis of ATP back to ADP and P_i is the common energy source for virtually all energy-requiring processes in the cell, such as mechanical work, active transport, and biosynthesis of macromolecules.

Molecular oxygen is the ultimate acceptor of the electrons. When constantly supplied, O_2 provides a high-potential electron sink that ensures overall exergonicity of some 1.2 eV of cell respiration. As a whole, the mitochondrial respiratory chain translocates 5 protons across the inner mitochondrial membrane per transferred electron, thereby creating an electrochemical proton gradient of ca. 0.2 V across it (Figure 1). It follows that, overall, the process of cell respiration can operate relatively close to thermodynamic equilibrium where the free energy of the driving redox reactions ($\sim$1.2 eV) closely matches the free energy of the generated proton gradient ($\sim$1.0 eV). This is quite different from photosynthetic energy transductions, where typically a large amount of solar light energy is lost as heat.

The O_2 reduction chemistry in solution takes place as shown in equation (2).

$$4e^- + 4H^+ + O_2 \longrightarrow 2\,H_2O \quad (2)$$

O_2 is chemically quite inert owing to its triplet ground state, but thermodynamically it is highly oxidizing ($E_{m,7}$ = 0.815 V). This combination makes it highly fitted for its role in cell respiration, where its reduction requires activation at the bimetallic Fe[II]/Cu[I] active site of the respiratory enzyme, but also making transport of the inert O_2 molecule possible by the hemoglobin/myoglobin pathway before reaching the point of consumption in the cells[2] (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***).

The molecular machinery that catalyzes the reaction in equation (2) is contained within the respiratory enzyme (Warburg's Atmungsferment), a complex membrane-spanning assembly of polypeptides also called *cytochrome oxidase*, Complex IV (Figure 1), or cytochrome aa_3. The latter terminology is based on the two A-type heme groups (*see* ***Iron Porphyrin Chemistry***) found in all mitochondrial cytochrome oxidases. In bacteria, the heme composition varies and hemes B and O are also encountered.[2] In addition, bacteria often express a quinol oxidase that is structurally and functionally homologous to cytochrome *c* oxidase, but utilizes a hydroquinone as electron donor. As shown in Figure 1, the immediate source of electrons to cytochrome *c* oxidase is the small, water-soluble hemoprotein, cytochrome *c*, from which the designation 'cytochrome oxidase' originated. In fact, cytochrome oxidase belongs to a large superfamily of structurally and functionally homologous enzymes, the 'heme-copper oxidases'.[3] The subscript '3' in cytochrome aa_3 is of historical origin and due to David Keilin, who named the O_2-binding heme 'a_3' to distinguish it from 'heme *a*', which does not bind ligands. Thus, for example, the major heme-copper oxidase in *E. coli*, which is a quinol oxidase, is called *cytochrome* bo_3 because it contains B (protoheme) and O type[4] hemes, of which the latter binds O_2.

As implied by the above description, cytochrome oxidase is the terminal member of the so-called respiratory chain and functionally located at the confluence of the electron current

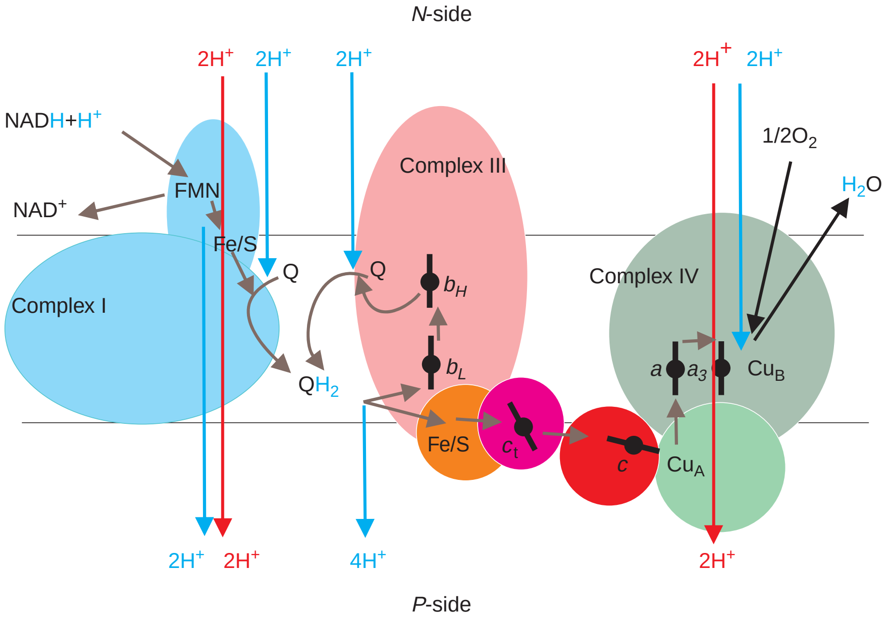

Figure 1 The mitochondrial respiratory chain. Electron transfer (brown arrows) between the three major membrane-bound complexes (I, III, and IV) is mediated by ubiquinone (Q/QH_2) and the peripheral protein cytochrome *c* (*c*). Transfer of protons linked to the redox chemistry is shown by blue arrows; red arrows denote proton translocation. NAD^+: nicotinamide adenine dinucleotide, FMN: flavin mononucleotide, Fe/S: iron-sulfur center; b_H, b_L, and c_1 are the heme centers in the cytochrome bc_1 complex (Complex III). Note the bifurcation of the electron transfer path on oxidation of QH_2 by the heme b_L – Fe/S center. Complex IV is the subject of this review. *N* and *P* denote the negatively and positively charged sides of the membrane, respectively

maintained by respiration, and of the oxygen current that in higher animals is initiated in the lungs, and sustained by the hemoglobin/myoglobin system.

The free energy drop in the cytochrome *c* oxidase reaction is greater than 0.5 eV. Rather than merely dissipating this free energy as heat, mechanisms have evolved within the heme-copper oxidases that provide for coupling electron transfer to proton translocation across the membrane,[2,5] as shown in Figure 1. The thermodynamically important charge-translocating stoichiometry in this process is *two* electrical charge equivalents per transferred electron. Thus, in order to describe the overall function in the membrane, equation (2) should be replaced by equation (3),

$$4e^-_{(P)} + 8H^+_{(N)} + O_2 \longrightarrow 4H^+_{(P)} + 2H_2O \qquad (3)$$

where '*N*' and '*P*' refer to the **n**egatively and **p**ositively charged sides of the inner mitochondrial or bacterial membrane. Note that the protons consumed in the reduction of O_2 to water ('substrate' protons) are specifically taken up from the inside of the membrane, while the electrons are donated by cytochrome *c* from the opposite side (Figure 1). This means that the redox chemistry is itself oriented with respect to the membrane and that it contributes to charge separation and therefore to energy conservation. Note also that in the quinol oxidases four additional protons per O_2, originating from the oxidation of hydroquinone, are released to the outside of the membrane.[6]

In summary, the heme-copper oxidases provide two crucial functions in cell respiration: O_2 activation/reduction and energy conservation by redox-linked proton translocation. Significant progress has been made in this field since the first edition of this series in the understanding of both structure and function. X-ray structures at atomic resolution have now been solved for several heme-copper oxidases,[7–12] and this has provided an important basis for further functional work. A summary of the recent advances that have been made in understanding the architecture of the heme-copper oxidases and their metal-containing active sites and a discussion of insights into the molecular mehanisms of operation are presented here with special emphasis on important issues that still remain to be solved.

2 STRUCTURE

2.1 Overall Structure

The mammalian cytochrome oxidase consists of 13 subunits, of which the three heaviest (subunits I, II, and III) are encoded in mitchondrial DNA. The additional 10 smaller subunits are encoded in nuclear DNA, and do not have counterparts in the bacterial enzymes. Their function is still mostly enigmatic, but many of them have been

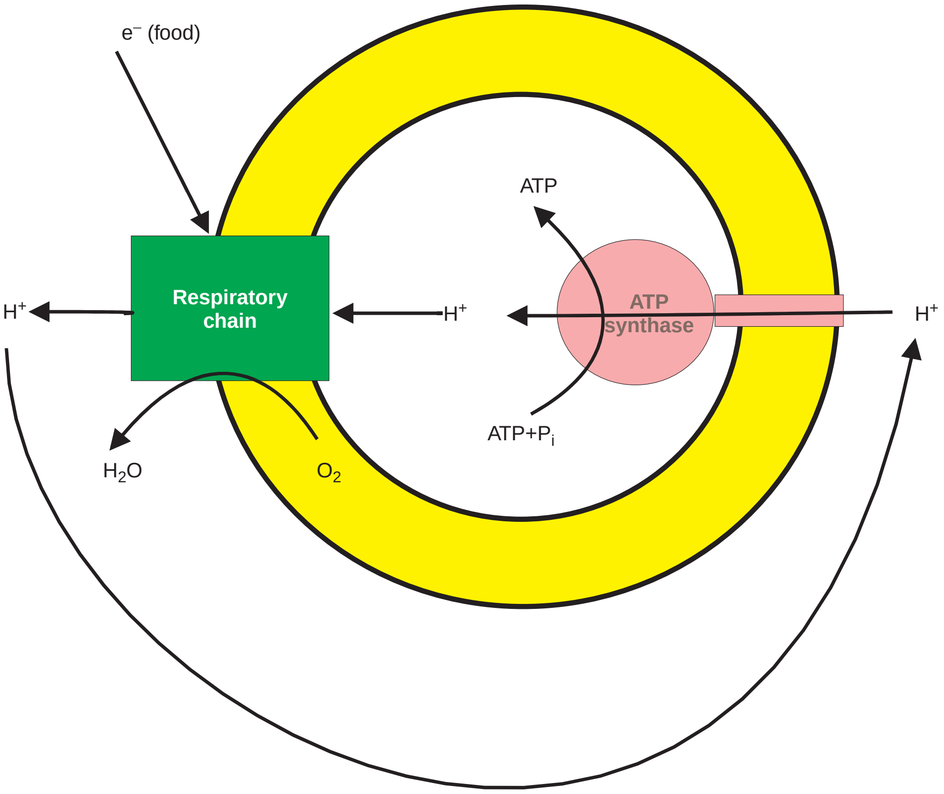

Figure 2 The chemiosmotic theory of respiration. The mitochondrial or bacterial membrane (yellow) provides resistance to proton conduction. The respiratory chain generates a proton electrochemical gradient across the membrane by redox-coupled proton translocation (Figure 1). This gradient is used as the driving force for synthesis of ATP, as catalyzed by the H^+-ATP synthase in the same membrane

implicated in enzyme regulation and/or assembly.[13,14] The bacterial oxidases are structurally much simpler, usually containing the homologs of subunits I, II, and III, although there are examples of distantly related heme-copper oxidases that only have the homolog of subunit I. Yet, the bacterial enzymes carry out both O_2 reduction and redox-linked proton translocation, usually with the same efficiency as the enzyme from mitochondria. Subunit I forms the functional core of the enzyme and invariably binds three redox-active metal centers, two hemes, and one copper ion (see Figure 3a and below). Subunit II forms a globular β-barrel structure on the P-side of the membrane that caps the domain in subunit I with the two heme groups, and is anchored to the membrane by two membrane-spanning helices. The β-structure entails most of the binding site for the electron donor, cytochrome *c*, and contains a fourth redox-active site, Cu_A, in most cytochrome *c* oxidases. The interaction of cytochrome *c* with the oxidase has been extensively studied and is mainly due to electrostatic interactions.[15] The Cu_A center is lacking from the quinol oxidases despite the presence of subunit II.[11] Subunit I from mitochondrial and some bacterial cytochrome *c* oxidases also comprises a Mg–binding site, which is absent from the quinol oxidases, and which lies near the interface between subunit I and the globular domain of subunit II.

Subunit III has no bound metal ions. Although it is the second-heaviest subunit, relatively little is known about its function. Its genetic deletion causes misassembly of the enzyme, while biochemical deletion decelerates proton transfer via the D-pathway (see below) in subunit I, and the subunit III-depleted enzyme becomes spontaneously inactivated after a number of turnovers, which is linked to loss of the Cu_B center.[16] A role of subunit III as an oxygen reservoir has also been proposed.[17,18]

2.2 Proton Transfer Pathways

As implied by equation (3), and by the location of the O_2 reduction site in the structure, proton transfer across the cytochrome oxidase protein is required for function, which necessitates proton-conducting pathways for three specific purposes, that is, to transfer the four ‘substrate’ protons from the N-side of the membrane into the site of O_2 reduction, for uptake of the four ‘pumped’ protons (per O_2 reduced) that are translocated across the membrane coupled to the redox reaction, and for release of these protons to the opposite side of the membrane (exit pathway). Site-directed mutagenesis data indicated the presence of two proton transfer pathways from the N-side of the membrane toward the binuclear heme

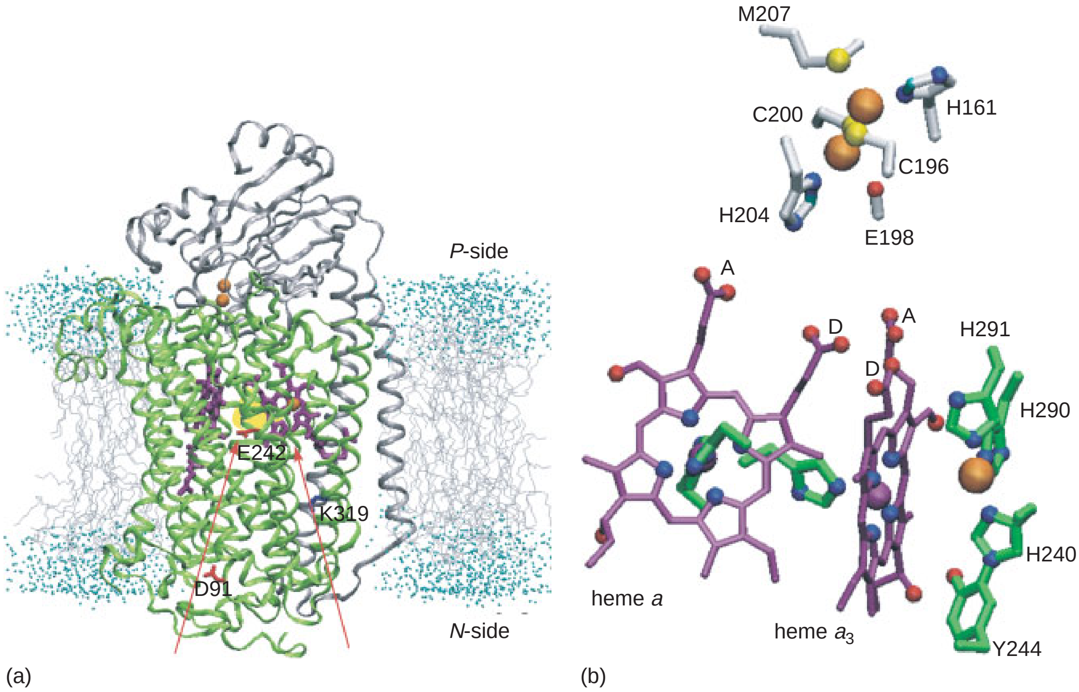

Figure 3 Cytochrome *c* oxidase structure (based on the structure of the enzyme from bovine heart mitochondria;[23] PDB code 1V54), modeled into a phospholipid membrane (gray) surrounded by water molecules (blue spheres) (Liisa Laakkonen, unpublished). (a) only subunits I (green) and II (gray) are shown. Hemes *a* (left) and a_3 (right) are shown in magenta, the copper ions (bimetallic Cu_A, and Cu_B near heme a_3) as orange spheres. Two proton transfer pathways in subunit I are indicated by red arrows, and some key residues in these pathways are indicated in red (D91 and E242 in the D-pathway) or blue (K319 in the K-pathway). A hydrophobic cavity between E242, the D-propionate of heme a_3, and the heme-copper site is indicated in yellow. *P* and *N* denote the positively and negatively charged sides of the membrane. (b) structure of the redox centers. Hemes and copper ions are colored as above. Oxygen: red; nitrogen: blue, sulfur, yellow. The bimetallic Cu_A (top) is coordinated by two histidines and two cysteines plus two weaker bonds to a methionine sulfur (M207) and a peptide oxygen (E198); all these residues are from subunit II. The A and D propionate groups of the hemes are labelled. The long hydroxyethyl farnesyl side chains of the hemes are truncated leaving only the hydroxyethyl group. The VMD program was used for the molecular graphics[29]

a_3-Cu_B site,[19] and the presence of these pathways was nicely corroborated and further specified by the crystal structures.

The so-called D-pathway in subunit I starts with a conserved aspartic acid near the *N*-side, and continues into the middle of the membrane domain with a series of hydrophilic amino acids and several bound water molecules (Figure 3a). The latter were predicted by computational methods[20,21] and were subsequently identified in the refined crystal structures.[9,12,22,23] The D-pathway proper ends at a conserved glutamic acid residue at the bottom of a hydrophobic cavity, still some 10 Å away from the site of O_2 reduction (Figure 3a). Further proton conductivity to the latter site is not evident from the crystal structures. The so-called K-pathway (mostly also in subunit I) is quite different. A conserved lysine residue either connects toward the *N*-side via a water molecule and a serine residue in subunit I (S255), or via a conserved glutamic acid residue (E62) in one of the membrane-spanning helices of subunit II. This pathway is lined by threonine and/or serine residues and appears to end at a key tyrosine moiety close to the O_2 reduction site (Figure 3a, b).

Based on the X-ray structure,[24] a third proton transfer pathway (the H-pathway) was suggested by Yoshikawa and coworkers to be involved in proton pumping. This structure extends from the *N*- to the *P*-side of the membrane, passing close to the heme *a* site at its formyl substituent, and a conserved arginine residue with strong contact to the formyl. Mutagenesis of residues in this pathway in the bacterial enzymes do not, however, cause changes in proton transfer activity or efficiency of proton translocation.[25] Yet, a recent study employing an ingenious hybridization of bovine heart and human cytochrome oxidase reports that mutation of an aspartic acid residue in this pathway (which is absent in the bacterial enzymes) leads to loss of proton pumping.[23] Hence, the role of this pathway has been reopened, as well as the question of whether different proton translocation mechanisms might be operable in mitochondria and bacteria. In the present author's opinion, the latter seems improbable in view of the very high degree of conservation of the subunit I structure between bacteria and mitochondria (see also below).

Identification of the exit pathway of the pumped protons is much poorer. Experimental evidence has suggested that it starts from a domain that includes the D-propionate of heme a_3 (Figure 3b) and its ion pair, a conserved arginine.[26,27]

However, the domain on the P-side of the propionate/arginine pair is rich in hydrophilic residues and water molecules, making it difficult to identify a unique proton exit path based on the structure.

2.3 Structure of Redox-active Metal Centers

Subunit I entails the functonally most important redox sites, which are conserved among all heme-copper oxidases (Figure 3b). A binuclear heme-copper site, where the Fe–Cu distance is <5 Å is the site of O_2 binding and reduction. The copper ion (Cu_B) is located on the distal side of the heme; it has three histidine ligands plus an OH^- or aquo ligand in some states of the catalytic cycle, as demonstrated by EXAFS and ENDOR spectroscopy.[28] Site-directed mutagenesis data had correctly predicted the histidine ligands of the heme a, heme a_3, and Cu_B centers.[2] The oxygen-binding heme is usually high spin, six-coordinate, with a histidine as the proximal axial ligand, and magnetically coupled to Cu_B (*see* ***Iron Porphyrin Chemistry***; ***Magnetism of Transition Metal Ions***). The distal Fe ligand is possibly a water molecule, or a hydroxide anion in some low-spin states (see below). Upon reduction of this heme it assumes a five-coordinate, high-spin geometry. The second heme group (heme a in the mitochondrial enzyme) lies very close to heme a_3, nearly at van der Waals contact and almost at a right angle (Figure 3). Heme a (hemes b or o in some bacteria) is low spin and six-coordinate with histidines as axial ligands.[2]

The optical and magnetic resonance properties of the Cu_A center were long noted to be unusual. The reason for this is now understood: the center consists of two adjacent Cu ions. Five of the 6 metal ligands were correctly predicted by mutagenesis data, as summarized before.[2] The structure of the Cu_A center (Figure 3b) is reminiscent of binuclear iron-sulfur centers where Fe is replaced by Cu and inorganic sulfur by cysteine sulfur.[18] Cu_A functions as a single electron transfer center where the only accessible redox states are formally Cu[I]Cu[I] (reduced) and Cu[II]Cu[I] (oxidized), the latter having the unique EPR signature.

3 FUNCTION

3.1 Electron Transfer Processes

As summarized earlier,[2] there is consensus with regard to the sequence of electron transfer in cytochrome oxidase. The Cu_A center is the initial acceptor of electrons from cytochrome c ($k \sim 3 \times 10^8\,M^{-1}s^{-1}$). This electron transfer depends crucially on a conserved tryptophan residue in subunit II ca. 5 Å away from the Cu_A center.[15] Then follows fast electron equilibration between Cu_A and the low-spin heme ($k_f \sim 10^4\,s^{-1}$; $k_r \sim 5 \times 10^3\,s^{-1}$, k_f and k_r denoting the forward and backward rate constants). Babcock[2] concluded that the low-spin heme acts as an 'electron-queuing' point for controlled electron injection into the binuclear heme a_3-Cu_B center, and although there are unsolved questions with regard to this property, it is still considered valid and will be given special attention in this review.

In its purest form, electron transfer between the low-spin heme and the binuclear heme-copper center may be studied following photolysis of CO from heme a_3 in 'mixed-valence' enzyme, where the binuclear site is reduced and heme a and Cu_A are oxidized. Several groups have described the ensuing electron equilibration with heme a as a process with a 3-μ s time constant.[30] This reaction is independent of pH and unaffected by exchanging water with deuterium oxide, and hence apparently due to pure electron transfer. However, according to the empirical electron tunneling theory of Dutton *et al.*[31] the electron transfer rate at the very short heme–heme distance should be three orders of magnitude faster, that is, in the nanosecond regime (*see* ***Long-range Electron Transfer in Biology***). Likewise, recent extended Hückel level calculations[32] have suggested a maximum rate of $3 \times 10^8\,s^{-1}$. Although experimental evidence for such fast electron transfer has been presented,[33] it has been disputed[34] and the issue remains open.

3.2 Dioxygen Binding and Reduction

The flow-flash technique of Gibson and Greenwood[35] and its low-temperature counterpart pioneered by Chance,[36] in conjunction with a variety of spectroscopic techniques, have continued to provide important new insights in the mechanism of O_2 reduction. The structure of some of the central intermediates in the process have been revised since the last edition of this review (Figure 4).

Photodissociation of CO ('flash') from the reduced enzyme after mixing with O_2 ('flow') in the dark has been the main method of initiating the reaction. Some concern has been voiced as to the possibility that this technique might introduce artifacts due to CO, but results using a rapid O_2 mixing system without CO have confirmed the applicability of the 'flow/flash' technique.[37] Yet, it has been shown by infrared spectroscopy that upon photolysis, the heme a_3-bound CO is first transferred in less than a picosecond to the nearby Cu_B, to which it remains bound for about a microsecond at room temperature[38] before diffusing out of the enzyme, as also verified by EXAFS data.[39]

Two experimental starting conditions are often employed, *viz.* the fully reduced and the 'mixed-valence' enzyme (Figure 4). Though not shown here, the first observed event upon the enzyme's reaction with O_2 is a transient (ca. 2 μs) weak ($K_d \sim 8\,mM$) binding of the incoming dioxygen to Cu_B, which might be limited by the dissociation of CO from the copper ion.[40] This and related phenomena have lent credit to the idea of a 'ligand shuttle[41]' where the incoming O_2 molecule must transiently replace any ligand that might

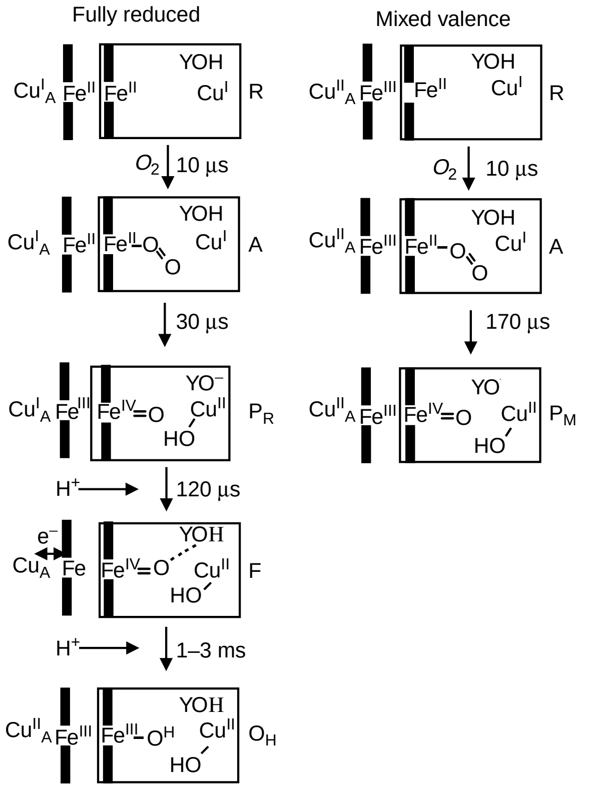

Figure 4 Oxidation of reduced cytochrome *c* oxidase by O_2. Tentative structures of intermediate states observed when starting the reaction from fully reduced or 'mixed-valence' enzyme. The rectangle denotes the heme a_3-copper B site, where Y is tyrosine-244 covalently bonded to the copper ligand H240 (Figure 3b). The formal redox states of heme *a* and the Cu_A center are shown on the left side of the rectangle

occupy the fourth coordination site of Cu_B[I] before binding to heme iron. Next, the heme a_3-O_2 adduct is formed (Chance's Compound A)[36] in ca. 8-μs at room temperature, as shown by both optical and Raman spectroscopy.[2] The binding of O_2 to the heme iron is surprisingly weak ($K_d \sim 0.25$ mM) considering that the Michaelis constant (K_M) is less than 1 μM. This high operational affinity for O_2 is very important *in vivo* because the rate of cell respiration must be sufficient even at the low local tissue concentrations of O_2. On the other hand, a high binding affinity would require energy expenditure that would lessen the free energy available for ATP synthesis. In cytochrome oxidase, the low K_M is instead secured by fast O_2 diffusion into the binding site (ca. $3 \times 10^8\ s^{-1}M^{-1}$), most likely via a distinct route in the protein,[17,21] and by kinetic trapping of the bound O_2 by electron transfer,[36,42] which is much faster than the rate of enzyme turnover. The latter is usually limited by the rate of electron delivery from earlier parts of the respiratory chain.

In the mixed-valence enzyme, O_2 binding and formation of Compound **A** is followed by a single reaction, as distinguished by optical and Raman spectroscopy (Figure 4).[2] This is the ca. 200-μs formation of Chance's 'Compound C,'[36] which has a prominent absorption band at 607 nm and a red-shifted Soret spectrum, relative to the fully oxidized enzyme. This species, also called the $\mathbf{P_M}$ state of the binuclear heme-copper site, was originally suggested to have a ferric **p**eroxide-cupric structure[2,43] consistent with the observations that the same state may be formed by treating the oxidized enzyme with a ferric/cupric binuclear site with hydrogen peroxide, or by withdrawing two reducing equivalents from this ferric/cupric site by an energy-dependent reversal of the reaction in mitochondria. In the last decade it has become clear, however, mainly from two sets of ingenious experiments, that heme a_3 is not in a peroxy form in the $\mathbf{P_M}$ intermediate. The Raman studies by Kitagawa and coworkers[44] using oxygen isotope-labelled O_2 showed that the O–O bond is already broken in the $\mathbf{P_M}$ state, and these data strongly suggested a ferryl heme-iron structure (Fe=O) (*see* ***Iron Porphyrin Chemistry***). In agreement with this, the experiment of Fabian *et al.*,[45] also using isotope-labelled O_2, showed that one of the two oxygen atoms could be recovered from water when the enzyme reached the $\mathbf{P_M}$ state, again indicating scission of the O–O bond at the $\mathbf{P_M}$ level of the reaction. Actually, already much earlier Weng and Baker[46] had insightfully pointed out the likelihood of a ferryl heme in $\mathbf{P_M}$ because the Soret spectrum of this compound is very similar to that of the the **F** state of the bimetallic center that is encountered later in the catalytic cycle, and which was correctly interpreted as such from the early optical and redox titration data with mitochondria.[43]

Since the O–O bond is broken in the EPR-silent $\mathbf{P_M}$, state, four redox equivalents must have been transferred to effectively reduce dioxygen to two oxygenous entities equivalent to water in the redox sense. Oxidation of ferrous to ferryl heme-iron accounts for two electrons, copper oxidation to cupric for one, but the source of the fourth electron equivalent is not obvious. Much interest has been raised toward a conserved tyrosine residue in the binuclear site that is uniquely covalently bonded to one of the three histidine ligands of Cu_B (Figure 3b).[12,24,47] The major proposal is that this tyrosine is the source of the fourth electron (and a proton), forming a neutral tyrosine radical in the $\mathbf{P_M}$ state.[48,49] This was supported by the experimental work of Proshlyakov *et al.*,[50] who showed specific reactivity of the tyrosine toward iodide in the $\mathbf{P_M}$ state, and this view has also been suported by DFT calculations.[51] The alternatives are a heme Fe[V]=O state (*see* ***Iron Porphyrin Chemistry***), suggested by Kitagawa *et al.*,[52] a Cu_B[III] state, for which there is no precedent in biology, however, or that the electron donor may be another amino acid than tyrosine. At any rate, the majority view at this time is that the $\mathbf{P_M}$ intermediate has the structure Fe[IV]=O; Cu_B[II]-OH; tyr-O·.

The above findings entail a fundamental piece of information. After binding to the reduced heme-copper site, dioxygen is fully reduced in the next reaction step to metal-bound oxide and hydroxide by electron and proton transfers within the site itself. From measurements of transmembrane

electrical potential in liposomes inlaid with the enzyme, it can be concluded that this reaction is indeed not coupled to generation of proton electrochemical potential.[53] Even very small movements of charged particles (protons) in a direction perpendicular to the membrane would have been detected with this technique. Formation of $\mathbf{P_M}$ thus precedes the steps in the catalytic cycle that conserve energy. This reaction transfers the high redox potential (electron affinity) of the O_2/H_2O redox couple to the enzyme's heme-copper site to yield at least two highly oxidizing species, ferryl heme iron and the tyrosine radical. Subsequent electron transfer from cytochrome *c* to these centers is thus exergonic and linked to uphill proton translocation and charge separation across the membrane. This insight also explains why the catalytic cycle can be readily reversed when driven by a high proton electrochemical gradient in intact mitochondria, from the oxidized ferric cupric state ($\mathbf{O_H}$, Figure 5) back to the $\mathbf{P_M}$ state, but not further to evolve O_2.[43]

When the fully reduced enzyme is allowed to react with O_2, a more complicated sequence of events ensues (Figure 4),[2] since now electrons are available also in the heme *a* and Cu_A centers. After formation of the O_2 adduct (compound A), the next step is a ca. 30-µs event which involves electron transfer from the low spin heme to the binuclear site. As reported by Morgan *et al.*,[54] the optical spectrum of the state formed is indistingishable from that of $\mathbf{P_M}$ if the absorption change owing to oxidation of heme *a* is accounted for. In contrast, Einarsdóttir *et al.*[55] have claimed that the spectrum of this $\mathbf{P_R}$ state formed from the fully **r**educed enzyme is different from that of $\mathbf{P_M}$, and that $\mathbf{P_R}$ does not represent a structurally

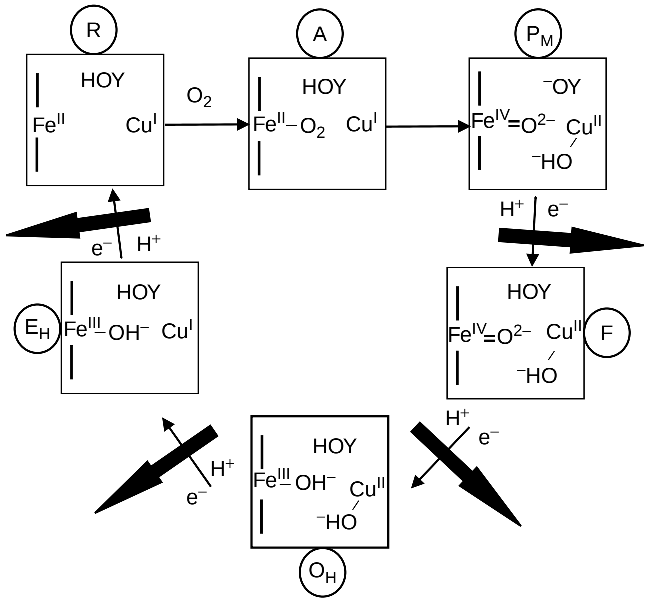

Figure 5 The catalytic cycle and its linkage to proton translocation. States **R** through $\mathbf{O_H}$ are equivalent to those in Figure 4. Large arrows denote translocation of one proton across the membrane (proton pumping). For details, see the text

homogeneous entity, but rather a mixture of **P** and **F** states. In their alternative branched reaction mechanism, the **A** state decays in part into what we call $\mathbf{P_R}$ here, and in part into state **F** with net uptake of a proton. However, such early proton uptake disagrees with time-resolved measurements of membrane potential, which is not generated during the conversion of **A** to $\mathbf{P_R}$.[53] Moreover, contrary to Ref. 54, there is indeed resonance Raman evidence[44,52] for $\mathbf{P_R}$ formation ($\nu_{Fe=O} = 804\,cm^{-1}$) before **F** ($\nu_{Fe=O} = 785\,cm^{-1}$) when the fully reduced enzyme reacts with O_2. Morgan *et al.*[56] showed that $\mathbf{P_R}$ is the state that exhibits an unusual EPR signal from Cu_B[II], indicating an interaction with another paramagnetic center nearby, the ferryl heme iron.[57] Thus, $\mathbf{P_R}$ may have the structure Fe[IV]=O; Cu_B[II]-OH^-; tyr-O^- (Figure 4). It decomposes spontaneously in ca. 60–100 µs (depending on the source of the enzyme) to the ferryl-cupric state **F**, without further electron transfer into the binuclear center, but with net uptake of one proton.[2] Thus $\mathbf{P_R}$ and **F** are equivalent electronically, but the latter has one more proton taken up via the D-pathway, probably to protonate the tyrosinate, as recent FTIR experiments have suggested (P.R. Rich, personal communication).

While the binuclear site has very similar Soret band spectra in states $\mathbf{P_M}$, $\mathbf{P_R}$, and **F**, they differ considerably in the Q band (*see* ***Iron Porphyrin Chemistry***). Thus both $\mathbf{P_R}$ and $\mathbf{P_M}$ show a prominent sharp absorption maximum at 607 nm with high absorptivity, whereas **F** has a broad maximum at 580 nm with a much lower extinction coefficient. This difference, like the $20\,cm^{-1}$ difference in $\nu_{Fe=O}$ observed in Raman experiments, may be due to a different hydrogen-bonding pattern on the distal side of the heme[44,49] caused by the additional proton present in **F**. There may be stronger hydrogen bonding to the ferryl oxygen in **F** relative to **P**, which would be consistent with the lower $\nu_{Fe=O}$ as well as with its larger shift on substituting D_2O for H_2O. Additional hydrogen bonding in **F** may either be due to an aquo ligand of Cu_B (which is OH^- in **P**), or to protonation of the tyrosine, which may donate a hydrogen bond to Fe=O via a water molecule within the site (Figure 4). Such distal hydrogen bonding in **F** may induce strain that compromises an otherwise axial symmetry of the Fe=O structure in **P**, which could explain the large spectral perturbation of the Q band.

The electron originally at Cu_A becomes equilibrated approx. equally between heme *a* and Cu_A with the same kinetics as the **F** state is formed (Figure 4). This electron is finally transferred to the binuclear site, together with uptake of another proton via the D-pathway, and the **O** state is formed in ca. 2–3 ms. Different forms of the **O** state that differ in spectroscopic and kinetic parameters have long been described in the literature,[58,59] but the structural basis for these differences remains unclear. Most recently Verkhovsky *et al.*[60] reported a distinct difference in function, where reduction of the enzyme in state **O** was coupled to proton translocation only when such reduction followed immediately after oxidation of the reduced enzyme by O_2. The structure of the binuclear

site in state **O** is thus of great interest. Resonance Raman data have shown iron-bound hydroxide in recently oxidized enzyme.[44,61] Thus, a possible structure for this state is Fe[III]-OH^-; Cu_B[II]-OH^-; tyr-OH, which has also been supported by *ab initio* calculations.[62] Re-reduction of heme a_3 and Cu_B in the **O** state to form state **R** is known to be associated with net uptake of approx. two protons (Figure 5).[63]

3.3 Proton Pumping and Protonation of the Binuclear Site

The scheme of the catalytic cycle depicted here (Figure 5) is by no means proven correct in all respects. For example, the site that accepts the substrate proton (*e.g.* tyrosinate or hydroxy-ligand of Cu_B) is still uncertain. Notwithstanding this uncertainty, the catalytic scheme in Figure 5 has been drawn to follow two key principles: first, proton translocation (see below) is driven by uptake of a substrate proton to the binuclear site,[64,65] and second, translocation of one proton occurs in association with each one of the four electron transfers to the binuclear site.[60,66] These two principles dictate that the protonatable oxygenous sites that are formed as a result of O–O bond splitting (ferryl oxygen, Cu-bound hydroxide, tyrosine radical), and which together will take up four protons in the complete cycle, will take up one proton at each single electron transfer step. This principle differs from the proposed mechanisms of Michel[67] and Popovic and Stuchebrukhov,[68] in which proton translocation does not occur in association with the first (**O** → **E**) or second (**E** → **R**) electron transfer, respectively, but in both cases only *after* the **R** state has reacted with O_2. In both these proposed models the binuclear center is already fully protonated in the **E** state, that is, prematurely relative to the principles outlined above. A remaining distal OH^- ligand on heme a_3 in the **E** state (Figure 5) is, however, consistent with recent results of Brzezinski *et al.*,[69] who showed that the conversion of **R** back to **E** in the isolated enzyme at high pH is associated with release of one proton that most likely derives from a water molecule cordinated to heme a_3, forming a low-spin ferric hydroxide species that was detected by EPR. The structure $\mathbf{O_H}$ for the oxidized site in Figure 5 is metastable,[60,66] and almost certainly different from the structure of the oxidized enzyme as isolated, which is also supported by *ab initio* calculations.[62] The exact changes that occur on relaxation of the metastable $\mathbf{O_H}$ state are unknown to date, however, and this is another important issue that remains to be solved, not least because it may highlight the structural requirements of active proton translocation.

3.4 Proton Translocation Mechanisms

Several details of the proton translocation mechanism have been revealed since the previous edition of this series. Thus, the proton transfer pathways have been elucidated (see above), and near consensus has been reached that all protons that are pumped across the membrane will pass through the D-pathway (but see Ref. 23). However, as discussed above, there is not yet consensus with respect to the identity of the reactions in the catalytic cycle that are coupled to proton translocation. Major uncertainties start when considering the fate of the protons beyond the glutamic acid in the D-pathway. Also, the ‘pump element’ that links proton translocation to electron transfer remains to be identified. In the histidine cycle type of mechanism[7,64] a dissociable histidine ligand of Cu_B was proposed to be the ‘pump element’. This proposal was based on the notion that all four proton-pumping steps in the catalytic cycle would occur in the **P** → **F** and **F** → **O** steps, as suggested by the dependence of the **P** ↔ **F** and **F** ↔ **O** equilibria on the [ATP]/[ADP]·[P_i] ratio in mitochondria at a high electrochemical proton gradient.[70] However, subsequent kinetic data with cytochrome oxidase incorporated in vesicles showed unequivocally that this is not the case, but that one proton is pumped during each of these steps.[60,66] It is still not fully understood why the mitochondrial experiments overestimated the charge translocaton stoichiometry. One possibility suggested by Michel[67] is significant proton leaks across the mitochondrial membrane at the high proton electrochemical potential employed. This would compromise the assumption of near equilibrium in the system and cause artifactually high charge translocation stoichiometries.

It is known that the D-pathway transfers the pumped protons, but it also transfers substrate protons to be consumed at the binuclear site, at least those consumed during the $\mathbf{P_M}$ → **F** → $\mathbf{O_H}$ reactions.[71,72] Mutation of the lysine in the K-pathway (Figure 3a) hardly affects these reactions, but strongly inhibits reduction of heme a_3 and blocks the reversal of the **E** → **R** reaction step.[73] Measurements of charge translocation in reconstituted oxidase vesicles suggested that also the $\mathbf{O_H}$ → $\mathbf{E_H}$ reaction is blocked by this mutation.[74,75] One important problem, already alluded to, is indeed why two proton transfer pathways are required, especially since the two do not discriminate between pumped and substrate protons, as first assumed.[7]

Iwata *et al.*[7] suggested that the D-propionate of heme a_3 may provide the entry into the proton exit pathway of proton pumping, and this has received experimental support.[26,27] Tsukihara *et al.*[23] (supporting information) and Popovic and Stuchebrukhov[68] criticized this proposal on the basis of the strong ion pair formed between this propionate and a conserved arginine. However, a proton-accepting role of the propionate may be transient and dependent on fluctuations of the arginine-propionate structure.[76,77] The problem remains that both substrate and pumped protons must be transferred through the D-pathway via the glutamic acid, which calls for a molecular ‘switch’ that transfers the proton from the glutamic acid in a controlled fashion, either to be pumped or to be consumed. There are, however, at least two possible scenarios where a redox state dependent switch may not be required. If the first proton taken up is transferred to the pump rather than to the binuclear site purely for thermodynamic reasons (*i.e.* if

the pK_a of the former is much higher),[78] no switching function is necessary. Alternatively, if the first proton is transferred to the binuclear site (having the highest pK_a), and this causes a conformational change that raises the pK_a of a pump site, the next proton will automatically be transferred to be pumped.[77]

The model by Siegbahn *et al.*[78] proposed the key 'pump element' to be the A-propionate of heme a_3 (Figure 3b), which according to their DFT calculations can have a higher proton affinity than the binuclear site itself. However, one experimental drawback of this model is the finding that mutations of the conserved aspartic acid that strongly interacts with this propionate has little effect on enzyme activity, and no effect on the efficiency of proton pumping.[79,80] The model by Brzezinski and Larsson[77] attributes a conformational change and a concomitant rise in the pK_a of the propionate/arginine pair to the deprotonation of glutamic acid when its proton is delivered to the binuclear center. However, such a key role of the glutamic acid carboxyl group is difficult to reconcile with proton pumping by some of the more distanty related heme-copper oxidases in which a tyrosine residue has replaced the glutamate.[81,82] Of course, here we assume again that the same mechanism of proton translocaton is shared by all heme-copper oxidases.

The model recently proposed by Popovic and Stuchebrukhov[68] was based on electrostatic calculations and claimed H291 to be the 'pump element'. H291 is one of the ligands of Cu_B (Figure 3b), and was proposed to be deprotonated at the Nδ1 position when the binuclear center is oxidized, or when it receives a proton.[68] Apart from the deviation of this model from the two basic principles outlined above, it stands in contrast to the electrostatic calculations by Kannt *et al.*[83] according to which the Cu_B ligands H291 and H290 are neutral (*i.e.* singly protonated) even in the fully oxidized enzyme.

As already discussed, the model proposed by Tsukihara *et al.*[23] depends on the so-scalled H-pathway of proton transfer and on the function of an aspartic acid that is not conserved in the bacterial oxidases. This model also depends crucially on the formyl group and on the hydroxyethyl farnesyl side chain of heme *a*. Many proton-pumping bacterial oxidases, such as cytochrome bo_3 from *E. coli*, have replaced heme *a* with a protoheme (heme B) that lacks both the formyl and the farnesyl side chain. Therefore, this model is restricted to heme *a* – containing oxidases, and implies different mechanisms of proton translocation in different members of the heme-copper oxidase superfamily.

Yoshikawa *et al.*[18] made the important statement that 'the role of heme *a* may be the biggest mystery in the structure and function of cytochrome *c* oxidase'. It is indeed not at all obvious why all heme-copper oxidases have a low-spin heme group very close to the binuclear heme-copper site, especially since direct electron transfer from Cu_A to that site (if it occurred) would take place across almost the same distance. In the cytochrome *c* oxidases such direct electron transfer is effectively prevented, perhaps due to the bound Mg, the coordination sphere of which lies on the shortest path between Cu_A and heme a_3. The Mg site is indeed lacking from the quinol oxidases, which also lack Cu_A, and where electrons from a bound quinol on the back of the low-spin heme are transferred via that heme group to the binuclear site.[11]

The enigmatic role of heme *a* may also be related in an interesting way to Babcock's important conclusion[2] that it is an 'electron-queuing' point, and that further electron transfer to the binuclear center is strictly controlled by proton uptake.[84] It occurred to us[76] that this queuing function, as well as the unique positioning of heme *a* in the structure, may provide the key to the proton-pumping mechanism. An electron that is 'queuing' at heme *a* will induce an electric field between this heme and the binuclear center, parallel to the membane. Such a field may have the effect of orienting water molecules in the hydrophobic cavity between the glutamic acid and the binuclear site (Figure 3a), and thus provide a redox state-controlled switch between proton pumping and proton consumption. The short distance between the two hemes, their position relative to the membrane, the proton-donating glutamic acid, the proton-accepting propionate, and the hydrophobic cavity between them are all prerequisites of this proposed mechanism.[76] In some ways this structure is reminiscent of that between the proton-donating D96 and the proton-accepting Schiff's base in the light-driven proton pump, bacteriorhodopsin.[85] Also in this latter case there is a hydrophobic cavity between proton donor and acceptor, which contains an array of water molecules that carries the proton across the 10 Å distance.[86] In cytochrome oxidase the role of the water molecules may be more intricate, however, because they may provide strictly redox state-controlled proton-conducting Grotthuss 'wires'[87,88] for proton translocation and consumption.[76]

4 CONCLUSIONS

The fundamental role of aerobic respiration for all higher organisms and for several prokaryotes has conferred specific characteristics on cytochrome oxidase, and on the large family of heme-copper oxidases more generally. Many of these characteristics have been revealed since the last edition of this series. The crystal structures of several heme-copper oxidases have been solved, generally confirming the coordination of the redox centers that had been worked out by site-directed mutagenesis combined with spectroscopic and other biophysical techniques. However, for example, the relative positioning of the two heme groups in the structure was not anticipated. The unique capability of catalyzing safe reduction of dioxygen to water is now fairly well understood mechanistically. In a single fast reaction step the weakly but rapidly bound O_2 is trapped by accepting four electrons locally from within the active site itself in a reaction that is much faster than turnover, therefore allowing fast cell respiration even at low O_2 concentrations. This step is not

coupled to energy transduction, but is designed to transfer the oxidizing potential of O_2 to the active site without spending energy on O_2 binding. As a result, the active site becomes highly oxidizing, and thereby poised to accept electrons in the four discrete reaction steps that follow. As pointed out by Babcock,[2] the strategy is strict proton control of these latter steps, which allows buildup of intermediates, and gives the opportunity to study catalysis and energy transduction in cytochrome oxidase by a variety of time-resolved biophysical techniques. But more important, the control by proton transfer has profound mechanistic implications because it allows coupling of the electron transfers to proton translocation. In cytochrome oxidase these single electron transfers are each coupled to translocation of *two* electrical charge equivalents whereby the energy transduction efficiency per electron is twice that encountered in photosynthetic reaction centers or in the cytochrome bc_1 complex, which operate according to Mitchell's redox loop principle.[1] Athough many mechanistic models have been presented, as discussed above, it is still not fully understood how this fundamental difference in function is resolved mechanistically.

Glossary

Acyl complex: a complex containing the grouping M−COR, where R is an alkyl or aryl group
Anti-Bredt alkene: a polycyclic alkene that contravenes Bredt's rules by having a C=C bond attached to a bridgehead carbon atom
Deuterioaldehyde: a compound of the general formula RC^2HO
Hofmann elimination: loss of a proton leading preferentially to the alkene carrying the smaller number of alkyl groups (cf. Saytzeff elimination below)
Isotopic scrambling: random incorporation of an isotopic substituent (usually deuterium) during a reaction
Kinetic isotope effect: the ratio $k\mathrm{H}/k\mathrm{D}$ of the rates of reaction of the normal substrate and the deuterated substrate. If a bond to deuterium is broken in the rate-determining step, the ratio is usually greater than 1
Saytzeff elimination: loss of a proton leading preferentially to the alkene carrying the larger number of alkyl groups (cf. Hofmann elimination above)

1 INTRODUCTION

The decarbonylation of carboxylic acid halides or aldehydes by complexes of the platinum group metals represents a modern, convenient method of descending a homologous series. Acid halides are particularly useful starting materials since most are decarbonylated to alkenes, while the major product from an aldehyde is the alkane. The utility of the reaction is increased by the fact that chiral groups retain their configuration throughout the reaction. If the reactants are scrupulously dried, decarbonylation of deuterioaldehydes represents a means of specifically labeling the product with deuterium at the site of the original formyl substituent.

The reactions may be carried out either stoichiometrically or catalytically. Normally, economy dictates that the reaction is carried out catalytically at temperatures between 150 and 200 °C. Addition of a carbonyl acceptor permits the catalytic reaction to be carried out at room temperature with simple substrates.

The first stage in the reaction is oxidative addition of the acyl compound, RCOX (X = H, halide) to the low-valent, coordinatively unsaturated metal complex (*see Oxidative Addition*). The acyl complex so formed rearranges to an alkyl carbonyl complex, which subsequently undergoes *reductive elimination* of the products. The carbonyl group abstracted from the organic substrate is incorporated in the resulting transition metal carbonyl complex. If the substrate or an added reagent displaces the carbonyl ligand from its complex, then the reaction is catalytic.

2 SCOPE OF THE REACTION

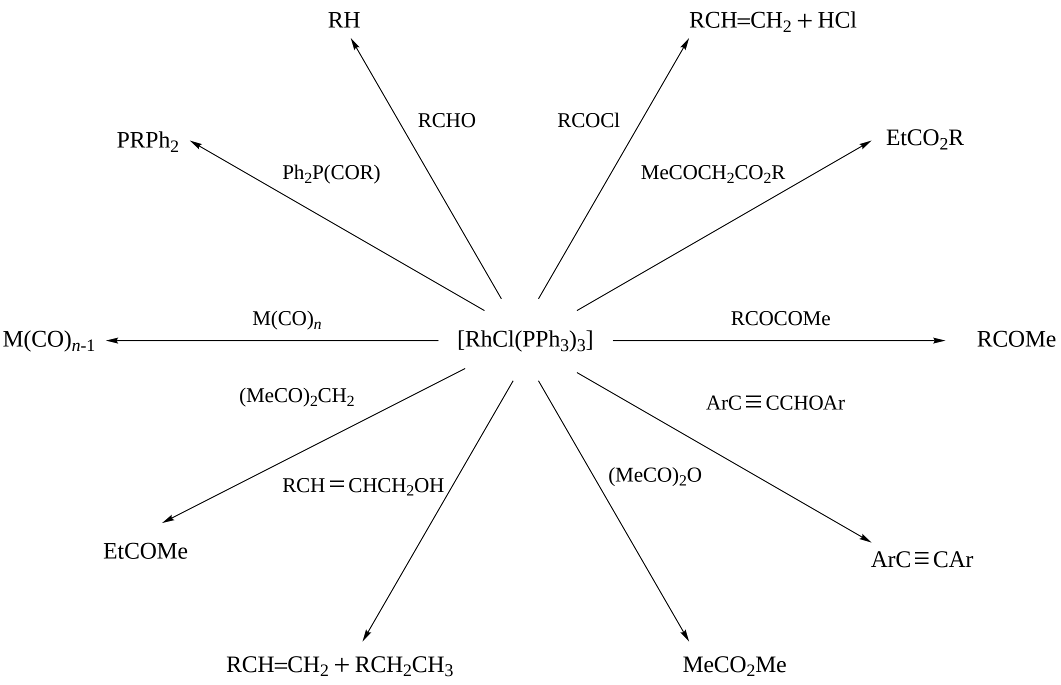
Many transition metal carbonyl complexes have been prepared, often inadvertently, by allowing a metal halide or polyhalometallate to react with a ligand in an organic solvent with carbon−oxygen bonds. Indeed, carbonyl abstraction is an important synthetic route to *trans*-$[MCl(CO)(PPh_3)_2]$ (M = Rh, Ir) or $[OsHX(CO)(ZPh_3)_3]$ (X = Cl, Br; Z = P, As) and related osmium(II) complexes.

Other carbonyl complexes can be obtained from the reactions between existing complexes and organic solvents, which incorporate oxygen. Thus, *mer*-$[ReCl_3(PMe_2Ph)_3]$ abstracts carbon monoxide from refluxing dimethylamino-ethanol to form *trans*-$[ReCl(CO)(PMe_2Ph)_4]$. The *mer*-tribromo complex reacts analogously with formic acid.

Since these initial discoveries, it has been found that a wide variety of substrates can be decarbonylated by transition metal complexes. Rhodium complexes are the most widely used since their products are usually the very stable *trans*-$[RhCl(CO)L_2]$ complexes.

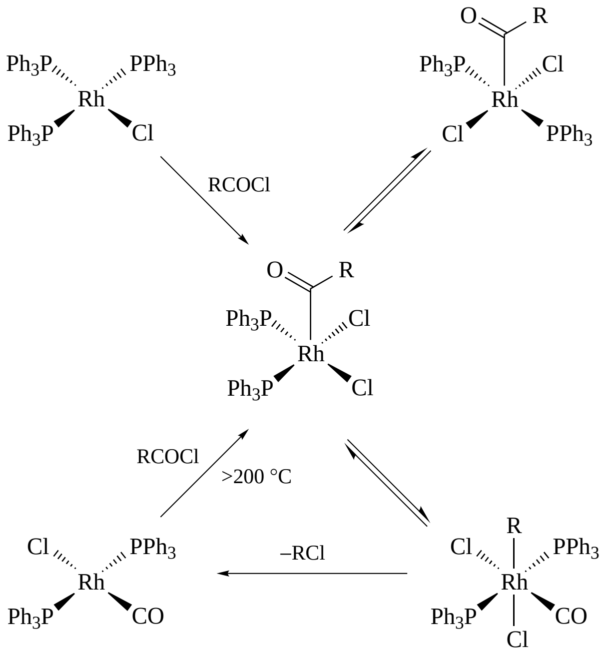
Acyldiphenylphosphines, aromatic ketoalkynes, allylic alcohols, metal carbonyl complexes, or acid anhydrides can be decarbonylated by $[RhCl(PPh_3)_3]$, while α, β- and certain other diketo compounds are semi-decarbonylated by this complex (Scheme 1). Many binary transition metal carbonyl complexes undergo metathetical reactions with $[RhCl(PPh_3)_3]$. These metathetical reactions also occur if $[RhCl(PPh_3)_3]$ is used to decarbonylate acyl carbonyl complexes since ^{13}CO labeling of the acyl ligand has shown that a carbonyl ligand is abstracted. The product, $[(\eta^5\text{-}C_5H_5)Fe(CO)(COMe)PPh_3]$, arises from a triphenylphosphine attack on the intermediate $(\eta^5\text{-}C_5H_5)Fe(CO)(COMe)$ before it can rearrange to the methyl complex.[1]

Many of the above reactions are stoichiometric, which greatly limits their applicability because of the high cost of platinum metals. Fortunately the decarbonylation of



Scheme 1

aldehydes and acid chlorides is catalytic at the high temperatures required to decompose *trans*-[RhCl(CO)(PPh_3)$_2$]. Palladium(0) complexes also act as catalysts in the decarbonylation of acyl or aroyl cyanides at somewhat lower temperatures.[2]



Scheme 2

3 DECARBONYLATION OF ACID HALIDES

These decarbonylation reactions can be either stoichiometric[3] or catalytic.[4] The latter reactions are carried out at high temperatures in high-boiling, inert solvents such as benzyl chloride. The high temperatures are required to eliminate CO from the *trans*-[RhCl(CO)(PPh_3)$_2$] initially formed in these reactions. Other than this essential regeneration of the intermediate RhCl(PPh_3)$_2$, there is little reason to suppose that there are significant differences between the stoichiometric and catalytic reactions.

The catalytic cycle is shown in Scheme 2. The first step is the two-fragment oxidative addition of acid halide to *trans*-[RhCl(CO)(PPh_3)$_2$]. It has been demonstrated that the initial pentacoordinate acylrhodium(III) product is square pyramidal with cis basal triphenylphosphine ligands. This isomerizes to a more stable square-pyramidal complex with trans basal triphenylphosphine ligands. In both complexes, the apex of the pyramid is occupied by the acyl group. However, it has been clearly shown that only the cis square-pyramidal isomer undergoes alkyl migration to the vacant site on rhodium in the next step of the catalytic cycle.[5] It is now generally agreed that the migration of chiral alkyl groups takes place with retention of configuration.

The decarbonylation is completed by a reductive elimination reaction. The exact form of this reaction is determined

by the nature of the alkyl group. The alternatives available are reductive elimination of chloroalkane, or reductive elimination of HCl and release of alkene. The first process is restricted to aryl groups and those alkyl groups that contain no β-hydrogen atoms. The elimination again occurs with retention of configuration if a chiral alkyl group is present.

This duality is entirely analogous to that found in the decarbonylation of aroyl or acyl cyanides by [Pd(PPh$_3$)$_4$] as shown in equations (1) and (2).[2]

$$\text{ArCOCN} \xrightarrow{[\text{Pd(PPh}_3)_4]} \text{ArCN} + \text{CO} \qquad (1)$$

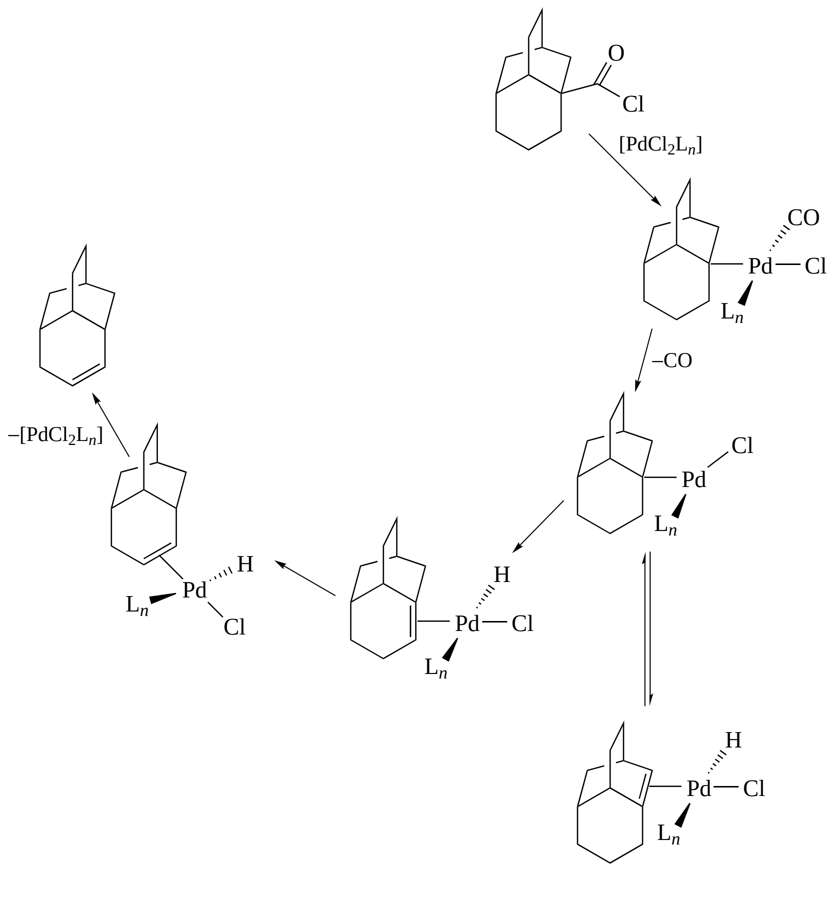
$$\text{RCH}_2\text{CH}_2\text{COCN} \xrightarrow{[\text{Pd(PPh}_3)_4]} \text{RCH}_2\text{CH}_2\text{CN} + \text{RCH{=}CHCN} \qquad (2)$$

That alkenes are formed from those alkyl groups containing a β-hydrogen atom strongly implies that the mechanism of alkene formation involves a β-hydride abstraction step. There is a very pronounced kinetic isotope effect when $C_6D_5CD_2CH_2COCl$ is decarbonylated, which indicates that not only does a β-deuteride abstraction take place but that it is also rate determining. Further evidence for the participation of a β-hydride abstraction comes from the decarbonylation of *erythro*- or *threo*-2,3-diphenylbutanoyl chloride, where the former yields the (E)-alkene and the latter the (Z)-isomer.

However, in other instances, postelimination reactions can change the nature of the products. The main difficulty arises from the readdition of the alkene initially produced to the hydrido complex. This can result in isotopic scrambling or isomerization of the alkene upon reelimination. The formation of internal alkene products from the [Pd(PPh$_3$)$_4$]-catalyzed decarbonylation of acyl cyanides (equation 2) may also arise from postelimination reactions between the alkene and [PdH(CN)(CO)(PPh$_3$)$_n$] initially formed. The importance of this reaction in isomerizing the anti-Bredt alkenes[6] formed by the catalytic decarbonylation of 3-chlorocarbonyltricyclo[5.3.1.0^{3,7}]undecane is shown in Scheme 3.

If the influence of these posteliminations can be minimized, it is possible to show that Saytzeff rather than Hofmann elimination takes place. The preference for hydrogen abstraction is tertiary > secondary > primary.[8]

Both pre- and postelimination reactions conspire to frustrate attempts to determine if the rhodium complex retains its original chloro ligand throughout the catalytic cycle. Experiments employing [RhCl(PPh$_3$)$_3$] in the catalytic decarbonylation of aroyl fluorides are not very successful. The reaction soon ceases, implying that halo ligand exchange has taken place and that fluoro complexes do not catalyze



Scheme 3

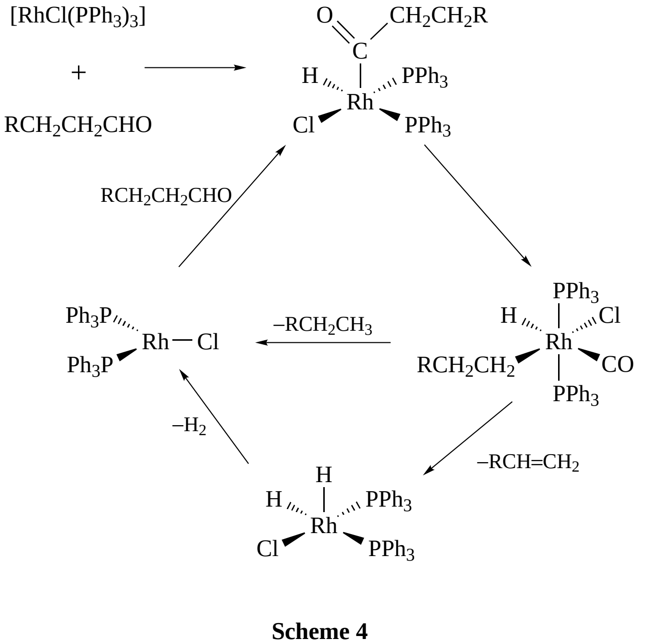
the decarbonylation reaction. Neither aroyl bromides nor iodides poison the catalyst in this way, but anomalous products are sometimes obtained from the decarbonylation of 2-iodobenzoyl halides because of the participation of benzyne intermediates.

Generally, the products formed by the catalytic decarbonylations of acid halides are easily predicted. Some of the few instances where this is not the case are the decarbonylations of pent-3-enoyl or 2-methylbut-3-enoyl chlorides. Here the formation of η^3-allyl complexes after decarbonylation results in several products being formed.[7]

4 ALDEHYDE DECARBONYLATION

The [$RhCl(PPh_3)_3$] catalyzed decarbonylations of aldehydes proceed in an entirely analogous manner to acyl halide decarbonylations, the first stage being the oxidative addition of aldehyde to a coordinatively unsaturated rhodium complex (Scheme 4). The acyl ligand then undergoes an alkyl group migration in which the configuration of the latter is retained. The reaction is completed either by reductive elimination of alkane or by β-hydride abstraction from the alkyl group and elimination of alkene. The final inorganic product is *trans*-[$RhCl(CO)(PPh_3)_2$].

The reaction is catalytic at high temperatures, but some thermolysis of many aldehydes occurs under these conditions. In the past, several attempts have been made to persuade the catalytic reaction to take place at lower temperatures. It is normally necessary to heat the reaction mixture to $>150\,°C$ in order to release carbon monoxide from *trans*-[$RhCl(CO)(PPh_3)_2$]. If the catalytic complex is replaced with [RhCl(CO)(dppp)], decarbonylation takes place at lower



Scheme 4

temperatures since the CO ligand is trans to phosphorus, not Cl, in this complex, and so the M–CO bond is more labile.

Employing a stoichiometric quantity of diphenylphosphoryl azide as a carbon monoxide receptor allows the reaction to proceed at a lower temperature. The azide reacts with *trans*-[$RhCl(CO)(PPh_3)_2$] to form a cyanate at room temperature. Alkene formation is suppressed when this reagent is employed, but higher aldehydes are not decarbonylated in its presence.[9]

Provided care is taken to avoid exchange with water, a kinetic isotope effect is noted when CDO groups are decarbonylated. This indicates that the rate-determining step of the reaction is the scission of the C–D bond. Deuteration studies have also shown that decarbonylation of RCDO yields RD.[10] Further, decarbonylation of Ar^1CDO and Ar^2CHO mixtures yields only Ar^1D and Ar^2H.[11]

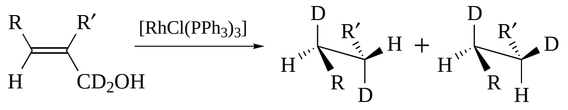
The formation of alkene from eligible substrates is not so pronounced as in the decarbonylation of acyl halides. Usually about 10% of alkene is obtained from alkyl intermediates bearing a β-hydrogen atom. The β-hydride abstraction reaction requires a vacant site on the catalyst to accept the abstracted hydrogen. The very low yields of alkenes found when diphenylphosphoryl azide is added to the reaction mixture suggest that this reagent also acts as a ligand and occupies the vacant coordination site required for hydrogen abstraction.

The decarbonylation reaction is not confined to aldehydes, but also embraces those compounds that have aldehyde tautomers. Thus, both carbohydrates and allylic alcohols can be decarbonylated. When glucose is allowed to react with *trans*-[$RhCl(CO)(PPh_3)_2$] in N-methylpyrrolidin-2-one, decarbonylation occurs and arabinitol is formed with retention of configuration. The decarbonylation of fructose to arabinitol is complicated by the simultaneous dehydration to furfuryl alcohol, which is the major product. Analogous reactions occur with lower carbohydrates; in the limit, glycolaldehyde is decarbonylated to methanol. Aldose derivatives can also be converted to their C_{n-1} analogues, but the yields are only about half of those obtained with the parent aldoses. Disaccharides usually give better yields.[12]

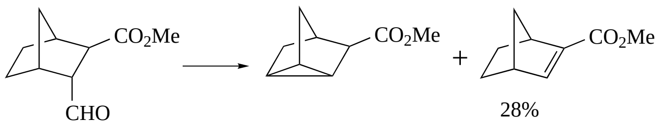
The formation of both erythro and threo products from suitable allylic alcohols containing CD_2OH groups implies that an η^3-allylic mechanism is involved in their decomposition (equation 3).

Not all decarbonylations give the expected product,[10,12] and the relative yields are influenced by the rhodium catalyst employed. Chlorotris(triphenylphosphine)rhodium(I) rapidly and selectively decarbonylated the *endo*-norbornene isomer shown in equation (4) to form a tricycline product, but [$Rh(dppp)_2$]Cl additionally forms an isomeric alkene. In the case of the corresponding exo-isomer (equation 5), [$RhCl(PPh_3)_3$] is the less selective catalyst.[13] It was also found that [$Rh(dppp)_2$]Cl was a superior catalyst

in bringing about the double decarbonylation shown in equation (6).[14]

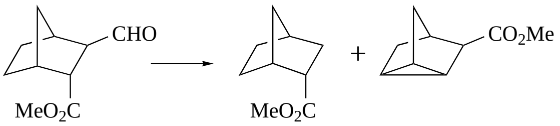


(3)



$[RhCl(PPh_3)_3]$	97%	
$[Rh(dppp)_2]Cl$	67%	

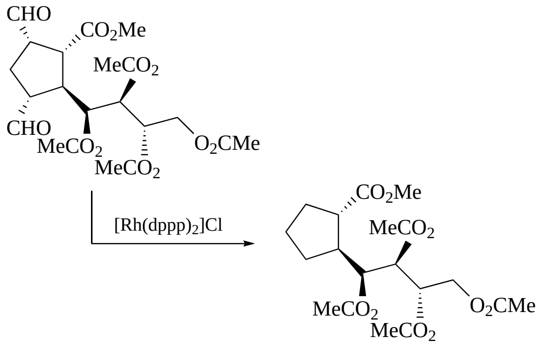
(4)



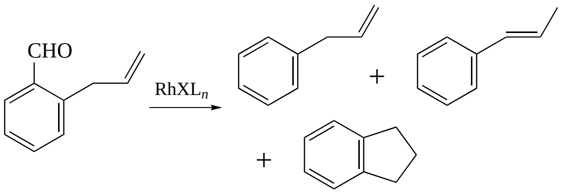
$[RhCl(PPh_3)_3]$	79%	8%
$[Rh(dppp)_2]Cl$	>99%	

(5)

It was noted in Section 3 that unsaturated acyl halides often formed anomalous products. This tendency is even more pronounced in the case of aldehydes. The decarbonylation of 2-allylbenzaldehyde gives a high yield of indan, and very

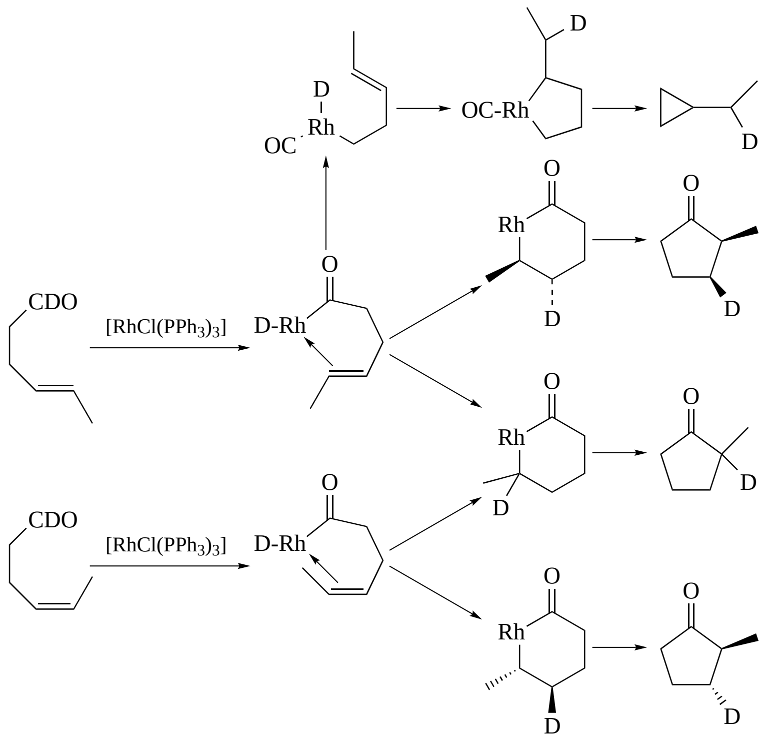


(6)



(7)

little allylbenzene is formed (equation 7). Some of the latter product is isomerized to prop-2-enylbenzene. The highest yield of indan occurs when the reaction is catalyzed by $[RhCl(PPh_3)_2]_2$ because no triphenylphosphine is released as it would be from *trans*-$[RhCl(CO)(PPh_3)_2]$. This allows indan formation to take place by utilizing the vacant coordination site on the monomer. Conversely, addition of PPh_3 to the mixture suppresses both indan formation and isomerization,



Scheme 5

showing the importance of the vacant site on the catalyst for both these reactions.[15]

Considerable information about the course of aldehyde decarbonylations has been gleaned from the decarbonylations of alk-4-enals. Pent-4-enals form cyclopentanones in high yield in decarbonylations catalyzed by $[RhCl(PPh_3)_3]$. The major product from the decarbonylation of hex-4-enal is 2-methylcyclopentanone. As shown in Scheme 5, the cyclization reaction requires a vacant site on rhodium. The other products result from decarbonylation of the unsaturated acyl before cyclization can take place. In these cases, there is competition between addition of deuterium to C-1 of the alkenyl ligand or its addition to the alkene bond and the formation of an unstable metallocycle.[16]

Again the best catalyst for the cyclization is $[RhCl(PPh_3)_2]_2$, which does not release PPh_3 during the reaction. Conversely, low yields of cyclopentanone are obtained in the presence of added PPh_3 or dppe, which competitively coordinate to the vacant site required in the cyclization reaction.

In the analogous stoichiometric reaction, Milstein has correlated the yields of but-1-ene and *trans*-$[RhCl(CO)(PMe_3)_2]$.[17] It has also been reported that oct-6-enal can be cyclized to cyclohexanol.

However, cyclic ketones can themselves be decarbonylated by $[RhCl(PPh_3)_3]$ in high-boiling solvents. There appears to be no correlation with ring size since both 3-hexadecylcyclobutanone and cyclododecanone can be decarbonylated.[18]

1 INTRODUCTION

Defects play an important part in both the chemical and physical behavior of solids and much of modern science and technology centers upon the exploitation or suppression of the properties that defects confer upon a solid. The chemical and physical aspects of a defect are intimately connected, but for simplicity, defects are often portrayed as influencing only chemical or physical properties. Thus, defects such as dislocations, which have a profound effect upon the mechanical properties of a solid, also influence chemical properties such as rates of dissolution and reaction, although these chemical aspects are not always mentioned. Similarly, defects that can be considered as more chemical in nature, such as impurity atoms, have profound effects on the physical properties of materials, as witnessed by 'doped' semiconductors (*see* ***Semiconductors***; ***Semiconductor Interfaces***).

The concept of a defect has undergone considerable evolution over the course of the last century. The simplest notion of a defect is a mistake at normal atom site in a solid. These structurally simple defects are called point defects. Not long after the recognition of point defects, the concept of linear defects, dislocations, was invoked to explain the mechanical properties of metals. In later years, it became apparent that planar defects, including surfaces, and volume defects such as rods, tubes, or precipitates, also have important roles to play in influencing the physical and chemical properties of the host matrix. More recently, it has become apparent that interactions between point defects are of considerable importance, and the simple model of isolated point defects is often inadequate with respect to prediction of the structural, chemical, or physical properties of solids.

Besides the multiplicity of defects that can be envisaged there is a wide range of host solid phases within which such defects can reside. The differences between an alloy, a metallic sulphide, a crystalline fluoride or a silicate glass are significant from both a chemical or physical viewpoint. By default, defects have come to be associated with crystalline solids. This is because a crystal has a regular repetition of atoms throughout its volume. A disturbance of this regularity then constitutes the defect. In this sense, the nature of a defect in, for example, a glass, is difficult to picture.

In this entry, the principal *chemical* features of defect populations (defect chemistry) will be described from the restricted viewpoint of crystalline inorganic solids. The influence of defects upon mechanical properties will be excluded and defects that may have greatest relevance to physical properties will be treated from the point of view of chemical importance. Defects in molecular crystals and amorphous and glassy solids will be omitted (*see* ***Noncrystalline Solids***), as will the important areas of alloys (*see* ***Alloys***), thin films (*see* ***Thin Film Synthesis of Solids***), and carbon nanotubes and related nanoparticles (*see* ***Carbon: Fullerenes***). References to the literature before 1994 are to be found in the corresponding article in the first edition of this Encyclopedia.[1]

There have been two significant changes in the decade since this latter publication. There has been a rapid expansion in computational studies of defects, mirroring the accelerating improvement in computer hardware and software, which are covered in detail elsewhere (*see* ***Solids: Computer Modeling***).[2,3] In addition to calculations of point defect energies, calculations have been applied to the study of defect clusters, the assessment of the most favorable sites for metal insertion into a host structure, defect migration paths, the structure of 'active sites' on heterogeneous catalysts (*see* ***Heterogeneous Catalysis by Metals***; ***Oxide Catalysts in Solid-state Chemistry***), and the calculation of the properties of surfaces and of thin films.

Within recent years, it has been realized, by virtue of increasing sophistication in structure determination, especially that provided by transmission electron microscopy, that many systems that were once described as containing high defect populations are, in fact, defect free. The structure is continuously modulated to remove the necessity for defects. This remarkable change of viewpoint is briefly reviewed in the final section of this article.

2 DEFECTS AND THE COMPOSITION OF SOLIDS

During the latter part of the nineteenth century and the early years of the twentieth century, there was considerable controversy over the composition of chemical compounds. It was clear that some solids, especially metallic alloys (*see*

Alloys), had a variable composition, despite the fact that the material seemed to retain its chemical integrity. Experimental data was less clear-cut about the composition of nonmetallic solids. Although some of these seemed to be rather like alloys and show a composition range, many others had, as far as could be detected at this epoch, no composition range at all.

For the development of chemistry, it was inevitable that the idea that compounds had a fixed composition came to the fore. Most compounds that could be easily investigated were molecular in nature, with fixed compositions, and fitted this concept perfectly. The alloys and other inconvenient solids were pushed to one side of traditional chemical studies, and ended up in technological disciplines such as metallurgy. There was a tacit recognition that simple chemical valence ideas did not apply to metals.

The increasing use of single-crystal X-ray diffraction for structural analysis (*see* ***Diffraction Methods in Inorganic Chemistry***) and powder X-ray diffraction for phase analysis (*see* ***Solids: Characterization by Powder Diffraction***), during the middle years of the last century, began to clarify matters. The definition of a chemical compound then became associated with that of a solid with a known crystal structure. In terms of this approach, it was proved that many metallic systems could retain the same crystal structure over wide composition ranges, while others, showed no tendency to composition variation. Inorganic solids were similarly disparate. Many seemed to possess no significant composition range at all, and these came to be called stoichiometric compounds. Others, just as clearly, appeared to retain the same crystal structure over wide composition ranges, and these became known as nonstoichiometric compounds.

The cause of nonstoichiometry was initially attributed to the presence of point defects in a structure. It was recognised that all ionic solids should, in principle, possess a composition range by virtue of a population of point defects.[4] Those solids with a vanishing composition range make up the stoichiometric compounds, and those with a measurable composition range are the nonstoichiometric compounds. The structural nature of the defects in a crystal is more complex. Defects interrupt the regularity of the surrounding crystal structure and give rise to stress fields, resulting in local strain. When defect density is small, a population of isolated point defects may provide a sound structural model for the interpretation of properties. However, as the defect density increases, strain can often be reduced by the association of defects, so that isolated point defects, as such, become replaced with clusters or extended defects. When stoichiometry is altered, electronic interactions can also occur, often greatly outweighing the stress, leading to point defect interaction. In many cases, the interaction energies are of the same order of magnitude as thermal energy. Thus, at low temperatures, defects tend to order. This ordering, particularly when promoted by long annealing times, can result in the formation of new structures in which the defects are eliminated. Intermediate stages of ordering are also common, in which clusters or aggregates of defects, exist. In both of these cases, the ordering may be lost at high temperatures. In such cases the low-temperature structure, which may be defect free or contain extended defects, is transformed into one in which a population of noninteracting point defects becomes a reasonable structural model. In the sections that follow, the temperature variation will not be repetitively stressed, but one should always be aware that defect structures investigated at room temperature may not occur in materials at high temperatures.

3 DEFECTS IN STOICHIOMETRIC MATERIALS

First approaches to the quantitative understanding of defects in stoichiometric crystals were published in the early years of the last century by Frenkel in Russia and Schottky in Germany. These workers described the statistical thermodynamics of solids in terms of the atomic occupancies of the various crystallographic sites available in the structure. Two noninteracting defect types were envisaged. Interstitial defects consisted of atoms that had been displaced from their correct positions into normally unoccupied positions, namely, interstitial sites. Vacancies were positions that should have been occupied but were not.

3.1 Monoatomic Solids

A monatomic crystal such as silicon can contain vacancies at normally occupied atomic positions, and interstitial atoms, called self-interstitials, at normally unoccupied sites in the

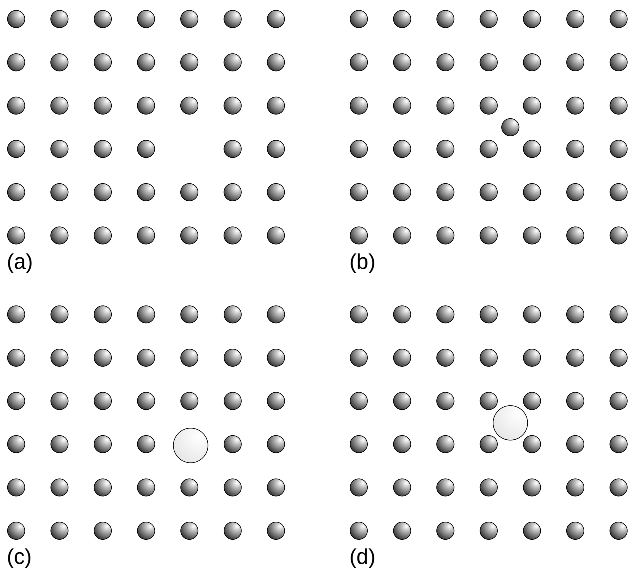

Figure 1 Idealised representations of point defects in a monatomic crystal. (a) vacancy, (b) (self) interstitial, (c) substitutional impurity or dopant, (d) interstitial impurity or dopant

solid (Figure 1(a), (b)). The Gibbs energy of a crystal containing a small number of these defects is lower than that of a perfect crystal, mainly owing to the entropy of the defect populations. Thus, a population of point defects is to be expected in a crystal, and such defects are called intrinsic defects. This defect population can be treated as a chemical equilibrium, and written:

$$\text{null} \rightleftharpoons \text{vacancy} \qquad (1)$$

The law of mass action in its simplest form, with concentrations instead of activities, can be applied if there is no interaction between the defects, to give an expression for the equilibrium constant, K_v:

$$K_v = \frac{n_v}{N} = \exp\left[\frac{-\Delta G_v}{RT}\right]$$

$$n_v = N \exp\left[\frac{-\Delta G_v}{RT}\right]$$

where n_v is the number of vacant sites per unit volume in a crystal, N is the total number of sites per unit volume and ΔG_v is the molar Gibbs energy of formation of the vacancies, R is the gas constant, and T the absolute temperature. The Gibbs energy, ΔG_v, is often replaced by the enthalpy of vacancy formation, ΔH_v.

A similar equation holds for the relationship between the number of self-interstitials and the equilibrium constant, K_i. The creation of a self-interstitial on one of N^* possible interstitial sites leaves a vacancy on one of the N normal lattice sites:

$$\text{null} \rightleftharpoons \text{interstitial} + \text{vacancy} \qquad (2)$$

$$K_i = \left(\frac{n_i}{N^*}\right)\left(\frac{n_v}{N}\right) = \exp\left[\frac{-\Delta G_i}{RT}\right]$$

As the number of interstitials and vacancies is the same, $n_i = n_v$, and:

$$n_i = \sqrt{NN^*} \exp\left[\frac{-\Delta G_i}{2RT}\right]$$

where ΔG_i is the molar Gibbs energy of formation of the self-interstitials. The Gibbs energy, ΔG_i, is often replaced by the enthalpy of interstitial formation, ΔH_i.

Under normal circumstances, both of these equilibria operate concurrently, and both types of defect are present in the crystal. However, it is often possible to assume that the only defect of importance is that with the lowest formation energy.

3.2 Impurities and Solid Solutions

Impurities are invariably present in solids, and in low concentrations, they may form point defects. The impurity atom can occupy atom sites normally occupied by the parent atoms, to form substitutional point defects, or can occupy interstitial sites, to form interstitial point defects (Figure 1(c), (d)).

If two solids have the same or very similar structures, and the component atoms have similar sizes, extensive substitutional solid solutions form. In the case of nonmetallic solids, oxidation number is important, since charge balance must be preserved over the composition range of the solid solution. Which atoms are regarded as the defects and which the matrix, will depend upon their relative concentration. For example, the corundum structure oxides Al_2O_3 and Cr_2O_3 form a continuous solid solution of formula $Al_{2-x}Cr_xO_3$, $(0 < x < 2)$, in which Al^{3+} cations in the structure are gradually replaced by Cr^{3+} cations. In solids with several atomic constituents, solid solution formation may be restricted to one of the component atoms, as in the pyrochlore structure oxides $Bi_2TlPb_2O_7$, and $Tl_2Pb_2O_7$, which form a continuous solid solution with a formula $Bi_{2-x}Tl_xPb_2O_7$, $(0 < x < 2)$. In cases where the atoms sizes differ sufficiently, only partial solid solution ranges occur, for example, $Sr_{1-x}Ca_xCuO_2$, $(0 < x < 0.6)$.

The physical and chemical properties of such solid solutions can vary in a dramatic fashion. In the $Bi_{2-x}Tl_xPb_2O_7$ system, for example, $Bi_2TlPb_2O_7$ is a red insulator while $Tl_2Pb_2O_7$ is black and shows metallic properties. The solid solution changes smoothly from insulating to metallic in its behavior. The bonding implications of these changes are of considerable chemical interest.

3.3 Balanced Populations of Point Defects

Balanced populations of point defects do not alter the anion to cation ratio, or overall stoichiometry of the crystal. In addition, the numbers of such defects must be such as to maintain charge neutrality. Calculations similar to those for monatomic solids show that the free energy of crystals containing such balanced populations of point defects is lower than that for a defect-free crystal, and these defects are also intrinsic defects, occurring in pure crystals under equilibrium conditions at all temperatures above 0 K. Two important examples of such balanced point defect populations have been described.

3.3.1 Schottky Defects

Balanced populations of vacancies on both the cation and anion sites in a crystal are known as Schottky defects. For example, if the crystal has a formula *MX*, then the number of cation vacancies must be equal to the number of anion vacancies, in order to maintain electrical neutrality. In such a crystal, a Schottky defect consists of 1 cation vacancy and 1 anion vacancy, although these need not be geometrically close together (Figure 2(a)). In a crystal of formula MX_2, there needs to be twice as many anion vacancies as cation vacancies. Similar considerations apply to compounds with

other compositions. As with monatomic solids, this defect population can be treated as a chemical equilibrium. For a crystal of composition *MX*:

$$\text{null} \rightleftharpoons \text{cation vacancy} + \text{anion vacancy} \tag{3}$$

If there is no interaction between the defects, the law of mass action in its simplest form, with concentrations instead of activities, yields an expression for the equilibrium constant, K_S:

$$K_S = \left(\frac{n_{cv}}{N}\right)\left(\frac{n_{av}}{N}\right) = \exp\left[\frac{-\Delta G_S}{RT}\right]$$

where n_{cv} is the number of cation vacancies and n_{av} the number of anion vacancies per unit volume, N the number of cation or anion sites per unit volume in the crystal, ΔG_S is the molar Gibbs energy of formation of the Schottky defects, R is the gas constant, and T the absolute temperature. Because n_{cv} is equal to n_{av} and to the number of Schottky defects present, n_S:

$$n_{cv} = n_{av} = n_S = N \exp\left[\frac{-\Delta G_S}{2RT}\right]$$

The Gibbs energy, ΔG_S, is often replaced by the enthalpy of Schottky defect formation, ΔH_S.

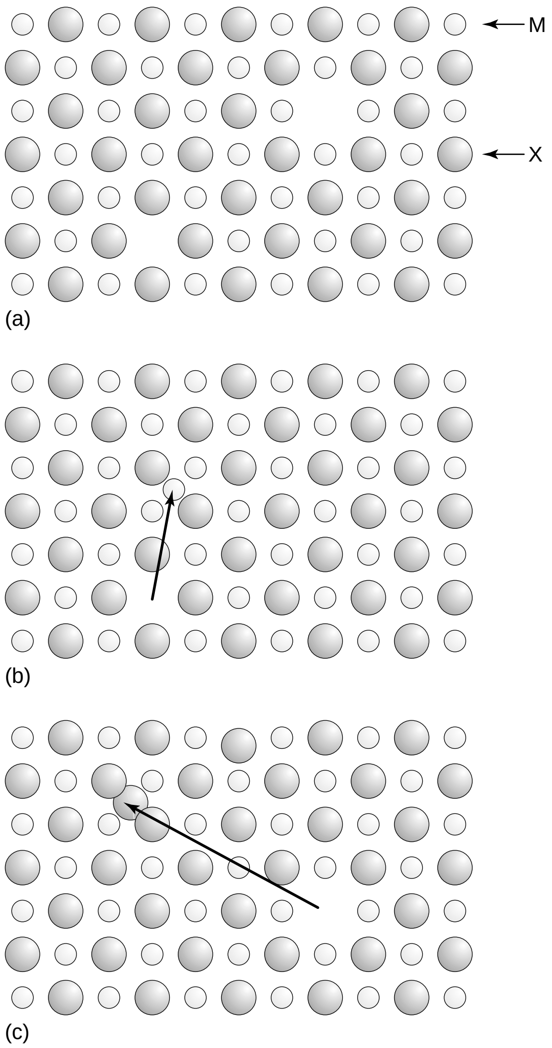

Figure 2 Idealised representation of balanced point defects in an ionic crystal of formula *MX*. (a) Schottky defects, (b) Frenkel defects on cation sites, (c) Frenkel defects on anion sites

3.3.2 Frenkel Defects

A population of vacancies on one subset of atoms created by displacing some atoms into normally unoccupied interstitial sites constitute a second arrangement of paired point defects, termed Frenkel defects (Figure 2(b), (c)). Because one species of atom or ion is simply being redistributed in the crystal, charge balance is not an issue. A Frenkel defect in a crystal of formula *MX* consists of one interstitial cation plus one cation vacancy, or one interstitial anion plus one anion vacancy. Equally, a Frenkel defect in a crystal of formula MX_2 can consist of one interstitial cation plus one cation vacancy, or one interstitial anion plus one anion vacancy. As with the other point defects, it is found that the free energy of a crystal is lowered by the presence of Frenkel defects and so a population of these intrinsic defects is to be expected at temperatures above 0 K. The calculation of the number of Frenkel defects in a crystal can proceed along lines parallel to those for Schottky defects. The appropriate chemical equilibrium for cation defects is:

$$\text{null} \rightleftharpoons \text{cation vacancy} + \text{cation interstitial} \tag{4}$$

The equilibrium constant, K_{cF}, is given by:

$$K_{cF} = \left(\frac{n_{cv}}{N}\right)\left(\frac{n_{ci}}{N^*}\right) = \exp\left[\frac{-\Delta G_{cF}}{RT}\right]$$

where n_{cv} is the number of cation vacancies and n_{ci} the number of cation interstitials per unit volume, N the number of occupied cation sites per unit volume that support Frenkel defects, N^* the number of available interstitial sites per unit volume, ΔG_{cF} is the molar Gibbs energy of formation of the cation Frenkel defects, R is the gas constant, and T the absolute temperature. Because n_{cv} is equal to n_{ci} and to the number of Frenkel defects present, n_F:

$$n_{cv} = n_{ci} = n_{cF} = \sqrt{NN^*} \exp\left[\frac{-\Delta G_{cF}}{2RT}\right]$$

The Gibbs energy, ΔG_{cF}, is often replaced by the enthalpy of Frenkel defect formation, ΔH_{cF}.

A similar equation can be written for Frenkel defects on the anion positions:

$$\text{null} \rightleftharpoons \text{anion vacancy} + \text{anion interstitial} \tag{5}$$

leading to:

$$n_{av} = n_{ai} = n_{aF} = \sqrt{NN^*} \exp\left[\frac{-\Delta G_{aF}}{2RT}\right]$$

where ΔG_{aF} is the molar Gibbs energy of formation of the anion defects.

3.3.3 Total Defect Populations

The defect equilibria represented by equations (3), (4), and (5) operate simultaneously. However, the defect formation energies generally differ considerably, and it is a reasonable approximation to assume that the only defect type of importance is that with the lowest formation energy. This may change with temperature.

3.4 Disordered Cation Compounds

Disordered cation compounds, also called superionic conductors (*see* ***Ionic Conductors***), are a group of materials that can be thought of as containing very high concentrations of cation Frenkel defects. The prototype material is silver iodide. The low-temperature polymorph, β-AgI, is a normal compound, but the high-temperature form, α-AgI, which is stable above 147 °C, possesses an unusually high ionic conductivity for a pure, stoichiometric phase. The structures of both α- and β-AgI derive from a body-centered cubic sublattice of iodine atoms. Within the unit cell, there are 6 octahedral, 12 tetrahedral, and 24 trigonal sites available for cation occupation. In the β polymorph, the two silver atoms per unit cell exclusively occupy two of the tetrahedral positions. In the α form, studies show that the Ag^+ ions are randomly distributed over the 12 tetrahedral positions, leading to the concept of a molten sublattice of Ag^+ ions moving like a liquid through a fixed matrix of I^- ions.

A number of other materials show similar behavior. At low temperatures, the compounds are normal and defect free while at some higher temperature all or part of the metal atom array becomes mobile with cations able to freely move over some or all of the various allowed cation sites in the unit cell. For example, the compound Ag_3CuS_2 has a distorted body-centered cubic packing of sulphur atoms with Ag atoms in distorted octahedral or tetrahedral sites and Cu atoms in linear coordination at room temperature. The cation structure disorders at 117 °C, leading to a high Ag^+ conductivity. The crystal structure of the closely related compound CuAgS shows that the sulphur atoms form a slightly distorted hexagonal close-packed array, in which the copper atoms are located. The Ag ions lie between the sulphur–copper layers. These Ag^+ ions show a progressively greater anisotropic thermal motion as the temperature rises, until, above 93 °C, they are essentially completely mobile, leading to extremely high silver ion conductivity. In the compound $Rb_4Cu_{16}I_{7+x}Cl_{13-x}$, $(-0.2 < x < 0.5)$, the 16 Cu atoms can occupy any one of 56 possible positions. The occupancy varies with temperature, and above room temperature, the phase shows high solid-state conductivity, in this case owing to mobile Cu^{2+} ions (*see* ***Halides: Solid-state Chemistry***).

4 DEFECTS AND NONSTOICHIOMETRY

4.1 Unbalanced Point Defect Populations

If cations or anions in a lattice are replaced by others that have a different valence, or alternatively if interstitial atoms or ions are added to the structure without compensating populations of vacancies, the composition of the crystal must change. Variable populations of such defects will lead to composition ranges of the solid phase and to additional electronic or optical properties. At low concentrations, these defects can be conveniently considered as point defects distributed at random throughout the structure. As the number of defects increases, interactions will lead to the formation of clusters or extended defects.

A number of materials show small but measurable departures from stoichiometry, which can be attributed to an unbalanced population of point defects. The best known of these compounds are probably the transition metal compounds with the halite (rocksalt) structure,[5] typified by NiO and CoO. However, a large number of other materials also fall into this class, for example, ZnO, CdO, Cu_2O, V_2O_3, VO_2, and NbO_2, and ternary oxides such as $BaTiO_3$. In some of these phases, the limited composition range spans both sides of the stoichiometric composition; NbO_2, for instance, has a reported composition range of from $NbO_{1.9975}$ to $NbO_{2.003}$. In others, the materials have a composition range only on one side of the stoichiometric composition. Cobalt oxide, CoO has a reported composition range from approximately $Co_{0.99}O$ to $Co_{1.00}O$ while for CdO the composition ranges from $Cd_{1.00}O$ to approximately $Cd_{1.0005}O$.

The nature of the defects is often difficult to ascertain. Nickel and cobalt monoxides are considered to accommodate composition changes by way of a population of vacancies on the normally occupied metal positions, while in the isostructural CdO the metal excess is usually considered to arise from interstitial Cd atoms.

4.2 Color Centers

When electrons or holes are trapped at defects in a solid, both the electronic and the optical properties are modified. Such composite defects are called color centers. Large numbers of these defects have been characterized, and the term includes defects that have absorption maxima outside the visible spectrum. The expression *color center* is thus used

in a generic sense to refer to defects and associated trapped electrons or holes that interact with electromagnetic radiation.

Many different types of high-energy radiation and chemical treatment will cause color centers to form in a crystal. Regardless of the method of formation, the color produced in any particular crystal is always the same.

4.2.1 Electron-excess Centers

The best-known electron-excess center, the F-center, consists of an anion vacancy plus a trapped electron. The defect arises in crystals that are slightly nonstoichiometric and contain a small excess of metal. F-centers were originally characterized in the alkali halides, the color being indicative of the host structure and not the excess metal. Thus, F-centers in sodium chloride are always yellow–orange, irrespective of whether the excess metal is sodium or another alkali metal. Similar metal excess F-centers exist in a rare blue-purple 'Blue John' form of fluorite, CaF_2, and bright red nonstoichiometric ZnO, containing small quantities of interstitial Zn atoms. Centers can exist that are capable of trapping more than one electron, leading to a multiplicity of related defects.

4.2.2 Hole-excess Centers

One of the commonest forms of hole-excess center imparts color to the minerals smoky quartz and amethyst. These minerals are forms of silica, containing aluminium as an impurity. The Al^{3+} substitutes for Si^{4+}, and to preserve charge neutrality equal amounts of H^+ are incorporated into the crystal. The smoky purple color arises in the electron deficient $[AlO_4]^{4-}$ group. It is formed when an electron is liberated from a neutral $[AlO_4]^{5-}$ group by ionising radiation is trapped on one of the H^+ ions present. Other hole centers have been described in a variety of crystals.

5 DEFECT CHEMISTRY

5.1 Kröger-Vink Notation: Defect Nomenclature

In order to describe the consequences of point defect populations, a notation is required analogous to that used in chemical equations. The most widely employed system is the Kröger-Vink notation, the principal features of which follow.

Vacancies Vacancies (empty *atom* sites) are indicated by the symbols V_M and V_X for metal, M, and nonmetal, X, sites respectively. Where confusion may occur with the atom vanadium, the symbol for a vacancy is written *Va*. Vacancies are created by the removal of neutral atoms from the crystal. This rule also applies to ionic solids. For example, in ionic NiO, V_{Ni} would imply the removal of a Ni^{2+} cation together with two electrons, that is, a neutral Ni atom. Similarly, V_O indicates a vacancy in the oxygen sublattice, and implies removal of an O^{2-} anion from the crystal together with the subsequent addition of two electrons to the crystal.

Interstitial atoms Interstitial atoms are denoted by M_i and X_i for metals and anions respectively. Interstitial atoms are regarded as neutral additives. Hence K_i represents an interstitial potassium atom, not an ion, in a crystal.

Impurity atoms Neutral impurity atoms are given their normal chemical symbol and the site occupied is written as a subscript. Thus, an Mg atom on a Ni site in NiO would be written as Mg_{Ni}. The same nomenclature is used if an atom in a crystal occupies the wrong site. Thus it is possible for M atoms to be on X sites, written as M_X, or X atoms to be on M sites, written as X_M. A potassium atom on a bromine site in KBr would be written as K_{Br}.

Associated defects Point defects that are associated or clustered are indicated by enclosing the components of such a group in parenthesis. For example, $(V_M V_X)$ would represent a defect in which two vacancies are associated as a vacancy pair.

Electrons and holes Free electrons are denoted by the symbol e', where the superscript $'$ represents the negative charge on the electron. Free holes are denoted by the symbol $h^\bullet$, where the positive charge is represented by the superscript $\bullet$.

Charges on defects Atomic defects may carry a charge, and in ionic crystals, this may be considered the normal state of affairs. The Kröger-Vink notation bypasses the problem of deciding on the real charges on defects by considering only effective charges on defects. The effective charge is the charge that the defect has with respect to the normal crystal structure. For example, a vacancy in the NaCl structure at a sodium position will have an effective charge of -1 relative to that normally encountered at that position. In order to distinguish effective charges from real charges, the superscript $'$ is used for each unit of negative charge and the superscript $\bullet$ is used for each unit of positive charge. Hence a vacancy at a sodium site in ionic NaCl would be written as V'_{Na} and a vacancy at a chlorine site would be written $V^\bullet_{Cl}$. The same principle applies to the other atomic defects mentioned. Thus $Zn_i^{2\bullet}$ would indicate a Zn^{2+} ion at an interstitial site that is normally unoccupied and hence without any preexisting charge. Similarly, substitution of a divalent ion such as Ca^{2+} for monovalent Na^+ gives a local electronic charge augmented by one extra positive unit, which is then represented as $Ca^\bullet_{Na}$. When a defect bears no effective charge and the situation needs to be emphasised, the superscript x is used, that is, K^x_{Na}.

The main features of the notation are summarised in Table 1.

5.2 Reaction Equations

The chemical accounting system that equations represent can be modified to take defect populations into account by using the following rules.

1. The number of metal atom sites must always be in the correct proportion to the number of nonmetal atom sites

Table 1 Summary of the Kröger–Vink notation

Type of defect	Notation
Nonmetal vacancy at nonmetal site	V_X
Metal vacancy at metal site	V_M
Interstitial metal	M_i
Interstitial nonmetal	X_i
Impurity metal (A) at metal site	A_M
Impurity nonmetal (Y) at nonmetal site	Y_X
Neutral vacancies	V_M^x, V_X^x
Nonmetal vacancy with effective positive charge	$V_X^\bullet$
Metal vacancy with effective negative charge	V_M'
Metal interstitial with effective positive charge	$M_i^\bullet$
Nonmetal interstitial with effective negative charge	X_i'
Free electron[a]	e'
Free positive hole[a]	$h\bullet$

[a]Concentrations of these defects are frequently designated by n and p, respectively.

in the crystal. As long as this proportion is maintained, the total number of sites can vary, since this simply corresponds to more or less substance present. If the crystal contains vacancies, these must also be counted in the total number of sites. Interstitial atoms do not occupy normal sites and so are not relevant when this rule is being applied.

2. The total number of atoms on both sides of the equation must be equal.
3. The crystal must always be electrically neutral. This means not only that the total charge on one side of the equation must be equal to the total charge on the other side, but also that the sum of the charges on each side of the equation must equal zero. In this assessment, both effective and real charges must be counted if both sorts are present.
4. Only neutral atoms are involved in chemical reactions. After reaction, neutral atoms can dissociate into charged species if this is thought to represent the real situation in the crystal.

As an example, consider the reactions that can occur when ZrO_2 is allowed to react with CaO to produce calcia-stabilised zirconia. In ZrO_2, there are twice as many anion sites as there are cation sites. Suppose that the Ca atoms are located on normal cation sites. Since the Ca atom is neutral, the effective charge at the site will be 4′ with respect to the charge normally encountered at a Zr^{4+} ion. In order to comply with rule (1), two anion sites must be created per added Ca atom. It is reasonable to place the oxygen atom from the CaO in one of these sites. The oxygen atom is neutral and carries an effective positive charge of 2•. The other site remains vacant, and carries an effective positive charge of 2•. The reaction equation is given by:

$$\mathrm{CaO(s)} \xrightarrow{\mathrm{ZrO_2}} \mathrm{Ca}_{\mathrm{Zr}}^{4'} + \mathrm{V}_{\mathrm{O}}^{2\bullet} + \mathrm{O}_{\mathrm{O}}^{2\bullet} \tag{6}$$

If it is thought that the compound is ionic, charge redistribution is allowed:

$$\mathrm{Ca}_{\mathrm{Zr}}^{4'} + \mathrm{V}_{\mathrm{O}}^{2\bullet} + \mathrm{O}_{\mathrm{O}}^{2\bullet} \xrightarrow{\mathrm{ZrO_2}} \mathrm{Ca}_{\mathrm{Zr}}^{2'} + \mathrm{V}_{\mathrm{O}}^{2\bullet} + \mathrm{O}_{\mathrm{O}}^{x} \tag{7}$$

In this equation, the substitutional calcium defect is now Ca^{2+}, (written $\mathrm{Ca}_{\mathrm{Zr}}^{2'}$), and the added oxygen is O^{2-} (written $\mathrm{O}_{\mathrm{O}}^{x}$ to emphasise this), and no longer a defect in the structure.

5.3 The Thermodynamics of Defect Populations

If macroscopic thermodynamics are applied to materials containing a population of defects, particularly nonstoichiometric compounds, the defects themselves do not enter into the thermodynamic expressions in an explicit way. However, it is possible to construct a statistical thermodynamic formalism that will predict the shape of the free energy-temperature-composition curve for any phase containing defects. The simplest approach is to assume that the point defects are noninteracting species, distributed at random in the crystal, and that the defect energies are constant and not a function either of concentration or of temperature. In this case, reaction equations similar to those described above, equations (6) and (7), can be used within a normal thermodynamic framework to deduce the way in which defect populations respond to changes in external variables.

To illustrate this approach, consider an anion-deficient oxide, MO_x. The appropriate defect chemical equation to describe this process could be, for example, equation (8).

$$\mathrm{O_O} + 2M_{\mathrm{M}} \rightleftharpoons \mathrm{V}_{\mathrm{O}}^{2\bullet} + 2M_{\mathrm{M}}' + \tfrac{1}{2}\mathrm{O_2(g)} \tag{8}$$

This describes the situation where oxygen is lost from the crystal, and the surplus electrons, two per lost oxygen, reside on separate metal atoms in the crystal. In formal ionic terms, two M^{2+} cations are transformed to M^{+} cations. In semiconductor terms, two electrons are trapped on separate M^{2+} cations. Chemically this process may be considered as equivalent to doping of MO with M_2O. The law of mass action, applied in its simplest form with concentrations instead of activities, in view of the supposed noninteraction of the defects, then gives an expression for the equilibrium constant, (9):

$$\mathrm{K} = [\mathrm{V}_{\mathrm{O}}^{2\bullet}][\mathrm{M}_{\mathrm{M}}']^2 \mathrm{p}_{\mathrm{O_2}}^{1/2} \tag{9}$$

For each vacancy two metal defects are created, hence

$$[\mathrm{M}_{\mathrm{M}}'] = 2[\mathrm{V}_{\mathrm{O}}^{2\bullet}] \tag{10}$$

and:

$$\mathrm{K} = 4[\mathrm{V}_{\mathrm{O}}^{2\bullet}]^3 \mathrm{p}_{\mathrm{O_2}}^{1/2} \tag{11}$$

The composition of the oxide, x in MO_x, depends upon the oxygen partial pressure via the relationship:

$$x \propto [V_O^{2\bullet}] \propto p_{O_2}^{-1/6} \quad (12)$$

In those cases where the trapped electrons are freed by thermal energy, making the compound into an n-type semiconductor, the electronic conductivity, σ_n, follows the relationship:

$$\sigma_n \propto p_{O_2}^{-1/6} \quad (13)$$

In general, for an anion-deficient (n-type) semiconducting oxide:

$$\sigma_n \propto x \propto [V_O^{2\bullet}] \propto p_{O_2}^{-1/m} \quad (14)$$

where m is a theoretically an integer, usually 4 or 6. Experimentally m is usually found to take a value between 3 and 7.

Cation deficient oxides $M_{1-x}O$ can be considered in the same way. An appropriate reaction equation could be:

$$2M_M + \tfrac{1}{2}O_2(g) \rightleftharpoons O_O + V_M^{2'} + 2M_M^{\bullet} \quad (15)$$

In formal ionic terms, two M^{2+} cations are transformed to M^{3+} cations. In semiconductor terms, two holes are trapped on separate M^{2+} cations. Chemically this process may be considered as equivalent to doping of MO with M_2O_3. If the holes are mobile, the oxide is a p-type semiconductor, with electronic conductivity σ_p, and it is possible to write:

$$\sigma_p \propto x \propto [M_M^{\bullet}] \propto p_{O_2}^{1/6} \quad (16)$$

In general, for a cation deficient (p-type) semiconducting oxide:

$$\sigma_p \propto x \propto [M_M^{\bullet}] \propto p_{O_2}^{+1/m} \quad (17)$$

where m is a theoretically an integer, usually 4 or 6. Experimentally m is usually found to take a value between 3 and 7.

5.4 Brouwer Diagrams

Defect populations and physical properties such as electronic conductivity can be altered and controlled by manipulation of the surrounding atmosphere. To specify the exact electronic conductivity of such a material, it is necessary to specify its chemical composition, the defect types and populations present, the temperature of the crystal and the surrounding partial pressures of all the constituents. It is extremely helpful if the defect concentrations can be displayed graphically as a function of some variable such as partial pressure of one of the components. A procedure introduced by G. Brouwer allows such figures to be compiled.

To construct such a diagram, a set of defect reaction equations similar to equations (6–17) is constructed, and expressions for the equilibrium constants of each are obtained. The assumption that the defects are noninteracting allows the law of mass action to be used in its simplest form with concentrations instead of activities. The logarithm of these expressions is obtained, and a graph is drawn of log[defect concentration] against an experimental variable such as the log[partial pressure] of the components. To simplify matters, only one defect reaction is considered to be dominant in any particular composition region; this being chosen from a knowledge of the chemical attributes of the system under consideration.

The procedure is best illustrated by an example. Suppose that a nonstoichiometric phase of composition MX can have an existence range, which spans both sides of the stoichiometric composition, $MX_{1.00}$. Assume that in this phase only vacancies are of importance, so that the stoichiometric composition will occur when the number of vacancies on the cation sublattice is exactly equal to the number of vacancies on the anion sublattice, which is, therefore, due to a population of Schottky defects. At other compositions, electrical neutrality is adjusted via mobile electrons or holes, leading to n-type or p-type semiconductivity. Thus there are four defects to consider, electrons, e', holes, $h^{\bullet}$, vacancies on metal sites, V_M, and vacancies on anion sites, V_X. Finally, assume that the most important gaseous component is X_2 as is the case in most oxides, halides, and sulphides.

In order to construct the diagram there are three equilibria of importance.

1. creation and elimination of vacancies, as Schottky defects:

$$\text{nul} \rightleftharpoons V_M^{2'} + V_X^{2\bullet}; \quad K_S = [V_M^{2'}][V_X^{2\bullet}] \quad (18)$$

2. creation and elimination of electronic defects:

$$\text{nul} \rightleftharpoons e' + h^{\bullet}; \quad K_e = [e'][h^{\bullet}] \quad (19)$$

3. change of composition, by interaction with the gas phase to produce cation vacancies:

$$\tfrac{1}{2}X_2 \rightleftharpoons X_X + V_M^{2'} + 2h^{\bullet}; \quad K_3 = [V_M^{2'}][h^{\bullet}]^2 p_{X_2}^{-1/2} \quad (20)$$

(A change in composition to produce anion vacancies:

$$X_X \rightleftharpoons \tfrac{1}{2}X_2(g) + V_X^{2\bullet} + 2e' \quad (20a)$$

is redundant.)

4. maintenance of electrical neutrality. Equations (20) and (20a) define the formation of charged species, so that the appropriate electroneutrality equation is:

$$2[V_M^{2'}] + [e'] = 2[V_X^{2\bullet}] + [h^\bullet] \qquad (21)$$

The four equations (19–21) are simplified using chemical intuition. For example, it is reasonable to suppose that at higher partial pressures of X_2 the number of anion vacancies and hence of electrons is unimportant. Equation (21) then becomes:

$$2[V_M^{2'}] = [h^\bullet] \qquad (22)$$

This expression is used, via substitution into equations (18–20) to obtain expressions for the defect types in terms of the constants K_S, K_e, K_3, and p_{X_2}.

$$[V_M^{2'}] = \tfrac{1}{2}(2K_3)^{1/3}p_{X_2}^{1/6} \qquad (23)$$

$$[V_X^{2\bullet}] = 2K_S(2K_3)^{-1/3}p_{X_2}^{-1/6} \qquad (24)$$

$$[h^\bullet] = (2K_3)^{1/3}p_{X_2}^{1/6} \qquad (25)$$

$$[e'] = K_e(2K_3)^{-1/3}p_{X_2}^{-1/6} \qquad (26)$$

It is now possible to plot log[defect concentration] versus log[p_{X_2}] as a set of four straight lines applicable to the high p_{X_2} region, as on the right hand region of Figure 3.

At moderate partial pressures of X_2, the assumption made above is replaced by the assumption that the crystal is an insulator and Schottky equilibrium is dominant. In this case:

$$[V_M^{2'}] = [V_X^{2\bullet}] \qquad (27)$$

This is equivalent to the assumption that K_S is a lot greater than K_e. The original equations are now reworked with this substitution to yield:

$$[V_M^{2'}] = [V_X^{2\bullet}] = K_S^{1/2} \qquad (28)$$

$$[h^\bullet] = K_3^{1/2}K_S^{-1/4}p_{X_2}^{1/4} \qquad (29)$$

$$[e'] = K_eK_S^{1/4}K_3^{-1/2}p_{X_2}^{-1/4} \qquad (30)$$

These are plotted to yield the middle part of Figure 3.

At lower partial pressures of X_2, it is more reasonable to consider that anion vacancies become dominant. The electroneutrality equation is now written as:

$$[e'] = 2[V_X^{2\bullet}] \qquad (31)$$

Once again, a set of equations relating the defect concentrations to the partial pressure of X_2 and the equilibrium constants K_S, K_e, and K_3 are written and plotted. The result is shown in the left hand part of Figure 3.

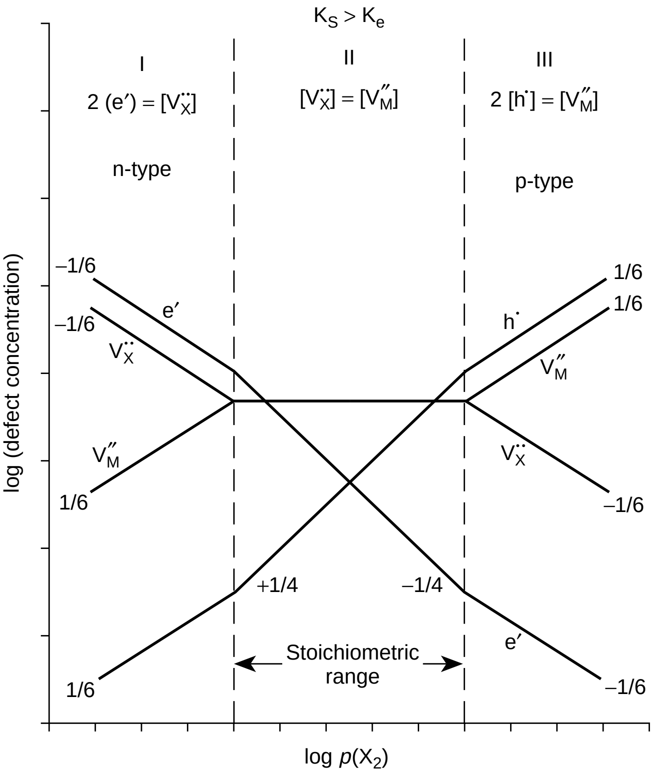

Figure 3 Brouwer diagram for a phase of approximate composition *MX* that responds to changes in composition by the electroneutrality conditions specified in the three regions I, II, III

The complete diagram shows three regions corresponding to low, medium, and high partial pressures of X_2 gas. It is apparent that the electron concentration starts high, in the n-type region I, and falls progressively to the p-type region III, while the hole concentration starts low in the n-type region I, and ends high in the p-type region III. The way in which the other defects vary in concentration is also readily determined from the figure. This variation gives a number of clues about the way in which the properties change as the partial pressure of X_2 and the composition alter. At the left, for example, there is high concentration of anion vacancies and so easy diffusion of anions is to be expected. Similarly, in region III we have a high concentration of cation vacancies, which would be expected to enhance cation diffusion.

The original assumption was that Schottky defect formation was preferred to the formation of electronic defects, and this is explicitly stated at the top of the figure. As Frenkel defect formation has been ignored altogether it is also possible to write $K_S > K_e \gg K_F$, where K_F would represent the equilibrium constant for a reaction that formed Frenkel defects in *MX*. Figure 3 contains all the assumptions made, as well as the way in which defect concentrations vary. Moreover, it is easy to see what changes will take place if the relative values of K_S and K_e are altered, and the graphical representation is able to present trends in a lucid fashion.

6 GROSSLY NONSTOICHIOMETRIC CRYSTALS

Inorganic phases with broad composition ranges are called grossly nonstoichiometric phases, and considerable effort has been put into the clarification of the structure of these materials. The initial model for such materials is to suppose that they contain high populations of vacancies or interstitials, to make up the compositional imbalance. A few examples of this approach, from among the many in the literature, are chosen as illustrative. It is possible that the examples cited will be shown to have more complex defect structures in the future.

6.1 Point Defect Populations

The perovskite structure, adopted by many compounds of nominal formula ABX_3, in which A is a large cation and B a medium size, often transition metal, cation, and X an anion, is prone to wide ranges of stoichiometric variation. Of these, the oxides have been most studied. The formula can be modified by doping on both the A sites and B sites to produce a wide variety of nonstoichiometric phases. For example, the perovskite $LaCoO_3$ shows considerable oxygen loss when the La is partly replaced by Sr, in $La_{1-x}Sr_xCoO_{3-\delta}$. In this and related lanthanide containing compounds, the oxygen deficit is regarded as being due to a population of oxygen vacancies. At some compositions, it has been shown that a combined Ln/Sr and O/vacancy ordering occurs.[6] The same is true of Fe-containing perovskites such as $Ln_{1-x}Sr_xFeO_{3-\delta}$, in which a population of disordered oxygen vacancies is present. Many compounds show pronounced oxygen vacancy ordering. The extreme example is $Sr_2Fe_2O_5$, in which the 'ordered oxygen vacancies' are assimilated to give the brownmillerite structure. At high temperatures the oxygen vacancies disorder to form a defect perovskite structure.[7] The brownmillerite structure, as well as other ordered phases occur in the $(Ba_{1-x}La_x)_2In_2O_{5+x}$ phases.[8] The perovskites $LaMnO_{3+\delta}$ and related doped derivatives are reported as oxygen excess materials. This terminology is misleading, as the structure contains vacancies on both La and Mn sites, while the oxygen structure is intact.

The material β-alumina has an ideal formula $Na_2Al_{22}O_{34}$. The structure is composed of slabs of 4 oxygen layers in a cubic close-packed arrangement with a structure resembling that of spinel, $MgAl_2O_4$, linked by more open layers containing the Na^+ ions. At normal temperatures, the Na^+ ions are distributed at random over the many available sites between the spinel-like slabs, to form a quasi-liquid layer. The real composition is variable and the phase always contains an excess of alkali metal. To maintain neutrality, two possible defects can be envisaged to compensate for the alkali metal ions, Al^{3+} vacancies in the spinel sheets or interstitial O^{2-} ions in the open sodium containing layers. In β-alumina, it appears that interstitial oxygen ions are favored. In this phase, therefore, there are two unbalanced point defect populations, mobile Na^+ ions, over the stoichiometric requirement, and interstitial oxygen ions. At low temperatures, there is considerable evidence that these defects order.

A number of other β-alumina related phases have been prepared. In some of these the spinel blocks have an increased thickness, the so-called β', β'' and β''' phases, while in others, the Na or Al components have been replaced with similar species. Related structures, such as $BaMgAl_{11}O_{17}$ doped with Eu^{3+}, are widely used as phosphors. Crystal-structure studies on such materials show that the defects present depend sensitively upon both temperature and the constituents of the phase. Large replacement ions, lanthanide or alkali metals, tend to occupy the interlayer regions as interstitial defects, but surprisingly, some also enter the spinel blocks as substitutional defects, in association with oxide ion vacancies.[9] Smaller ions occupy the spinel blocks as substitutional point defects. The delicate balance between oxygen interlayer interstitials and spinel block cation vacancies varies with composition. These defect interactions can often be successfully explored by using simulation techniques.[10] Ordering occurs at lower temperatures (*see* ***Ionic Conductors***).

The crystal structure, microstructure, and defect structures found in the superconducting phase $YBa_2Cu_3O_{7-\delta}$ have been intensively investigated (*see* ***Superconductivity***). Chemically, the material is a grossly nonstoichiometric phase with a composition range from $YBa_2Cu_3O_6$ to $YBa_2Cu_3O_7$. The structure is built up from the sequence of planes [CuO_2-Y-CuO_2-BaO-CuO_x-BaO]. Composition variation is confined to the CuO_x planes, and oxygen is lost from Cu-O-Cu-O chains, which converts square-planar coordinated Cu to linear coordinated ions. In the range between approximately $YBa_2Cu_3O_7$ and $YBa_2Cu_3O_{6.8}$, the oxygen vacancies appear to be disordered, at least on a macroscopic scale, although long annealing times may allow ordering to occur. At greater degrees of reduction, this does take place, and a variety of ordered oxygen vacancy superstructures occur, notably at the compositions $YBa_2Cu_3O_{6.75}$ and $YBa_2Cu_3O_{6.5}$. It is possible that other patterns of order will appear under different conditions of preparation or in phases in which Y is replaced by other rare earths, or the Ba by other alkaline earths.

6.2 Interpolation

Interpolation or intercalation (*see* ***Intercalation Chemistry***) is said to occur when additional species are placed into a host structure to change either composition or properties. At one extreme, intercalation can refer to the insertion of guest molecules into cage structures such as that of the zeolites (*see* ***Zeolites***), or between the layers of laminated compounds such as the clays (*see* ***Silicon: Inorganic Chemistry***). At the other extreme, the insertion of small atoms such as C or N into metal phases to form interstitial alloys (*see* ***Alloys***; ***Carbides: Transition Metal Solid-state Chemistry***; ***Nitrides: Transition Metal Solid-state Chemistry***), is included in the category. A large variety of structures can be found in such materials, and

in this section, a small number of examples relevant to defect chemistry are given.

The layer structure disulphides, such as $M_x TiS_2$ and $M_x NbS_2$, consist of layers of Ti or Nb in octahedral coordination, held together by weak bonds. Interpolation of metals between these layers is relatively easy, and materials such as $Li_x TiS_2$, in which the metal atoms are regarded as random interstitials, have been investigated as battery electrodes. Charge compensation is unnecessary, as extensive electron delocalization occurs. If the interpolated atoms are the same as those in the layers, Ti in TiS_2 for example, the composition can change from one stoichiometric extreme, TiS_2, to another, Ti_2S_2, (TiS). The interpolated atoms may be ordered to form intermediate phases such as Ti_8S_9, Ti_4S_5, Ti_3S_4, Ti_2S_3 and Ti_5S_8.

The perovskite-structure tungsten bronzes, which have a formula $M_x WO_3$, are formed by the reaction of metals with WO_3. The interpolated metal atoms occupy random cage sites between the corner-linked WO_6 octahedra that make up the WO_3 structure. The degree of filling is variable and the compounds have wide composition ranges. In the compound $Li_x WO_3$, x can vary continuously between the values of 0 and 0.5. For $Na_x WO_3$, x can vary between the limits of 0 and 0.11, and then from 0.41 to 0.95. The outer electrons of the interpolated atoms are delocalized, endowing the solids with metallic properties, and originally they were believed to be alloys, hence the name bronzes. The metallic nature of the materials obviates the need for counterdefects to maintain charge neutrality.

In addition to the perovskite-structure tungsten bronzes, two other tungsten bronze types exist that make use of interpolation to vary their compositions. These are both made up of corner-linked WO_6 octahedra, rearranged to form either pentagonal, square, or hexagonal tunnels. Variable filling of these tunnels by metal atoms gives rise to metallic materials with wide stoichiometry ranges. In the tetragonal tungsten bronze phases, the pentagonal and square tunnels in the structure are partly filled. These are typified by the compounds $Pb_x WO_3$ and $Sn_x WO_3$, in which x can take values of from approximately 0.16 to 0.26. The degree of interaction between the interpolated atoms is unclear, but ordering in the $Pb_x WO_3$ bronzes has recently been found to be a result of interactions between the interpolated Pb atoms with the underlying W atoms in the WO_6 framework, rather than due to a simple ordering of the interpolated atoms themselves.[11] Hexagonal tungsten bronzes contain large hexagonal tunnels that are partly occupied. The composition of the archetypal hexagonal tungsten bronze phase $K_x WO_3$ extends from $x = 0.19$ to $x = 0.33$.

The cathode material $Li_{1-x}CoO_2$ is an intercalation compound in which the Li^+ ions lie between layers of composition CoO_2. In theory, the composition range of the cathode material is from $LiCoO_2$ to CoO_2, that is, x varying from 1 to 0, the operational degree of nonstoichiometry is restricted, and x generally takes values in the range of 0 to about 0.45. Intercalation of lithium changes the layer stacking of the parent oxide framework. Cobalt oxide, CoO_2, is built of hexagonal close-packed (ABAB) layers of oxygen atoms, while $LiCoO_2$ has cubic (ABC) close packing. Intercalation is then accompanied by planar faulting in the matrix.

7 POINT DEFECT CLUSTERS

7.1 Crystals with Compositions Close to *MX*

Even when the departures from stoichiometry remain small, there are reasons for suspecting that the defect structures of nonstoichiometric phases are more complex than a picture of isolated point defects would suggest. Probably the best-documented example is that of $Fe_x O$, wüstite. This oxide exists over a composition range that varies from about $Fe_{0.89}O$ to $Fe_{0.96}O$ at approximately l300 K and that broadens with increasing temperature. Isolated iron vacancies are not present, but small groups of atoms and vacancies aggregate into elements of new structure, termed point defect clusters, which are distributed throughout the wüstite matrix (Figure 4). It is found that the clusters bear a strong resemblance to elements of Fe_3O_4, the next higher oxide to FeO. Structurally, therefore, the over-oxidised FeO can be regarded as a partly ordered assembly of fragments of the Fe_3O_4 (spinel) structure intergrown within the halite (NaCl) structure of FeO.

Many 3d-transition metal monoxides and sulphides show nonstoichiometric behavior. The high defect population is disordered at high temperature, but annealing usually produces a variety of phases containing ordered or partially ordered arrangements of defects. The nonstoichiometric oxides TiO and VO are typical examples. Samples cooled rapidly from high temperatures yield diffraction patterns that show diffuse scattering, indicative of short-range order and defect clustering. Slow cooling or annealing yields materials with complex arrangements of ordered metal and oxygen vacancies. A similar situation is found with the nonstoichiometric sulphides that lie near to the compositions FeS, ZrS, CrS, and the phases between digenite, (Cu_2S), and bornite, (Cu_5FeS_4). Under laboratory preparation conditions, diffraction patterns often show diffuse scattering indicative of defect clusters. Natural samples frequently reveal the presence of ordered superstructures.

7.2 Fluorite-related Structures

Compounds with structures related to that of fluorite, CaF_2 (*see* ***Fluorides: Solid-state Chemistry***), readily form solid solutions with other solids containing cations of a similar size to the fluorite host cation. Invariably the foreign cation substitutes for the host cation, and stoichiometric imbalance is taken up by the anion component of the crystal. The

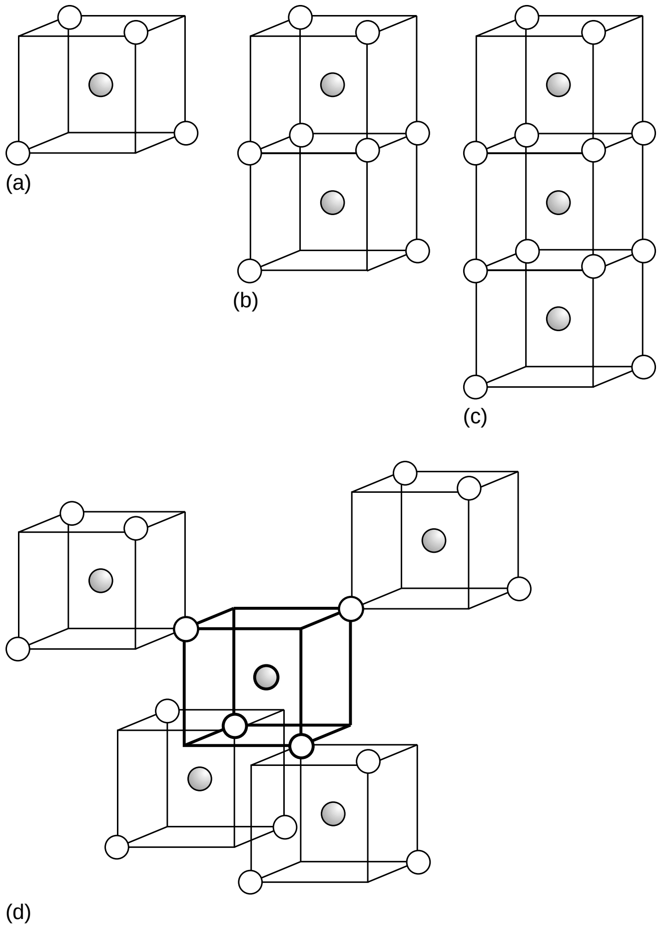

Figure 4 Point defect clusters in $Fe_{1-x}O$. The open circles represent cation vacancies and the shaded circles Fe^{3+} interstitials. The unmarked cube vertices are occupied by oxide ions. (a) 4:1 cluster, (b) 6:2 cluster, (c) 8:3 cluster, (d) 16:5 cluster. In (d), four 4:1 clusters are arranged tetrahedrally around a central cluster, drawn with heavy outline

resulting structures display considerable flexibility towards both an excess and deficiency of anions compared to the ideal composition MX_2. The real defect structure of many of these phases remains obscure.

7.2.1 Anion-deficient Structures

Anion-deficient structures can form by direct reduction of parent oxides, as with the lanthanide and actinide oxides PrO_2, CeO_2, TbO_2, UO_2 and PuO_2, among others (*see* ***Oxides: Solid-state Chemistry***). Reaction with lower valence compounds achieves the same result, as when ZrO_2, ThO_2 or HfO_2 are heated with Y_2O_3 or CaO. Notionally these phases contain anion vacancies. However, truly isolated vacancies have not been observed and structural rearrangements occur to form defect clusters. At lower temperatures, and within well-defined oxygen partial pressures regimes, these clusters are ordered. In this case, homologous series of phases may form, typified by the M_nO_{2n-2} oxides found in the Pr-O, Tb-O and Ce-O systems. In the Pr_nO_{2n-2} series, ($n = 7$, 9, 10, 11, 12), the defects appear to consist of pairs of anion vacancies oriented along a body diagonal of the fluorite-type cubic unit cell. Surrounding atoms relax to form a cluster with a composition of Pr_7O_{30}. Such clusters have been observed in the lanthanide oxides Pr_7O_{12}, Tb_7O_{12}, and in the ternary phases UY_6O_{12} and $Zr_{10}Sc_4O_{24}$. It has been suggested that the structures of all the Pr_nO_{2n-2} homologues are can be built from ordered arrangements of such clusters.

The structures of the defects in many anion-deficient fluorite structures are sensitive to composition. For example, in the Bi_2O_3-Nb_2O_5 and Bi_2O_3-Ta_2O_5 systems, MO_6 defect clusters have been identified at compositions close to Bi_2O_3, and pyrochlore-like M_4O_{18} clusters at greater Nb or Ta concentrations. Broadly speaking, modulated structures tend to form at lower defect populations (see Section 10) and defect clusters at higher defect populations.

7.2.2 Anion-excess Structures

The MX_{2+x} phases contain interstitial anions. As with the anion-deficient phases, these interstitials are not random point defects, but ordered or clustered. The earliest cluster geometry to be postulated was the [2:2:2] cluster in UO_{2+x}, the prototype anion-excess fluorite phase. The cluster is composed of 2 interstitial oxygen atoms displaced along $\langle 110 \rangle$, two interstitial oxygen atoms displaced along $\langle 111 \rangle$ in UO_{2+x} (Figure 5). Other cluster geometries have also been proposed in this oxide, and the defect structure of this well studied phase is still not completely resolved.

In many of the lanthanide oxyfluorides and related phases, different cluster geometries, (labelled [1:0:2], [1:0:3] and [1:0:4] in the above notation), are found. The type of cluster depends upon the size of the lanthanide present. Large cations, La–Nd, form only [1:0:3] clusters, while smaller cations, such as Sm, form [1:0:2] clusters, found in $SmO_{0.7}F_{1.6}$. In all of these systems, the cluster distribution seems to be a function of temperature.

A large number of anion-excess halides exist, especially fluorides formed by the reaction of M^{2+} difluorides with lanthanide and related trifluorides (*see* ***Fluorides: Solid-state Chemistry***). The archetypal system is CaF_2–YF_3, leading to phases $Ca_{1-x}Y_xF_{2+x}$. It is clear from diffraction data that defect clusters occur in these materials, and that at higher concentrations these order to produce a homologous series of phases. The nature of the clusters however has been difficult to determine. Earlier studies were interpreted in terms of pairs of anions, one ‘interstitial’ and one ‘normal’, aligned along the [110] direction. More recently, clusters that adopt geometries that are more complex have been suggested. In $Ca_{0.94}Y_{0.06}F_{2.06}$ and related phases, a cuboctahedral cluster is known to form. Different packing arrangements of these clusters lead to a homologous series of ordered phases of

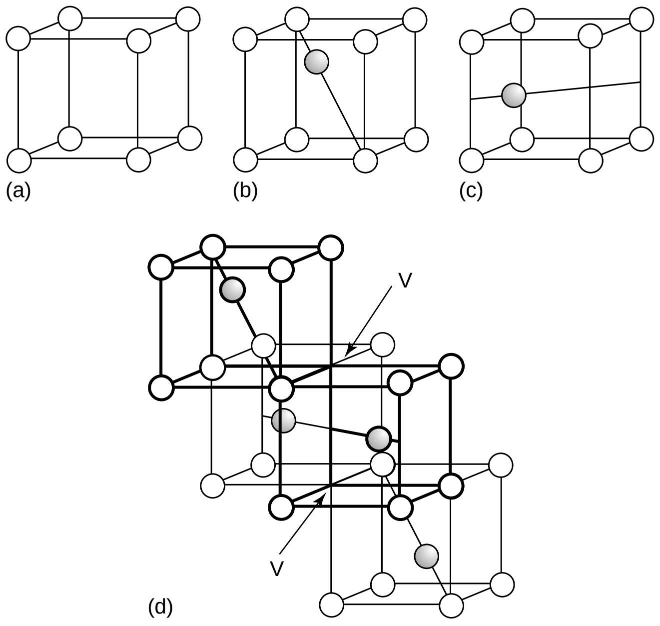

Figure 5 Defect cluster structures in UO_{2+x}. The parent structure is built from cubes with an oxygen ion at each corner (a), alternating with similar cubes containing a metal cation. Interstitial oxygen ions (dark circles), occupy empty cubes, but are displaced from the center along ⟨111⟩ (b), or ⟨110⟩ (c). The 2:2:2 cluster consists of four such cubes, two of which contain ⟨111⟩ interstitial oxygen ions and two of which contain ⟨110⟩ interstitial oxygen ions. The oxygen vacancies are marked V (d)

formula $M_{m-5}R_5X_{2m+5}$, where M is a divalent cation and R a trivalent cation. Examples of these phases are provided by the $m = 19$ member of the series, $Ca_{14}Y_5F_{43}$, the naturally occurring mineral tveitite, Ca_2YbF_7 and Ca_2LuF_7, which seem to be isostructural with the $m = 15$ phase Ca_2YF_7, ($Ca_{10}Y_5F_{35}$), and $Na_7Zr_6F_{31}$, which seems to be isostructural with the $m = 13$ phase, $Ca_8Y_5F_{31}$. Recent structural studies suggest that these defects may be best described in terms of modulated structures (see Section 10).

7.3 Microdomains

Statistical thermodynamic treatments of defect populations have lead to an explanation of existence of grossly nonstoichiometric crystals in terms of microdomains of ordered structure. The model considers that the nonstoichiometric matrix is made up of a mosaic of small regions of ordered defect-free structures, the microdomains. To account for stoichiometric variation, one can postulate that at least two microdomains with different compositions occur. However, compositional change might simply arise at the surface of the domain. For example, if there are compositionally identical microdomains, one of which is bounded by an anion surface and one by a cation surface, variation in the two populations can give rise to compositional variation. In a strict sense, as each microdomain is ordered, the concept of a 'defect' is redundant, except for the intermicrodomain boundaries. Nucleation concepts can be applied to derive the size of the microdomains as a function of the chemical potentials of the components. The results of the analysis suggest that the size of microdomains is small, and at one extreme, equivalent to defect clusters.

Microdomains within the perovskite-like slabs of layered perovskite phases in the Ba-Bi-O system illustrate these ideas.[12] The structures are layered perovskites with K_2NiF_4 related structures and gross changes in the Ba to Bi ratio are accommodated by the formation of a homologous series $Ba_{n+1}Bi_nO_{3n+1}$, made up of slabs of $BaBiO_3$ perovskite structure (see Section 8.4). In addition, subtle changes in the Ba to Bi ratio are accommodated by microdomains of ordered structure within the perovskite slabs themselves. These microdomains are ordered fragments of perovskite structure, and cation variation occurs at the interface between the microdomains in such a way that local excess or deficit of one cation over the other is accomplished.

Well-defined examples of microdomains are found in the $(1-x)ZrO_2 - xLn_2O_3$ (Ln = Ho, Dy, Tb, Gd) and $(1-x)CeO_2 - xY_2O_3$ system. The dioxide adopts the fluorite structure and the sesquioxides the C-type structure. For many years, it was thought that a continuous solid solution fluorite structure forms across this whole composition range. This is not so. Close to the dioxide, the composition balance is achieved by a population of microdomains of 13 to 14 nm diameter. Near to the sesquioxide, ordered vacancy pairs occur in the fluorite matrix. These two regions are separated by a narrow two-phase region.[13]

8 EXTENDED DEFECTS

8.1 Extended Defects and Nonstoichiometry

The point defect clusters described in earlier sections can be legitimately termed extended defects. In this section, defects that are less easily considered in terms of point defects will be described. Perhaps the best known of these are the planar boundaries, the most abrupt example being the crystal surface itself (*see* ***Surfaces***; ***Semiconductor Interfaces***).

Isolated planar boundaries within a crystal will constitute extended defects. Some boundaries, such as certain configurations of antiphase boundaries and twin boundaries, do not change the overall composition of the crystal. However, coordination polyhedra and nearest neighbor geometry different from those in the bulk are found near the discontinuity. These may provide sites for unusual chemical reactions or introduce significant changes in the physical properties compared to the defect-free phase. Other boundaries may cause a change in composition. If such boundaries are present in variable numbers and distributed at random, the crystal will be operationally nonstoichiometric. If the defects order, a series of new phases will be generated, each with a definite composition and

chemical formula. Each phase will be characterized by the separation between the ordered planar boundaries, which are no longer faults or defects, but integral structure elements.

Examples of such materials have been known for a number of years in the mineralogical field, where the terms 'intergrowth phases', 'polysynthetic twinned phases', 'polysomatic phases' and 'tropochemical cell twinning' have been applied to describe the structures.[14–16] In recent years, the application of electron microscopy has revealed the defect structures of vast numbers of phases containing extended defects. In this section, some well-characterized examples chosen are chosen for illustration.

8.2 Crystallographic Shear (CS) Phases

Crystallographic shear (CS) occurs mainly in the transition metal oxides WO_3, MoO_3, Nb_2O_5, and the rutile form of TiO_2 (*see* ***Oxides: Solid-state Chemistry***). Recently CS has been reported in an oxygen deficient perovskite, $PbMnO_{2.75}$.[17] A crystallographic shear plane is a planar fault that changes the anion to cation ratio without changing the shape of the anion coordination polyhedra surrounding the metal atoms significantly. In the oxides in which CS occurs, the metal coordination polyhedron is usually an octahedron of oxygen atoms. These are linked by corners or edges and corners to form rather open structures. On reduction, either by direct removal of oxygen or by reaction with lower valence compounds, the open structure collapses along specific crystallographic planes, the CS planes. The vector that describes the collapse, the CS vector, is equal to an oxygen–oxygen distance, and the operation effectively removes a complete plane of oxygen atoms from the structure. The lower oxides so produced are known as crystallographic shear phases, and CS families are known as homologous series. Disordered CS planes are known as Wadsley defects, both in the materials discussed in this section and in the block structures considered below.

The structurally simplest compounds that can be used to illustrate this process are the tungsten oxides. The structure of the parent oxide, WO_3, is made up of a three-dimensional array of corner-shared WO_6 octahedra (Figure 6(a)). Very slight reduction, to a composition of $WO_{2.9998}$, for example, results in a crystal containing a low concentration of planar faults randomly oriented on all possible {102} planes. The CS operation effectively eliminates a {102} plane of oxygen atoms from the structure. The defects consist of lamellae made up of blocks of four edge-shared octahedra in a normal WO_3-like matrix of corner-sharing octahedra (Figure 6(b)).

Continued reduction initially produces an increased density of disordered {102} CS planes, but as the composition approaches $WO_{2.97}$, they tend to become ordered. When the CS planes are perfectly ordered, the composition of the crystal is given by a formula W_nO_{3n-1}, where n is the number of octahedra separating the CS planes. An upper value of n is difficult to determine, owing to the coexistence of ordered and disordered CS planes, but a value of about 30 is reasonable,

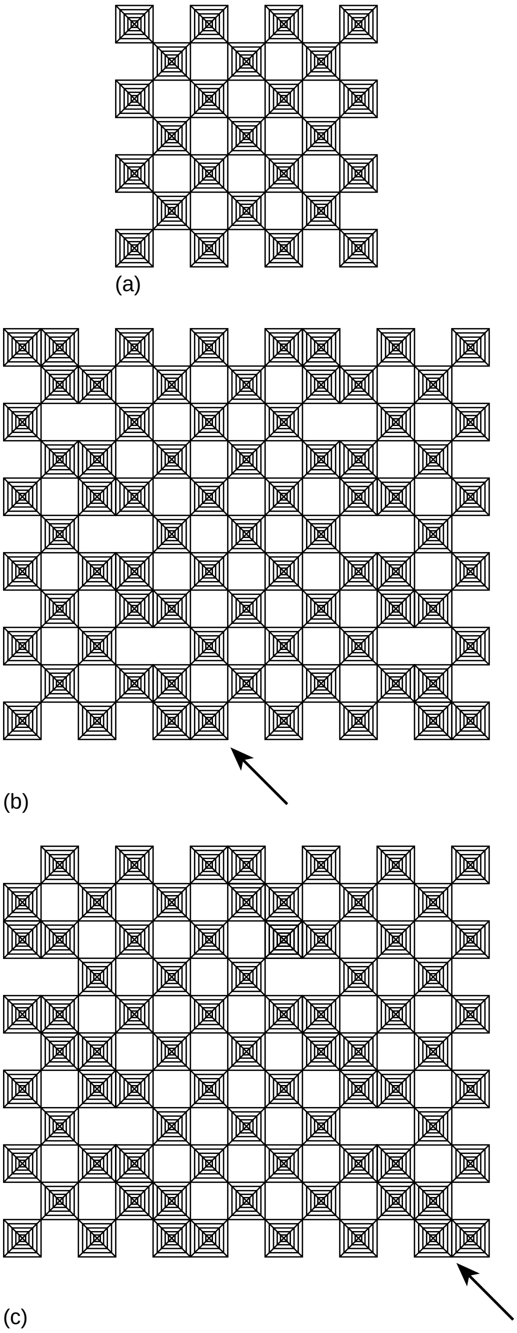

Figure 6 Crystallographic shear in WO_3 (a) the idealized structure of WO_3, drawn as corner-shared WO_6 octahedra, squares in projection (b) {102} CS planes (arrowed), consisting of blocks of four edge-shared octahedra (c) {103} CS planes (arrowed), consisting of blocks of six edge-shared octahedra

giving a composition of $WO_{2.9666}$. The lower limit of the {102} CS series corresponds to a formula of $W_{18}O_{53}$, with a composition of $WO_{2.9444}$.

Further reduction, to take the composition below about $WO_{2.93}$, produces a different CS structure, in which blocks of six edge-shared octahedra form (Figure 6(c)). The CS planes

lie on {103} planes, and are usually ordered, giving rise to the homologous series W_nO_{3n-2}. They occur within the approximate range $W_{25}O_{73}$, ($WO_{2.9200}$), to $WO_{16}O_{46}$, ($WO_{2.8750}$).

The reduction of the rutile form of TiO_2 is similar to that of WO_3. Small degrees of reduction are accommodated on {132} CS planes and ordered {132} phases occur at greater degrees of reduction, to form the homologous series Ti_nO_{2n-1}, with n taking values between approximately 15 to 37. Greater degrees of reduction use {121} planes, the changeover from {132} CS occurring at compositions between approximately $TiO_{1.93}$ and $TiO_{1.90}$. The {121} series also has the formula Ti_nO_{2n-1}, with n taking values between 4 and 9 or 10.

When reaction with other oxides is used to reduce the anion to cation ratio, CS families occur that are not found in the binary metal–oxygen systems, revealing that complex factors are involved in determining the planes upon which CS actually occurs. For example, when WO_3 is allowed to react with small amounts of Nb_2O_5 at temperatures above approximately 1250 °C, the CS planes lie on planes between {104}, with a series formula $(W, Nb)_nO_{3n-3}$, and {001}, with a series formula $(W, Nb)_nO_{3n-1}$. Reacting TiO_2 with between 0.7 and 6.5 mol% Li_2O produces a CS series in which the CS plane gradually changes from {021} to {051}.[18] If TiO_2 is allowed to react with Fe_2O_3, CS structures form on planes between {020} to {121}.

In any CS plane family, the amount of oxygen loss may be increased by decreasing the spacing between the defects or by changing their orientation. This is most easily understood by examples from the reduced tungsten oxides. Each block of four edge-sharing octahedra in a {102} CS plane eliminates one oxygen atom. Each block of six edge-sharing octahedra in a {103} CS plane eliminates two oxygen atoms, and so on. Rotation from {102} towards {103} at a constant CS plane spacing continuously increases the amount of oxygen lost. The initial step could be occasional insertion of blocks of six edge-sharing octahedra into a {102} CS plane. If these are ordered, the planes will take on indices somewhere between {102} and {103}. If disordered, the CS planes become curved or wavy. Continued interpolation of blocks of six edge-shared octahedra continues the reduction. Regions of such wavy CS planes lying between {104} and {001} are common in the Nb_2O_5-WO_3 system. Regions of well ordered CS planes with indices anywhere between {132}, at the oxygen rich end of the phase range to {121} at the oxygen poor end are found when rutile is reacted with Cr_2O_3 to produce a phase with a composition between approximately $(Ti,Cr)O_{1.93}$ and $(Ti,Cr)O_{1.90}$. Every composition prepared can have a different ordered arrangement of CS planes, with a definite spacing and CS orientation.

There are a number of uncertainties that remain concerning CS planes, notably the mechanism by which they form, and their stability relative to other defect populations. Electron microscopy has shown that CS planes can form extremely rapidly under the conditions holding during observation and that they extend along their length. This implies that the crystal can collapse directly to yield the fault plane. Other studies suggest that at high temperatures the predominant defect population consists of clusters of ‘interstitials’, which can be regarded either as CS plane nuclei or as point defect clusters. Although several mechanisms have been put forward to account for sideways movement of CS planes and hence lateral ordering, little direct evidence for how this takes place has been obtained.

8.3 Twinning

A twin plane in a crystal is a planar fault that acts as a mirror, in that the atoms on one side of the plane are mirrored in position with respect to those on the other. Not all twin planes produce composition changes, but some do. Many inorganic crystals prepared by conventional solid-state reactions, including sulphides such as In_2S_3, and oxides such as $Ca_3Mn_2O_7$ and $Ca_4Mn_3O_{10}$, are heavily twinned. These disordered boundaries constitute a high density of extended defects in the structures. They may form as a response to local compositional changes or in order to provide cation coordination polyhedra not available in the normal crystal.

When a twin plane introduces a composition change, a set of ordered twin planes would produce a new phase. Homologous series of phases will result if the spacing between the twin planes can take discrete values. Such phases, typified by lillianite, $Pb_3Bi_2S_6$, are found, for instance, in the PbS-Bi_2S_3 and PbS-Sb_2S_3 systems, and the phenomenon has been called tropochemical twinning.[16] When the twin planes are disordered, a nonstoichiometric phase with a measurable composition range will result. The resulting solid may be described as containing intergrowths of various members of the homologous series or as a twinned parent phase, depending upon the density of the faults.

Many structures can be thought of as built from twinned fragments within the unit cell. The phenomenon is referred to as chemical twinning (CT), or unit cell twinning. As the size of the twin fragments increases, different structure types arise, all related as in homologous series.

8.4 Planar Intergrowths

A large number of solids encompass a range of composition variation by way of intergrowth. In this situation, two (or more) crystalline materials with different compositions can interleave if they each have at least one structurally compatible crystallographic plane. The composition can vary from that of one of the parents to the other. When such intergrowths are perfectly ordered, no defects are present. However, disorder in the stacking of the different units naturally leads to a structure containing planar faults. Examples abound, including the hexagonal ferrites, in which different spinel-related slabs of structure coexist, extensive families of hexagonal perovskites, the $In_2O_3(ZnO)_n$ and related phases, and some polytypes.

For illustrative purposes, three perovskite related phases are described. Other examples are given in Sections 9 and 10.

K_2NiF_4-related structures, also called Ruddleston-Popper phases, are built of slabs of perovskite structure cut parallel to the (idealized) perovskite {100} planes united by way of lamellae of halite (NaCl) structure. The series formula for these compounds is $A_{n+1}B_nO_{3n+1}$ where A is a large cation, typically an alkali metal, alkaline earth or rare earth and B is a medium sized cation, typically a 3d transition metal cation. The first examples characterized were Sr_2TiO_4, $Sr_3Ti_2O_7$ and $Sr_4Ti_3O_9$, in which the perovskite slabs are derived from $SrTiO_3$ and the halite slabs from SrO.

Replacement of the halite layers in the above series by layers of composition Bi_2O_2 leads to a series of Aurivillius phases, with a general formula $(Bi_2O_2)(A_{n-1}B_nO_{3n+1})$, where A is a large cation, and B a medium sized cation. The best-known member of this series of phases is the ferroelectric $Bi_4Ti_3O_{12}$ in which $n = 3$ and A is Bi.

A third series of perovskite related intergrowths has a general formula $A_nB_nO_{3n+2}$, where A is a large cation, and B a medium sized cation, typified by the $(Na,Ca)_nNb_nO_{3n+2}$ series. The oxides are intergrowths of slabs of perovskite structure with the halite structure. They differ from the Ruddleston-Popper series in that the (idealized) perovskite slabs are sliced along {110} rather than {100}.

When prepared from mixed oxides, chemical homogeneity in these materials is hard to achieve. Under these circumstances, a variety of different n-values can be said to coincide in a crystal. The defects here are regarded as slabs of the halite type interspersed more or less at random in the perovskite-structure matrix.

8.5 Block Structures

The block structures are found in a group of niobium oxides (*see* ***Oxides: Solid-state Chemistry***), close in composition to Nb_2O_5. In the binary system, these oxides lie between the compositions $NbO_{2.5}$ and $NbO_{2.42}$, and in them two sets of CS planes intersect to divide the materials up into columns of corner-linked octahedra, with an NbO_3 stoichiometry. The columns, in projection, look like rectangular blocks, accounting for the common name of these materials. The phase range over which these structures occur is increased greatly by reacting Nb_2O_5 with other oxides, and it is possible to pass from phases with composition below $NbO_{2.5}$, formed by reaction with TiO_2, for example, to compositions above $NbO_{2.5}$, by reaction with oxides such as WO_3.

These changes of stoichiometry are brought about by changing the block sizes. Larger blocks push the overall stoichiometry towards MO_3 and smaller blocks towards MO_2. Composition change is thus achieved at the block periphery. Changes in local composition are taken care of by local rearrangements in the block sizes and the way in which they are packed together. Defects consisting of clusters or walls of inappropriate blocks are very common in these compounds.

An extensive family of 'tubular oxides' with formulae $(Bi_{2+x}Sr_{2-x}CuO_{6+\delta})_n(Sr_{8-y}Cu_6O_{16+z})$, with n taking integer values of between 4 and 7, are somewhat related to the block structures.[19] In these materials, walls of copper polyhedra form rectangular units containing perovskite-like structures. The arrangement of the rectangular units is very flexible, and defects very similar to those encountered in the block structures are common.

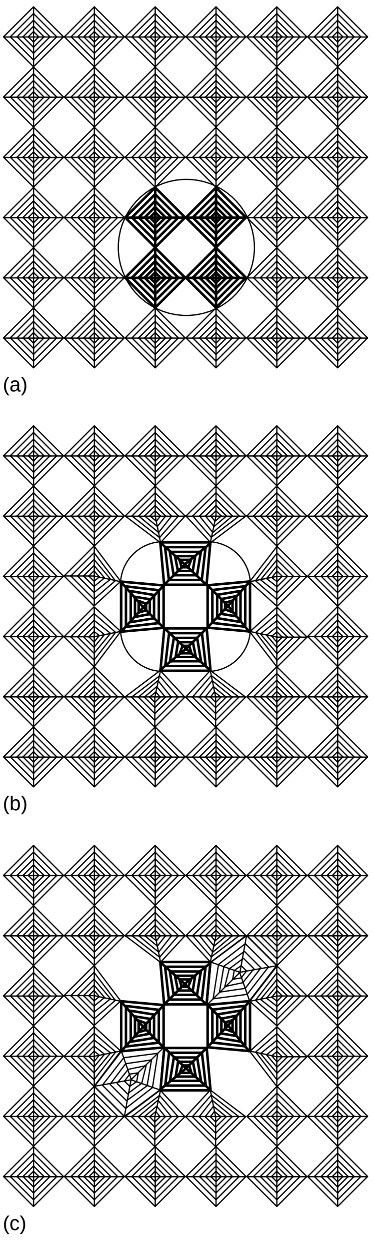

Figure 7 The generation of pentagonal columns in the WO_3 structure. Blocks of four octahedra, circled in (a), are rotated by 90° in (b) to produce four pentagonal tunnels. Filling of these tunnels by O-M-O chains produces pentagonal columns, two of which are shaded in (c)

8.6 Pentagonal Column and Related Phases

The extended defects just described are planar structures. An increasing number of solids are being described as made up of columnar elements of structure dispersed in a parent matrix. One of the best characterized of these materials are metal oxides that have, as their basic structural motif, the pentagonal column (PC). This unit consists of a ring of five MO_6 octahedra; the central pentagonal tunnel so formed being filled with an alternating chain of oxygen and metal atoms to form a pentagonal column (Figure 7). It is found that groups of PCs can coherently exist within a WO_3 or perovskite type of matrix. As a number of oxides adopt this structure or a distorted version of it, a wide range of PC phases can form. As in previous discussions, when the PC elements are perfectly ordered, one or more structurally related ordered phases such as Mo_5O_{14} or $Nb_{16}W_{18}O_{94}$ are generated. When the PC elements in the host structure are disordered, a nonstoichiometric compound is generated. Such disorder occurs, for example, when WO_3 is reacted with Nb_2O_5 for short periods at temperatures below about 1250 °C.

Walls of PC units can also intergrow with WO_3 to give ordered phases such as $U(Ta,W)_2O_8$ and others, which form in a number of U-W-M-O systems. Disordered materials in which the PC walls are unequally spaced are also common in samples prepared by solid-state synthesis.[20]

9 COMBINATIONS OF DEFECTS

In many crystals, several defect types contribute to the overall defect structure of the material. Three examples will be chosen as illustrative.

The intergrowth tungsten bronzes are typified by those found in the K_xWO_3 system. When the amount of potassium is less than the minimum needed to form the hexagonal tungsten bronze structure, $x < 0.19$, an intergrowth between the hexagonal tungsten bronze structure and WO_3 is found. The strips of hexagonal structure are normally two tunnels in width. Intergrowth tungsten bronzes are also known in other systems, including Rb-, Cs-, Ba-, Sn-, and Pb-WO_3. In the nonalkali metal intergrowth bronzes, single tunnels are preferred. In all these phases, the separation of the strips of hexagonal tunnels increases as the concentration of the large interpolated atoms decreases. Homologous series of compounds form when these are ordered. Defect structures consist of disorder in the disposition and widths of the lamellae of hexagonal tunnels and by the variable degree of filling of the hexagonal tunnels.

In the K_2NiF_4 series of phases described above, composition variation can take place by disorder in the width of the perovskite slabs, and the solid contains planar defects. In cases where the components of the intergrowth contain cations with a variable valence, additional defect structures can result. Many of these have been studied because of their physical properties, including $Sr_{n+1}V_nO_{3n+1-\delta}$ ($n = 1,2,3,\infty$), $La_2CuO_{4+\delta}$, $(La,Sr)_2CuO_{4+\delta}$, $La_2NiO_{4+\delta}$, $(La,Sr)_2NiO_{4+\delta}$ and phases in which the perovskite part of the structure contains Mn or Fe. In the oxygen rich compounds, the additional oxygen is in the form of interstitials. These oxygen defects are sometimes distributed at random, especially in the interlayer regions, while in some structures ordered arrangements have been reported. In phases that are oxygen poor, such as $Sr_2VO_{4-\delta}$ with δ taking values of 0.18, 0.29, 0.38, the oxygen deficit defects appear to be oxygen vacancies, which are distributed at random. In $LaSrNiO_{3.1}$ the oxygen vacancies appear to be ordered along one crystallographic direction. In $La_xSr_{2-x}FeO_{4\pm\delta}$, oxygen interstitials or oxygen vacancies, sometimes ordered, are found.

Unresolved complexity is found in the defect structures of the Bi and Tl containing superconducting oxides (*see* ***Superconductivity***). These compounds, closely related to the Aurivillius phases described above, form restricted homologous series, with formulae $TlBa_2Ca_{n-1}Cu_nO_{2n+3}$, $Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+4}$ and $Bi_2Ba_2Ca_{n-1}Cu_nO_{2n+4}$ with $n =$ 1, 2 or 3. The Cu atoms are contained in perovskite-like sheets 1, 2, or 3 layers thick, joined by Bi–O or Tl–O layers. Crystals consist of intergrowths of more than one thickness of perovskite layer and planar defects are commonplace. Additionally, the variable valence of the Cu creates an oxygen vacancy population. The extent to which any oxygen defects can order is not yet clear, but it is becoming apparent that many are modulated structures (see Section 10).

10 DEFECT ELIMINATION AND ASSIMILATION: MODULATED STRUCTURES

In recent years, a rapidly increasing number of grossly nonstoichiometric solids have been characterized that are essentially free of macroscopic defect populations, owing to advances in crystallographic techniques.[21,22] In general, these materials have a (conventional) underlying structure and an additional component that is modulated in one, two, or three dimensions. It has been found that nonstoichiometry is accommodated by continuous adjustment of the modulated part of the structure. In cases in which the modulation period fits exactly with the underlying structure that is commensurate with it, a normal crystallographic phase forms. In cases where the modulation is not commensurate with the underlying structure, the phase is an incommensurately modulated phase. As the recognition of this class of materials is relatively new, the nomenclature is not yet stable,[23] and a variety of other terms, notably incommensurate structures, vernier structures, chimney-ladder structures, layer misfit structures, and infinitely adaptive structures are also current in the literature. Not all forms of modulation involve composition

change, and only a small number of examples of modulated nonstoichiometric crystals are described here.

One of the prototypes of this behavior is the low-temperature form of tantalum pentoxide, L-Ta_2O_5. The structure of this phase is ill defined, even though it is a stoichiometric oxide, and the room temperature structure is a function of the prior thermal treatment temperature of the material. Reaction with other oxides, notably WO_3, ZrO_2 and Al_2O_3, gives rise to solids with a broad oxygen nonstoichiometry. However, each composition appears to generate a uniquely ordered structure, which have been termed *infinitely adaptive structures*.

The structures were originally described in terms of undulating chains of MO_7 pentagonal bipyramids, with a composition of M_3O_8. The cation coordination was described as a mixture of octahedral and pentagonal bipyramidal. Interstitial metal atoms situated in sites between sheets of pentagonal bipyramids were invoked to achieve the correct composition. It is now clear that the cations are in a hexagonal planar array and that the anion array is continuously modulated, and expands or contracts to fit the anion to cation ratio. In some places, the cation coordination is well represented by a pentagonal bipyramid, and in other places by an octahedron. Elsewhere the coordination polyhedra can be described as distorted variants of these.

Vernier structures have two interpenetrating substructures. One of these expands or contracts as a smooth function of composition, while the other remains relatively unchanged. Over much of the composition range, these are not in register, giving rise to an incommensurate structure with enormous 'unit cells'. Typical of this group are the barium–iron sulphides of formula $Ba_xFe_2S_4$, with x taking values from 1.0 to approximately 1.25, as in, for example, $Ba_{1.1250}Fe_2S_4$, $Ba_9(Fe_2S_4)_8$. Across the composition range of these phases, the Ba atoms are distributed evenly between rods of composition Fe_2S_2. The density of packing of the Ba chains fluctuates as a smooth function of the composition. As with other metallic solids, charge compensation relied upon electron delocalization. The Sr_xTiS_3 phases, where x can vary between 1.05 and 1.22, seems to be structurally similar.

The misfit layer compounds are typified by materials with a formula $MS_{1+x}(TS_2)_m$, in which T is a transition metal atom, Ti, V, Cr, Nb, or Ta, and M is a large atom such as Sn, Pb, Bi, with stereochemically active electron lone pairs, or a lanthanide. The structures are built from S-T-S layers, in which the metal T takes trigonal-prismatic coordination. These layers are interleaved with layers of the halite structure, usually two or three atom layers in thickness, with composition MS_x. This leads to a chemical formula of $[MS_x]_n(TS_2)_m$, where n varies from approximately 1.08–1.24, and m takes values of 1–3, depending upon the nature of T and M. A typical example is the compound $[(Ln_{1/3}Sr_{2/3}S)_{1.5}]_{1.15}\ NbS_2$. In all of the misfit layer compounds, the lattice parameter of the interpolated halite layers fit one lattice parameter of the TS_2 layer but not the other, so that in this direction, the match is irrational, and the MS_x layers are incommensurate with the (TS_2) layers in one direction. The nonstoichiometric variation of metal to sulphur ratio is not due to point defects or aggregates of these, but simply lies with the misfit between the two portions of the structure. Many other nonsulphide misfit layer structures are known.

The way in which the structures of nonstoichiometric phases have been revised, as better crystallographic techniques become available, is well illustrated the anion-excess fluorite-related systems. The prototypes of this family are formed in the YOF-YF_3 system, where it was originally believed that a solid solution existed over the approximate composition range $MX_{2.125}$ to $MX_{2.250}$. Careful powder X-ray diffraction replaced this idea with the idea that a homologous series of compounds with a general formula $Y_nO_{n-1}F_{n+2}$ might occur. Single-crystal studies refined the structures sufficiently for a vernier effect to be suggested. In this, the positions of the metal atoms were similar to those found in the fluorite parent structure. The anions were thought to take two forms, either as square nets, or as hexagonal nets. The square nets are identical to those found in the parent fluoride structure. The hexagonal nets are able to accommodate more anions per unit length that the square nets, so that as the anion stoichiometry changes, the ratio of the square to hexagonal nets alters. The coincidence of the anion and cation substructures (the pitch of the vernier), gave a measure of the unit cell of the phase. A similar evolution of understanding has occurred with $Nb_2Zr_{x-2}O_{2x+1}$, in which x takes values 7.1–12.0, (corresponding to $MX_{2.1409}$ to $MX_{2.0833}$) and $ZrO_{2-x}F_{2x}$.

The vernier model also turned out to be an approximation. It is now clear that although the metal atoms in these structures are similar to that found in the fluorite parent structure, the anion array is continuously modulated, and expands or contracts throughout the structure to fill the space optimally with respect to the chemical and crystallographic constraints that apply. Although for some modulation wavelengths the anion array is well described in terms of a square net or a hexagonal net, this is not universally correct, and the modulated description is a more accurate representation of the anion substructure.

Although modulation of the anion substructure occurs frequently in anion-excess fluorite structures, it may not be the unique mode of accommodating the stoichiometric imbalance. The phase $CeN_{0.222}O_{0.667}F_{1.333}$ prepared via shorter heating times produces a material that contains defect clusters. These are statistically distributed, in an anisotropic way, among the square anion-net planes of the parent fluorite structure. Long annealing of the sample causes these defect clusters to be assimilated into the structure.

Apart from annealing times, the structures described above are also sensitive to the preparation temperature. This is well illustrated by phases in the Bi_2O_3–TeO_2 system. At high temperatures, a nonstoichiometric anion-deficient fluorite structure seems to be stable between the composition limits Bi_2TeO_5 and $Bi_2Te_2O_7$, ($MO_{1.6667}$–$MO_{1.7500}$). This broad

nonstoichiometric phase range transforms to a modulated structure at lower temperatures. In this phase, the metal atoms are in the normal fluorite array, and the anions form a modulated net that flexibly adapts to the overall cation to anion ratio. The defects that are responsible for the high-temperature phase have yet to be clarified.

There is little doubt that many materials that at present are described as containing ordered arrays of point or extended defects will be successfully described as notionally defect-free modulated structures. For example, the intergrowth Aurivillius phases, described as containing extended planar defects, have recently been described compactly as modulated structures.[24,25] The same formalism has been applied to hexagonal perovskite structures[26,27] and superconducting copper oxides.[28] Others will certainly follow.

1 INTRODUCTION

Dielectric polarizabilities are useful for prediction of dielectric constants of new materials and compounds whose dielectric constants have not been measured, and in calculations of energies of the formation and migration of defects.[1,2] In addition, deviations from the polarizability additivity rule are useful in understanding certain physical properties such as thermodynamic functions[3] and ionic and electronic conductivity.[4–6]

Polarizabilities measure the response of ions or atoms to an electric field. Electronic polarizabilities, α_e, arise from deformation of the electron cloud relative to the nucleus and are given by the Lorenz–Lorentz equation:[7,8]

$$\alpha_e = 1\,b\left[(V_m)\frac{(n^2-1)}{(n^2+2)}\right] \quad (1)$$

where V_m is the molar volume, n is the refractive index, and b is assumed to be $4\pi/3$. Ionic polarizabilities, α_i, which arise from relative movements of positive and negative ions in ionic or partly ionic crystals, cannot be calculated or measured directly.

Dielectric polarizabilities, α_D, defined by Roberts,[9] include both ionic and electronic components, and are related to the measured dielectric constant, κ', by the Clausius–Mosotti (C–M) equation:

$$\alpha_D = \alpha_e + \alpha_i = 1\,b\left[(V_m)\frac{(\kappa'-1)}{(\kappa'+2)}\right] \quad (2)$$

where κ', the real part of the complex dielectric constant, is measured in the range 1 kHz to 10 MHz.[9–11] Assumption of point dipole ions and cubic symmetry leads to $b = 4\pi/3$.[12,13] The Clausius–Mosotti equation is strictly valid only for compounds where the molecule or ion has cubic symmetry, but has been found to be approximately valid for a number of noncubic crystals.[9,10,14–18]

The molecular polarizability of a complex substance can be broken up into the molecular polarizabilities of simpler substances according to

$$\alpha(M_2M'X_4) = 2\alpha(MX) + \alpha(M'X_2) \quad (3)$$

This rule can be applied to both electronic and dielectric polarizabilities, but here we discuss the rule only insofar as it applies to dielectric polarizabilities. The molecular or oxide additivity rule has been applied to hydrates,[19,20] to the compounds $MTiO_3$ where M = Mg, Ca, Sr, and Ba,[21] to dolomite ($CaMg(CO_3)_2$), zircon ($ZrSiO_4$), and spinel ($MgAl_2O_4$),[22] to several titanates and zirconates and $KMgF_3$,[11] and to a variety of minerals.[14]

Molecular polarizabilities of complex substances can also be broken up into ion polarizabilities according to

$$\alpha(M_2M'X_4) = 2\alpha(M) + \alpha(M') + 4\alpha(X) \quad (4)$$

Sets of empirical electronic ion polarizabilities, α_e, were derived from the Lorenz–Lorentz relation and the additivity rule using the alkali halides and alkaline earth chalcogenides by many investigators[23–26] and using a variety of minerals by Lasaga and Cygan.[14] These polarizabilities were found to be useful in predicting refractive indices.

A set of 18 dielectric ion polarizabilities, α_D, derived from cubic compounds by Roberts,[9] assuming $\alpha_D(O^{2-}) = 2.387$ Å^3 was found to give agreement between observed and calculated total compound polarizabilities of ∼5%. A second set of 11 dielectric ion polarizabilities was derived by Lasaga and Cygan,[14] assuming $\alpha_D(O^{2-}) = 2.37$ Å^3 for application to minerals. Using these ion polarizabilities, agreement between observed and calculated total polarizabilities of 24 common minerals was ∼10% with some individual deviations as large as 20%.

Although molecular polarizabilities are known with precision, the apportionment between cation and anion polarizabilities is a difficult problem. This situation is analogous to the apportionment of cation and anion crystal radii. Roberts[9] arbitrarily assumed $\alpha_D(O^{2-}) = 2.387$ Å^3 whereas Lasaga and Cygan[14] did not specify the source of their value of 2.37 Å^3.

Unlike studies on electronic polarizabilities, we have no calculated values of ion dielectric polarizabilities to rely on. One approach is to estimate a value for the maximum polarizability of oxygen. Thus, $\alpha_D(O^{2-})$ can be derived from an oxide whose total polarizability is contributed primarily by the polarizability of O^{2-}. Because B^{3+} has the lowest polarizability of the commonly occurring cations, the ideal choice would be B_2O_3. Using $\alpha_D(B_2O_3) = 6.15$ Å^3 derived from Be_2BO_3OH, $CaB_2Si_2O_8$, $MgAlBO_4$, $Zn_4B_6O_{12}$, and BaB_2O_4,[17] we find $\alpha_D(O^{2-}) < 2.05$ Å^3. The next most useful reliable compound is BeO. From BeO, we fix $\alpha_D(O^{2-})$ at a

value which does not result in a negative cation polarizability, i.e. $\alpha_D(O^{2-}) < 2.213$ Å^3.

Alternatively, we can assume the values of $\alpha_D(Be^{2+})$ and $\alpha_D(O^{2-})$ to be related by the r^3 law[27] ($\alpha \propto r^3$) using BeO and a variety of simple oxides with both 'bonded radii'[28] and crystal radii.[29] Using this scheme, $\alpha_D(O^{2-})$ varies from 1.97 Å^3(BeO) to 2.55 Å^3 (CaO) using bonded radii and 2.15 Å^3 (BeO) to 2.87 Å^3 (CaO) using crystal radii. Thus, using bonded radii we would choose a value of $\alpha_D(O^{2-}) = 2.0–2.5$ Å^3. Using both criteria, we arrive at a value of $\alpha_D(O^{2-})$ between 2.0 and 2.3 Å^3. As for crystal radii, oxygen polarizability appears to depend on interatomic distance, but as we shall see, it is often convenient to assume a constant oxygen polarizability.

Most of the early studies of electronic polarizabilities assumed cation and anion polarizabilities that do not vary with the crystal environment. However, Tessman *et al.*[23] noted considerable variation of the oxide ion polarizability ($\alpha_e(O^{2-}) = 0.9–3.2$ Å^3) and were able to correlate this variation with the volume occupied by the oxygen ion. Other investigators subsequently noted the dependence of experimental oxygen polarizabilities on their environment in the crystal.[30,31] Ruffa[32] concluded that anion polarizabilities were strongly increased as lattice interaction decreased, and Wilson and Curtis[24] found a significant dependence of anion polarizabilities on interatomic distances in alkali halides. Coker[25] found significant improvement in agreement between calculated and observed molar polarizabilities for alkali halides and alkaline earth chalcogenides when the anion polarizability was allowed to vary; large increases in anion polarizability were observed as the size of the cation was increased. More recently, Mahan,[33] in a theoretical study, found constant cation polarizabilities but concluded that anion polarizabilities are affected by their crystalline environment.

2 POLARIZABILITIES OF SIMPLE OXIDES

Oxide dielectric polarizabilities can be measured directly from dielectric constants of some of the simple oxides using the Clausius–Mosotti relation (equation 2) or derived indirectly from the dielectric constants of complex oxides and the oxide additivity rule (equation 3). Table 1 summarizes the accurately known values of oxide polarizabilities. These values can be used to check the oxide additivity rule.

Table 2 shows that agreements between observed dielectric polarizabilities and those calculated from the sum of the oxide polarizabilities according to equation (3) are typically 1%. This excellent agreement indicates that oxide polarizabilities can be used in conjunction with the C–M relationship to predict dielectric constants of many compounds.

Table 1 Mean dielectric constants and molar polarizabilities of simple oxides

3 ION POLARIZABILITIES

According to equation (4), total molar dielectric polarizability of a compound can be calculated (α_{calc}) as a simple linear combination of individual ion polarizabilities, α(ion):

$$\alpha_{calc} = \sum_{I=1}^{N} n\,\alpha(\text{ion}) \qquad (5)$$

Here, I varies over the total number (N) of types of ions (I) in the formula unit and n is the number of ions of type I

Table 2 Comparison of observed and calculated single crystal dielectric properties of well-behaved compounds

	Observed and calculated polarizabilities from oxide polarizabilities[a]			Observed and calculated dielectric constants from ion polarizabilities[b]

[a]Using the C–M equation and oxide polarizabilities from Table 1. [b]Using the C–M equation and ion polarizabilities from column 2 of Table 3.

in the formula unit.[34] With sufficient measurements of α_{obs}, ion polarizabilities, α(ion), can be used as a set of refinable parameters in a least squares procedure which minimizes the function:

$$\sum_{i=1}^{M} w_i(\alpha_{obs} - \alpha_{calc})^2 \quad (6)$$

Here i varies over the number of measurements of α_{obs} for a variety of compounds and $w_i = \sigma_i{}^{-2}$, where σ_i is the estimated % error in the experimental dielectric constant. In practice it is necessary to fix one polarizability, preferably in such a way that its errors do not seriously affect the overall errors of the other ions; we have arbitrarily assumed the value for $\alpha_D(B^{3+}) = 0.05$ Å^3. This assumption results in $\alpha_D(O^{2-}) = 2.01$ Å^3.

As discussed in Section 1, both theoretical and experimental oxygen electronic polarizabilities depend on their crystalline environments.[33,35–38] The fluoride ion polarizability is less dependent on near-neighbor distances than that of the oxide ion. An oxide ion polarizability dependence on V_{ox}, the volume occupied by the oxygen, is consistent with the concept of bonded radii devised by Gibbs and Boisen,[28] where anion radii vary with the bond length of the M–O bond and V_{ox} increases from 13.8 Å^3 in BeO to 27.8 Å^3 in CaO; $\alpha_D(O^{2-})$ increases from 1.94 Å^3 to 2.57 Å^3. The oxide radius in compounds containing Na–O bonds is 1.22 Å, whereas the oxide radius in compounds containing tetrahedral Si–O bonds is 0.95 Å. Thus, the concept of cation electronic polarizabilities that are constant and oxygen ion polarizabilities that vary approximately with lattice constant and oxygen molar volume is well established.

3.1 Oxygen Polarizability Independent of Oxygen Molar Volume

In one scheme, oxygen dielectric polarizabilities, $\alpha_D(O^{2-})$ are assumed not to depend on oxygen molar volume, V_{ox}. Dependence of $\alpha_D(O^{2-})$ on V_{ox}, as described by Tessman *et al.*,[23] shows up as greater deviations from additivity in compounds having larger interatomic distances and large oxygen molar volumes, such as SrO ($V_{ox} = 33.2$ Å^3) and BaO ($V_{ox} = 42.4$ Å^3). This scheme has the advantage of simplicity of application and is, in general, valid for most oxidic compounds which generally have $V_{ox} = 15–25$ Å^3.

The results from least squares refinements of α_D(ion) made using experimental polarizability data from 129 oxides and 25 fluorides[34] are given in Table 3. The second column in Table 3 was calculated by fixing the parameters m and N in equation (7) at 0.001 and 1.0, respectively. The polarizabilities listed in this column are recommended for use with most oxides and fluorides, and in particular, for calculation of dielectric constants.

Although ignoring the oxygen molar volume correction allows more rapid calculation of estimated dielectric constants, the additivity deviations (Δ) are larger for compounds such as SrO ($\Delta = -3.3\%$) and BaO ($\Delta = -8.6\%$) with $V_{ox} > 25$ Å^3. Most of the calculated uncertainties in refined ion polarizabilities are small, i.e. <0.01 Å^3. These uncertainties are unrealistically low; a more reasonable estimate of the uncertainty is ~0.05 Å^3 for the smaller ions such as Al^{3+} and Si^{4+} and ~0.1 Å^3 for larger ions such as Ca^{2+} and Y^{3+}. In cases such as Cs^+, Tl^+, Co^{2+}, Ni^{2+}, Cu^{2+}, Eu^{2+}, Sb^{3+}, Ce^{3+}, Ce^{4+}, Zr^{4+}, As^{5+}, V^{5+}, Sn^{4+}, U^{4+}, Th^{4+}, and Nb^{5+}, the uncertainties are larger because the ratio of the number of observed molar polarizabilities to refined ion polarizabilities is rather low and the observed total polarizabilities have larger errors. Figure 1 shows a periodic table of ion dielectric polarizabilities prepared from column 2 of Table 3.

3.2 Oxygen Polarizability Dependent on Oxygen Molar Volume

In a slightly more complex scheme, $\alpha_D(O^{2-})$ is assumed to depend exponentially on V_{ox}, the volume occupied by an oxide ion, as proposed by Bussmann *et al.*[39] The parameter V_{ox} is easily calculated for all compounds whose structure is known. Then

$$\alpha_D(O^{2-}) = \alpha_{D_0}(O^{2-}) + m(V_{ox}^N) \quad (7)$$

where $\alpha_D(O^{2-})$ = polarizability of oxygen in a compound having oxygen molar volume, V_{ox}; $\alpha_{D_0}(O^{2-})$ = polarizability of oxygen at an arbitrary value of V_{ox}; and m, N = parameters to be fitted. Polarizabilities of cations and F^- are presumed to be independent of the compound in which the ions are found.

Assuming a linear relationship between $\alpha_D(O^{2-})$ and V_{ox} ($N = 1.0$) (see equation 7), m refines to a value of 0.022. This results in a better fit for SrO ($\Delta = +1.5\%$) and BaO ($\Delta = -3.1\%$). Using the stronger dependence of $\alpha_D(O^{2-})$ on oxygen molar volume given by the exponential relation (equation 7) results in a refined value of $N = 2.0$. This results in a slightly worse overall fit between observed and calculated total polarizabilities, but the fit to SrO ($\Delta = +0.02\%$), BaO ($\Delta = -2.4\%$), and most rare earth oxides is somewhat better. This set of ion polarizabilities[34] is included in column 1 of Table 3 for use with compounds having $V_{ox} > 25$ Å^3.

3.3 Comparison with Previous Sets of Ion Polarizabilities

The set of dielectric polarizabilities found in Table 3 appears to be significantly different from the sets of Roberts[9] and Lasaga and Cygan.[14] However, the differences arise primarily because of the large difference in $\alpha_D(O^{2-})$: 2.01 Å^3 (Table 3) vs. 2.387 Å^3[39] or 2.37 Å^3.[14] Roberts and Lasaga and Cygan chose these latter values because they had no

data from borates or beryllates; use of $\alpha_D(O^{2-}) = 2.387\,Å^3$ results in negative polarizabilities for B^{3+} and Be^{2+}. The polarizabilities in Table 3 are more reliable because of the use of more accurate dielectric constants from a larger number of compounds involving more ions. The problem of relative values of cation and anion polarizabilities still remains, but based on the r^3 law and the concept of bonded radii the values obtained from the least squares procedure seem reasonable.

4 ESTIMATION OF DIELECTRIC CONSTANTS

Rewriting the C–M relation (equation 2) gives an expression for estimating the dielectric constant of a compound of known structure type:

$$\kappa' = \frac{(3V_m + 8\pi\alpha_D^T)}{(3V_m - 4\pi\alpha_D^T)} \tag{8}$$

where α_D^T = total dielectric polarizability. Total polarizabilities can be evaluated using either the oxide polarizabilities listed in Table 1 where they are available, or ion polarizabilities listed in Table 3. Table 2 compares the observed dielectric constants, κ'_{obs}, of a variety of borates, aluminates, gallates, silicates, germanates, phosphates, arsenates, and vanadates with the dielectric constants, κ'_{calc}, calculated from ion polarizabilities and equation (8). In general, the Clausius–Mosotti equation appears to allow estimation of mean dielectric constants of nonferroelectric oxides and fluorides having $V_{ox} < 25\,Å^3$ to within about 2% of their actual values.

Most nonferroelectric oxides and fluorides fall in this category of 'well-behaved' compounds, but some materials exhibit larger deviations.[4,34] Such deviations between observed and calculated dielectric constants can frequently be traced to factors which are known to increase κ': ionic or electronic conductivity, ferroelectric behavior, the presence of H_2O or CO_2 in channels or large cavities, or the presence of dipolar impurities other than H_2O. A further cause of large deviations from additivity is the presence of 'rattling' or 'compressed' cations having unusually large or small cation polarizabilities, respectively.

Table 4 illustrates examples of compounds showing substantial deviations of typical observed and calculated polarizabilities and dielectric constants. Poor agreement in the case of $KTiOPO_4$ is probably caused by motion of K ions which results in electrode polarization and consequent higher dielectric constants. Deviations from additivity occur even when the conductivity is negligible at room temperature.

Conductivity in $LiGaO_2$, $Ca_5(PO_4)_3F$, and PbF_2 occurs at high temperatures with the abnormally high polarizabilities, probably indicating residual cation or anion disorder present at room temperature. The deviation in PbF_2 is possibly caused by the disorder inherent in anion–Frenkel pairs. Dielectric constants of Fe_2SiO_4 (fayalite) vary widely. The example in

Table 4 Total polarizabilities and calculated dielectric constants of materials with large deviations from the additivity rule

Compound	$\langle\alpha^T_{obs}\rangle$	$\langle\alpha^T_{calc}\rangle$	δ (%)	$\langle\kappa'_{obs}\rangle$	$\langle\kappa'_{calc}\rangle$	δ (%)

Table 4 is associated with high losses and the presence of Fe^{3+}, leading to space charge polarization.

The effect of RE^{3+}–F dipolar complexes on observed dielectric constants of RE-doped fluorites can be seen in Table 4. Polarizabilities and dielectric constants are elevated much more than would be anticipated from the introduction of the rare earth alone. For example, 1% ErF_3 substituted in BaF_2 raises the dielectric constant by 19%, compared to an expected reduction of <0.5%.

Perhaps the most interesting deviations from additivity are associated with 'rattling' and 'compressed' cations. The 'rattling' cation effect has been described by Dunitz and Orgel[40] as a progressive 'loosening of the central cation at the center of its surrounding octahedron to off-center displacements characteristic of ferroelectric and antiferroelectric substances' as the size of the central cation in an octahedron decreases. Conversely, a 'tightening' of the central cation occurs as the size of the central cation in a polyhedron increases. In most structures, displacements of cations or anions result in polyhedral distortions. However, in certain structures, crystal symmetry prevents the distortion and the rattling cation phenomenon occurs. Table 4 shows examples of 'rattling' cations in $CaYAlO_4$, $LiAlSi_2O_6$ (spodumene), $K_{0.92}Na_{0.08}AlSi_3O_8$ (orthoclase), $Mg_3Al_2Si_3O_{12}$ (pyrope), $Ca_2Al_{2.5}Fe_{0.5}Si_3O_{12}OH$ (epidote), $Ca_2Al_3Si_3O_{12}OH$ (zoisite), $Ca_2MgSi_2O_7$ (akermannite), and $Ca_2ZnSi_2O_7$ (hardystonite).[34] Frequently associated with these large positive deviations of additivity are unusually large entropy and thermal vibration parameters, accompanied by smaller than normal apparent bond valences. Figure 2 shows

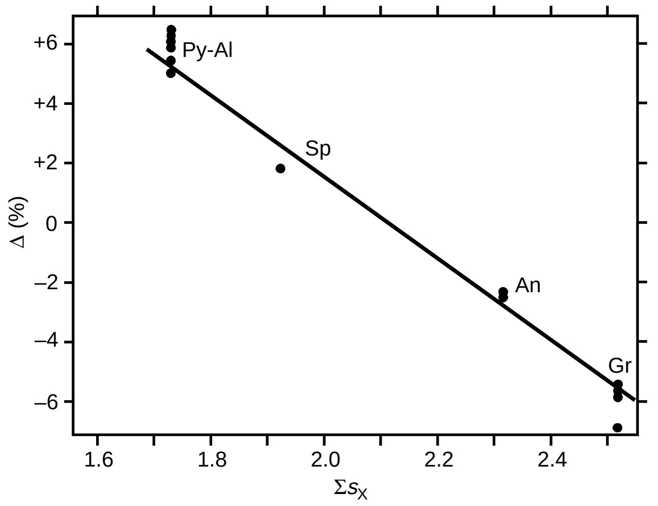

Figure 2 Deviations from the oxide additivity rule vs. apparent bond valence of the divalent ion in silicate garnets of the type $M_3M'_2Si_3O_{12}$. Py-Al = pyrope-almandine ($Mg_{2-x-y}Fe_xCa_yAl_2Si_3O_{12}$); Sp = spessartine ($Mn_3Al_2Si_3O_{12}$); An = andradite ($Ca_3Fe_2Si_3O_{12}$); Gr = grossular ($Ca_3Al_2Si_3O_{12}$). (Reproduced by permission of the Mineralogical Society of America from R.D. Shannon and G.R. Rossman, *Am. Mineral.*, **77**, 94)

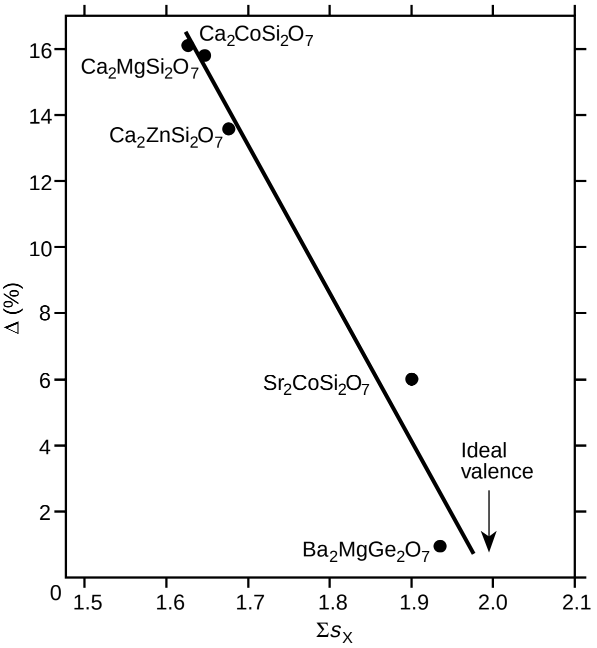

Figure 3 Deviations from the oxide additivity rule vs. apparent bond valence of the divalent M ions in a series of melilite compositions of the type $M_2M'M''_2O_7$. (Reprinted from R.D. Shannon, K. Iishi, T.H. Allikm, G.R. Rossman, and J. Liebertz, *Eur. J. Mineral.*, 1992, **4**, 1241. By permission of Schweizerbart'sche Verlagsbuchhandlung)

the correlation between additivity deviations and apparent bond valence of the divalent ion in a series of silicate garnets of the type $M_3{}^{2+}M_2{}^{3+}Si_3O_{12}$. Figure 3 shows a similar plot for a series of melilite compositions of the type $M_2M'M''_2O_7$ where the apparent bond valences of the divalent M ions deviate significantly from the ideal value of 2.

Examples of 'compressed' cations are Ca in $CaNdAlO_4$ and $Ca_3Al_2Si_3O_{12}$ (grossular) and Sr in $SrLaAlO_4$. Correspondingly, smaller than anticipated entropy in grossular and enhanced apparent bond valences of Ca and Sr in grossular, $CaYAlO_4$, and $SrLaAlO_4$ are observed.

1 INTRODUCTION

Diffraction is a coherent scattering of waves (radiation) from an object, the size of which is comparable with the wavelength. The scattering must be elastic, that is, without a change of energy of the quantum and hence of the wavelength. In this case, the waves scattered from different parts of the object can interfere, in some directions reinforcing each other (when their phases coincide), in other directions canceling each other out (if the phases are opposite). Thus the diffraction pattern is a succession of peaks and troughs, from which one can extract information about the structure of the diffracting object. The sizes of atoms being of the order of 10^{-10} m, three types of radiation have comparable wavelengths: X rays, thermal neutrons, and electrons. Electron diffraction is widely used to determine the structures of molecules in gases, which give continuous diffraction patterns with relatively few features. Thus, only relatively simple molecules can be characterized. The crystal, on the other hand, is like a microscopic diffraction grating, with a long-range order (periodicity) of atoms and molecules in all three dimensions, therefore its diffraction pattern comprises a large number of sharp, well-separated peaks ('reflections'), carrying enough information to determine three-dimensional structures of even the most complex chemical species. This makes single-crystal diffraction methods (especially with X rays, which are the easiest to generate and detect) by far the most important technique for elucidating the structures, not only of inorganic solids, but also of molecular compounds generally. Neutron diffraction is even more informative than X ray, but the sources of neutrons are scarce and expensive. Electron diffraction is used mainly for structural studies of semicrystalline solids, textures, surface layers, contacts between phases and transitional structures, and so on.[1]

The importance of X-ray diffraction (XRD) in the history of chemistry is hard to overstate. When Laue's students Friedrich and Knipping first observed this effect in 1912,[2] the physical reality of atoms was still doubted; the diffraction photographs were the first *visible* proof of their existence. The structural chemistry of silicates, immensely important in mineralogy and geology, has been rationalized[3] entirely by X-ray crystallography: the classical chemical and spectroscopic analyses could do nothing with these insoluble materials. The chemistry of boranes and organometallic π-complexes after 1950 and of metal clusters since 1960s, with their repercussions in the theory of the chemical bond, were only possible because X-ray diffraction provided a ready technique for fast characterization of such compounds. In fact, the first cluster ($[Ta_6Cl_{12}]Cl_2 \cdot 7H_2O$) had been synthesized in 1907,[4] and the first d metal π-complex (Zeise's salt, $K[PtCl_3(H_2C{=}CH_2)]$) in 1827,[5] but the nature of either was not understood until the X-ray studies in 1950[6] and 1954,[7] respectively. The surprising structures of ferrocene and fullerene had been suggested by chemists' intuition, but X-ray studies provided the ultimate confirmation. Indeed, fullerene must have been produced by the ton in the late 19th century, when Voltaic arcs between carbon electrodes were the principal method of public lighting, but even had somebody managed to isolate it, there would have been no means of studying it at that time. Such achievements are possible, because in a good single-crystal X-ray diffraction experiment, the experimental observations outnumber the unknowns (atomic coordinates and vibrational parameters) by a factor of 10. In this, XRD is unique among physical methods, which often have more unknown than known parameters. Thus, XRD requires no a priori model to solve a structure and therefore can cope with a totally novel and unexpected product, while structure determination by spectroscopic methods relies basically on comparison with known 'fingerprints' for certain moieties, linkage types, and so on.

X-ray (as well as neutron) crystallographers elegantly exploited many technological and computational advances in the last decades. Before 1960, solving a structure of moderate complexity required months, sometimes years, of hard work. In the 1970s, automated diffractometers, (mainframe) computers, and new software reduced this time to weeks or even days, and X-ray crystallography evolved from the method of last resort to a routine technique of chemical analysis with affordable timescale. As such, X-ray diffraction became economically advantageous over more traditional methods, notwithstanding large capital investment in the equipment. Crucially, XRD requires very little material: a complete structure determination can be made with a crystal of 0.01 mg or less without necessarily destroying even that. Since the first edition of the EIC, massive replacement of point detectors with area detectors again reduced the duration of the experiment, from days to hours. With an exponential

accumulation of structural results and emergence of online databases providing easy access to them,[8] it is now practical to obtain novel results (structural correlations)[9] by statistical analysis of the structures already known, rather than the experiment itself being the sole object of the research program (see Section 4).

This article is divided into three major sections: background to the techniques, their practical aspects, and inspection of the results. No attempt has been made to repeat the excellent textbooks, both classical and new, which expound the complete theory of X-ray or neutron diffraction and full details of the experimental techniques.[10–22] Our aim is to give the reader (an inorganic chemist) a general outlook of the subject, basic knowledge necessary to practice the techniques and to use and interpret the results intelligently (particularly in application to their own research), and a key for further reading of the extensive literature available.

2 BACKGROUND TO DIFFRACTION TECHNIQUES

2.1 Basics of Crystal Symmetry

A crystalline solid is one in which atoms and molecules (more strictly, the mean positions around which they thermally vibrate) form a regular three-dimensional array, corresponding to a free energy minimum of the crystalline state. It is always possible to select a small parallelepiped of the crystal space in such a way that repetitions (parallel translations) of this parallelepiped in all three dimensions will reproduce the entire crystal structure. This parallelepiped is called the unit cell and is defined by three noncoplanar vectors (**a, b, c**) forming its edges. These vectors are also the (smallest) translations by which the unit cell should be shifted to fill the whole crystal space. Thus, once we know the contents of one unit cell, we know the entire crystal structure. By convention, the positive directions of **a, b**, and **c** are chosen so as to make them a right-hand set. These directions are also chosen as the axes x, y, and z of the crystal coordinate system (Figure 1(a)). The scalar dimensions of the unit cell are described by three edge lengths (a, b, c) and three angles between them (α, β, γ). Note that a point (e.g. position of an atom) in a unit cell is described in crystallography by 'fractional coordinates', for example, each coordinate is given as a fraction of the lattice repeat (translation) in that direction.

Compared to the unit cell, a macroscopic crystal can be regarded as infinitely large. Thus, a NaCl crystal of 1 mm^3 contains 10^{19} unit cells. Ignoring its finiteness, each vertex of the unit cell and every one generated by translations are physically identical: the atomic environments and all physical properties at these points are the same. An (infinite) three-dimensional array of such points in space is called the crystal lattice. Note that the latter is only a mathematical device to describe the crystal's regularity and is *not* synonymous with the crystal structure itself, which is an array of physical objects (atoms and molecules). Thus, a lattice point need not (although in some structures *can*) coincide with the center of an atom or a molecule, and a molecule need not lie entirely within a 'box' of a unit cell, without being bisected by its face (boundary).

A unit cell, as defined above, can be chosen in many different ways, but the meaningful choice is such as reflects the symmetry of the structure (e.g. a square prism for a structure having a fourfold axis), even if this means choosing *not* the smallest possible unit cell. For this reason, a unit cell can have lattice points not only in its vertices (primitive cell, denoted P) but besides also in its center (body-centered, or I), or in the center of each face (face-centered, F), or in the centers of two opposite faces (base-centered). The latter is denoted A, B, or C, depending on whether the centered faces are opposite to the lattice vectors **a**, **b**, or **c**, respectively. There are only seven different types of lattice symmetry, known as crystal systems, each corresponding to a distinct shape of the unit cell (Table 1). Taking into account all centering conditions compatible with each crystal system, there are 14 different types of lattices in all, known as Bravais lattices (Figure 2). A trigonal unit cell can contain two additional lattice points with the coordinates $\frac{1}{3}, \frac{2}{3}, \frac{2}{3}$ and $\frac{2}{3}, \frac{1}{3}, \frac{1}{3}$, but usually such a centered lattice is described by a geometrically equivalent primitive lattice, called rhombohedral (R), with the unit cell volume three times smaller.

A lattice plane is a plane passing through at least three noncolinear lattice points. The direction of such a plane is described by a set of three integers h, k, and l, written in parentheses as (*hkl*) and known as Miller indices (originally introduced[23] to describe external crystal faces, which must always be lattice planes). It means that the plane intersects the axes x, y, and z at the distances from the origin, equal to rational fractions of the corresponding unit cell parameters, that is, a/h, b/k, and c/l, respectively (Figure 1(b)). Miller indices should not be confused with those for crystallographic directions, given in square brackets as [*uvw*] and representing the vector $u\mathbf{a} + v\mathbf{b} + w\mathbf{c}$, radiating from the origin. A zone is defined as a set of lattice planes, whose intersections are all

Table 1 Relations between unit cell parameters and lattice symmetry

Crystal system	Bravais lattices	Unit cell constraints	Laue symmetry
1. Triclinic	P	$a \neq b \neq c, \alpha \neq \beta \neq \gamma$	$\bar{1}$
2. Monoclinic	P, C	$a \neq b \neq c, \alpha = \gamma = 90°, \beta > 90°$	$2/m$
3. Orthorhombic	P, C, I, F	$a \neq b \neq c, \alpha = \beta = \gamma = 90°$	mmm
4. Tetragonal	P, I	$a = b \neq c, \alpha = \beta = \gamma = 90°$	$4/m$ or $4/mmm$
5. Trigonal	P, R^a	$a = b \neq c, \alpha = \beta = 90°, \gamma = 120°$	$\bar{3}$ or $\bar{3}m$
Rhombohedral[a]	R	$a = b = c, \alpha = \beta = \gamma < 120°$	Ditto
6. Hexagonal	P	$a = b \neq c, \alpha = \beta = 90°, \gamma = 120°$	$6/m$ or $6/mmm$
7. Cubic	P, I, F	$a = b = c, \alpha = \beta = \gamma = 90°$	$m\bar{3}$ or $m\bar{3}m$

[a]Alternative setting for centered trigonal lattices.

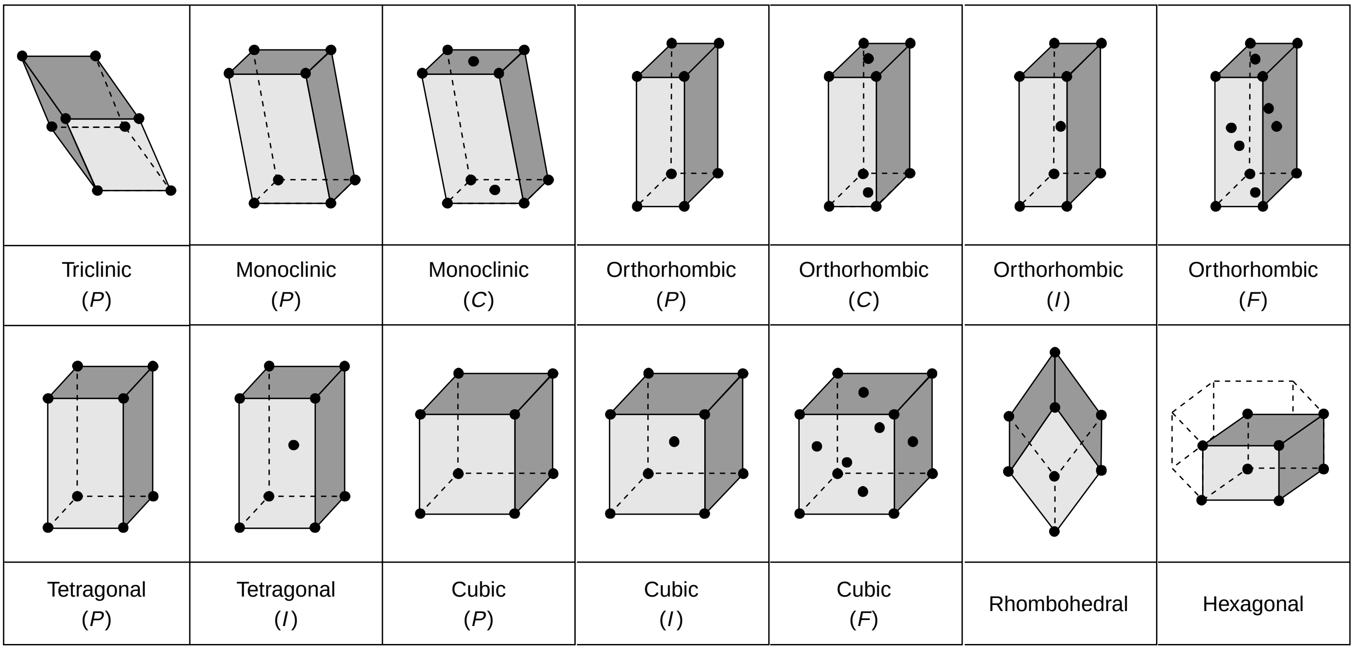

Figure 2 The 14 Bravais lattices

parallel. The common direction of these intersections is called the zone axis (Figure 3).

Symmetry operation is an operation transforming an object into an (apparently) identical one. Lattice translations are the symmetry operations present in any crystal structure by definition. Besides them, a structure may (or may not) have other symmetry operations, performed about a certain point, line or plane, which is called an element of symmetry. There are two types of symmetry operations: those which involve an overall shift (translation) and those which leave at least one point of an object unmoved. The latter operations can apply both to crystal structures and to finite, isolated objects. Repeating such operations two or several times will bring the object back to the original position. The following symmetry elements of this type can be found in crystals.

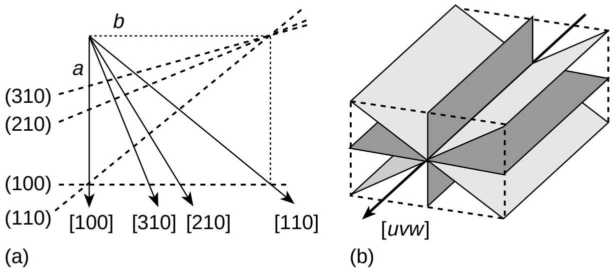

Figure 3 (a) Crystallographic directions (bold) and planes (dotted); (b) a zone of planes with its axis [*uvw*]

1. An n-fold rotation axis is a line, rotation about which through $360°/n$ leaves the object indistinguishable from the original. Only axes with $n = 2$, 3, 4, and 6 can be present in crystals, all others being incompatible with translational symmetry.

2. An inversion center, or center of symmetry (designated $\bar{1}$), is a point. If an object lies at a distance r from this point, its symmetry-related object lies at the same distance in the opposite direction. Thus, if a center of symmetry lies at the origin (0, 0, 0) of the unit cell, for each atom with coordinates x, y, z there will be an equivalent one with coordinates $-x, -y, -z$.
3. A mirror plane, designated by the letter m. For example, a mirror plane parallel to the xy plane and passing through the origin will convert an object at x, y, z into one at $-x, y, z$.
4. A rotatory-inversion axis combines a rotation around a line through 360°/n with inversion through a specific point on this line. Axes with $n = 3$, 4, or 6 (designated $\bar{3}$, $\bar{4}$, and $\bar{6}$) are possible in crystals, that with $n = 2$ is equivalent to a mirror plane, which is perpendicular to the twofold axis and passes through the inversion center.

These operations can be combined into 32 self-consistent sets, known as point groups. Because the outer form ('habit') of a crystal depends on the crystal structure, point groups describe all possible crystal forms, classified correspondingly into 32 crystal classes.

Symmetry operations which involve shifts, can apply *only* to regularly repeating infinite patterns, like crystal structures. A repeated application of such an operation brings the structure not to the original position, but to a different one, separated from the original by an integer number of lattice translations. There are two types of such ('translational') symmetry elements (see Table 2), besides primitive lattice translations **a**, **b**, **c**.

- Screw axes, designated by a number with a subscript (n_q), combine a rotation by 360°/n (see i) with a shift parallel to this axis and equal to the lattice repeat in this direction, multiplied by q/n. Screw axes possible in crystals are 2_1, 3_1, 3_2, 4_1, 4_2, 4_3, 6_1, 6_2, 6_3, 6_4, and 6_5. Note that the operations of axes 3_1 and 3_2, 4_1 and 4_3, 6_1 and 6_5, 6_2 and 6_4, respectively, are mirror images of each other. Such axes are called right-handed if $q < n/2$, left-handed if $q > n/2$, and without hand if $q = n/2$.
- Glide planes combine a reflection in a mirror plane with a shift parallel to this plane. They are called a, b, and c planes when the shift equals 1/2 of a cell edge (i.e. **a**/2, **b**/2, and **c**/2, respectively), n planes when it equals 1/2 of (any) face-diagonal or body-diagonal of the unit cell, and d (so-called 'diamond') planes when it equals 1/4 of such diagonal.

Note that rotation axes and translations are 'perfect symmetry elements': they transform an object into a perfectly identical one, while inversion centers and planes are 'imperfect': they change an asymmetric object (molecule) into one of different 'handedness' (an enantiomer).

There are 230 possible combinations of symmetry elements of types (i) to (vi) with lattice translations, called crystallographic space groups. They describe the symmetries of all crystal structures that can exist, although not all have been actually observed so far. A space group symbol includes a capital letter describing the lattice type, followed by the essential symmetry elements present. A comprehensive description of each space group can be found in Reference.[24]

Table 2 Systematic absences related to lattice centering and translational elements of symmetry

		Related translation	Reflections affected	Conditions for systematic absence
A-centered lattice			hkl	$k + l \neq 2n$
B-centered lattice			hkl	$h + l \neq 2n$
C-centered lattice			hkl	$h + k \neq 2n$
F-centered lattice			hkl	$h + k, k + l$, or $h + l \neq 2n$
I-centered lattice			hkl	$h + k + l \neq 2n$
R lattice on hexagonal axes				
obverse setting			hkl	$-h + k + l \neq 3n$
reverse setting			hkl	$h - k + l \neq 3n$

2.2 Diffraction Summary

2.2.1 Directions of Diffracted Beams

X rays (electromagnetic waves) passing through crystal make electrons of atoms oscillate about their nuclei and

become sources of secondary radiation of the same frequency. Thus X rays are scattered from electron clouds. In the process, the phase of the X-ray wave is altered by 180°, but because this change happens to *all* waves, it is ignored in the following treatment of diffraction geometry. Neutrons are scattered only by atomic nuclei, and electron beam by the electrostatic potential of atoms, which is contributed to by both nuclei and electrons, but mainly the latter.

Waves scattered from different parts of a crystal structure can reinforce each other only if they arrive in phase, that is, if their path lengths D differ by an integer number of wavelengths. This applies also to atoms separated by one lattice translation, and must be true in all three dimensions, therefore Laue (1912) derived the following conditions for X-ray diffraction:

$$\Delta D_1 = \mathbf{a}(\mathbf{s} - \mathbf{s}_0) = a(\cos\alpha_n - \cos\alpha_0) = n_1\lambda$$
$$\Delta D_2 = \mathbf{b}(\mathbf{s} - \mathbf{s}_0) = b(\cos\beta_n - \cos\beta_0) = n_2\lambda$$
$$\Delta D_3 = \mathbf{c}(\mathbf{s} - \mathbf{s}_0) = c(\cos\gamma_n - \cos\gamma_0) = n_2\lambda \quad (1)$$

where $\mathbf{s}_0$ and $\mathbf{s}$ are unit vectors along the directions of the incident and diffracted beams, n are integers (orders of diffraction), α, β, and γ are the angles between the incident beam (subscript 0) or the diffracted beam (subscript n) and the axes x, y, and z, respectively.

Bragg[25] in 1913 drastically simplified the picture, assuming that X rays are 'reflected' from a lattice plane as light is reflected from a mirror, the angle of incidence being equal to the angle of reflection, θ. A diffraction beam occurs only at certain θ values, when the waves reflected from all parallel planes are all in phase, that is, path differences between waves reflected from adjacent planes equal an integer number of wavelengths λ (Figure 4), as defined by Bragg's law:

$$n\lambda = 2d_{hkl}\sin\theta \quad (2)$$

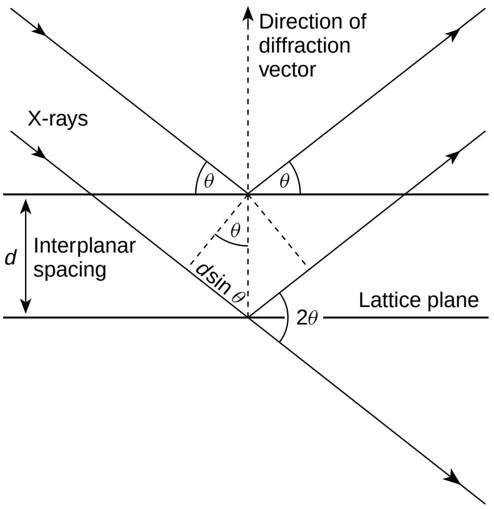

Figure 4 Bragg's law illustrated

Thus each diffracted beam is regarded as a 'reflection' from a plane with Miller indices (*hkl*) and is named by the same indices. Since d_{hkl} depends on the unit cell parameters, as $d_{hkl} = X/Y$, where

$$X = [1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2\cos\alpha\cos\beta\cos\gamma]^{1/2} \quad (3)$$

$$Y = \left[\left(\frac{h}{a}\right)^2 \sin^2\alpha + \left(\frac{k}{b}\right)^2 \sin^2\beta + \left(\frac{l}{c}\right)^2 \sin^2\gamma - 2\left(\frac{kl}{bc}\right)(\cos\alpha - \cos\beta\cos\gamma) - 2\left(\frac{lh}{ca}\right)(\cos\beta - \cos\alpha\cos\gamma) - 2\left(\frac{hk}{ab}\right)(\cos\gamma - \cos\beta\cos\alpha)\right]^{1/2} \quad (4)$$

it is possible to determine the unit cell if λ and the directions of several diffracted beams are known.

These and other calculations can be greatly simplified, using the concept of the reciprocal space[14] (which has the dimension of reciprocal length, $Å^{-1}$) and of reciprocal crystal lattice in this space. The reciprocal lattice vectors, $\mathbf{a}^*$, $\mathbf{b}^*$, and $\mathbf{c}^*$, are related to those of the direct lattice ($\mathbf{a}$, $\mathbf{b}$, and $\mathbf{c}$) by the relationships

$$\mathbf{a}\cdot\mathbf{a}^* = \mathbf{b}\cdot\mathbf{b}^* = \mathbf{c}\cdot\mathbf{c}^* = 1 \quad (5)$$
$$\mathbf{a}^*\cdot\mathbf{b} = \mathbf{a}^*\cdot\mathbf{c} = \mathbf{b}^*\cdot\mathbf{a} = \mathbf{b}^*\cdot\mathbf{c} = \mathbf{c}^*\cdot\mathbf{a} = \mathbf{c}^*\cdot\mathbf{b} = 0 \quad (6)$$

which means that $\mathbf{a}^*$ is perpendicular to the ($\mathbf{b}$, $\mathbf{c}$) plane, $\mathbf{b}^*$ to the ($\mathbf{a}$, $\mathbf{c}$) plane, and $\mathbf{c}^*$ to the ($\mathbf{a}$, $\mathbf{b}$) plane (see Figure 5). The full relationships for all lattice symmetries can be found elsewhere.[14,26] Each point of the reciprocal lattice corresponds to a certain Miller plane of the direct lattice and is designated by the same indices *hkl*. Note that it therefore corresponds also to a possible Bragg reflection, which makes this concept indispensable in interpreting diffraction patterns.

Another useful mathematical image in reciprocal space is the sphere of reflection, introduced by Paul Ewald and named after him.[27] The Ewald sphere (Figure 6(a)) has the diameter of 2/λ, coinciding with the direction of the incident beam (wavelength λ). The crystal (in direct space) is placed at the

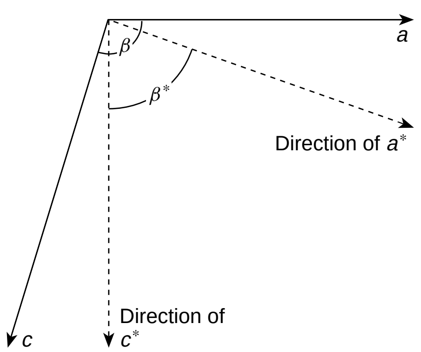

Figure 5 Relationship between reciprocal and direct lattices for a monoclinic unit cell; shown in the **ac** (≡ $\mathbf{a}^*\mathbf{c}^*$) plane

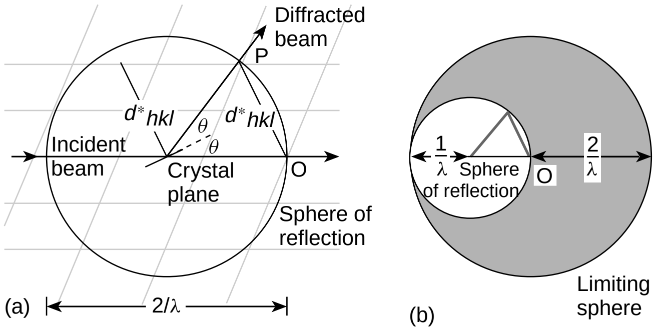

Figure 6 (a) The Ewald construction illustrated. (b) Limiting sphere and sphere of reflection

center C of the sphere. The corresponding reciprocal lattice, drawn at the same scale as the Ewald sphere, is placed with its origin O at the point where the incident beam emerges from the sphere. If the crystal is rotated, the reciprocal lattice also rotates around O. Whenever another reciprocal lattice point P with indices *hkl* touches the surface of the sphere, Bragg's law (and Laue conditions) are satisfied for the Miller plane with the same indices *hkl*, and a diffracted beam emerges in the *CP* direction. Note that although the number of the reciprocal lattice points is infinite, the number of observable reflections is limited to those points which can, in principle, pass through the Ewald sphere, that is, those lying within the radius of 2/λ from O (Figure 6(b)).

The alternative is to vary the size of the Ewald sphere (i.e. the wavelength) until it touches a reciprocal lattice point. In practice, this is achieved by using an incident beam of 'white radiation' with a continuous spectrum of wavelengths. Historically, this was the first X-ray technique (Laue method), later eclipsed by methods using monochromatic radiation but recently resurgent with the introduction of image plate detectors (see below).

2.2.2 *Intensities of Diffracted Beams*

From the unit cell dimension one can calculate the directions of a diffracted beam, but not its intensity, which depends on the types and positions of atoms in the cell. Inversely, these positions cannot be determined without the knowledge of intensities, except in a few simplest structures (e.g. NaCl), where all atoms occupy the lattice points. The intensity I_{hkl} of a reflection depends on many factors.[10,13] Thus, for X-ray diffraction,

$$I_{hkl} = \frac{e^4\,\Omega}{m^2c^4V} I_0\lambda^3 LPTE|F_{hkl}|^2 \tag{7}$$

where I_0 is the intensity of the incident beam, Ω is the volume of the crystal, V the volume of the unit cell, e and m are the charge and mass of the scattering particle, in this case electron (that is why the contribution of nuclei, with much greater m, is negligible). L is the Lorentz factor,[28] accounting for the time needed for the reflection to pass through the Ewald sphere. P is the polarization factor. X rays produced by a (laboratory) source are not polarized, but they (like any electromagnetic radiation) undergo polarization when reflected. Thus if the primary beam is monochromatized by reflection from a crystal (see below), the radiation reaches the sample in a partially polarized state, which affects the intensity of the diffracted beam in a way dependent on the θ angle. Both L and P are dependent on θ and the precise geometry of the particular X-ray instrument. Together the modifications of the intensity data for these two effects are referred to as the 'Lp correction'.[29] The transmission factor T depends on the absorption of X rays in the crystal (see below). The extinction factor E accounts for two different effects: the diffracted beam being diffracted again in the crystal ('primary extinction') and the decrease of the incident beam intensity I_0 during its progress through the crystal, because some energy is taken away by the diffracted beam ('secondary extinction').[30]

But in the first place, I_{hkl} depends on the structure, that is, on the distribution of electron density in the unit cell. This dependence is represented by the structure factor F_{hkl} of a reflection,

$$F_{hkl} = \int_V \rho(xyz) \exp[2\pi i(hx + ky + lz)]\,\mathrm{d}V \tag{8}$$

where ρ is the electron density at a point with the fractional coordinates x, y, z. Equation (8) can be drastically simplified if we present ρ not as a continuous function but as a superposition of atoms,

$$F_{hkl} = \sum_j f_j \exp[2\pi i(hx_j + ky_j + lz_j)] \tag{9}$$

where f_j is the atomic scattering factor (form factor) for the j-th atom and x_j, y_j, z_j are the fractional coordinates of

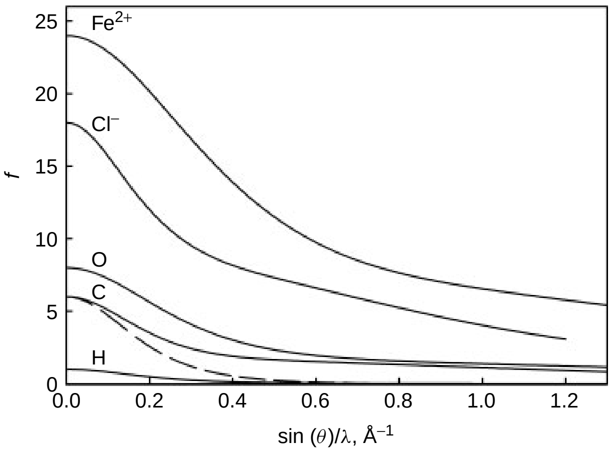

Figure 7 Variation of X-ray form factors, f, with sin θ/λ. Solid lines: stationary atoms, dashed line: C atom with $U = 0.1$ Å^2

this atom. For X-ray diffraction, f_j is not a constant but a function of $\sin\theta/\lambda$ (Figure 7), steadily decreasing from the maximum value equal to the total number of electrons in the atom and approaching zero at high $\sin\theta/\lambda$.[13] This dependence is due to the fact that the size of an electron cloud of an atom is comparable with the wavelength. By contrast, neutrons are scattered only by atomic nuclei, which can be regarded as point scatterers, and hence neutron equivalents of f_j, so-called scattering lengths b_j, are practically angle-independent.[21] The curves of f_j are presumed invariant for a given element in any structure and are calculated by means of quantum mechanics (Hartree-Fock theory),[31,32] presuming the atom to be isolated (ground state) and spherically symmetrical. This 'spherical-atom model' may look a rash, even absurd, simplification: we ignore the existence of chemical bonds in molecules or solids! However, for most practical purposes this approximation is sensible, because the maximum of the electron density peak of an atom (especially a heavy atom) is defined mainly by the core electrons, belonging to the closed inner electron shells, which are unaffected by bonding. The hydrogen atom, which lacks core electrons, is an exceptional case (see below). Only for the most ionic structures does it make sense to use f_j, calculated for ions, rather than neutral atoms (but still spherically symmetrical).

The structure factor is a complex number, expressing both the amplitude $|F_{hkl}|$ and the phase angle α_{hkl} of the scattered wave:

$$F_{hkl} = |F_{hkl}|\exp[i\alpha_{hkl}] = A_{hkl} + iB_{hkl} \tag{10}$$

$$A_{hkl} = \sum_j [f_j \cos 2\pi(hx_j + ky_j + lz_j)] \tag{11}$$

$$B_{hkl} = \sum_j [f_j \sin 2\pi(hx_j + ky_j + lz_j)] \tag{12}$$

$$\alpha_{hkl} = \tan^{-1}\left[\frac{B_{hkl}}{A_{hkl}}\right] \tag{13}$$

For a centrosymmetric structure, α_{hkl} can equal only 0 or 180° (i.e. F having signs $+$ or $-$, respectively), for a noncentrosymmetric structure it can have any value. Owing to the translational symmetry of crystals, $\rho(xyz)$ can be considered as a periodic function in three-dimensional space and expressed by the Fourier transform of equation (8),

$$\begin{aligned}\rho(xyz) &= \frac{1}{V}\sum_{hkl} F_{hkl}\exp[2\pi i(hx + ky + lz)] \\ &= \frac{1}{V}\sum_{hkl} |F_{hkl}|\exp[2\pi i(hx + ky + lz - \alpha_{hkl})]\end{aligned} \tag{14}$$

Thus if we know the moduli (amplitudes) and the phase angles of X-ray reflections, we can calculate the distribution of electron density in the unit cell, that is, find the atomic positions. Finding $|F_{hkl}|$ from I_{hkl} is straightforward, but the values of α_{hkl} are lost in all usual diffraction experiments.[33] Determining (reconstructing) phase angles remains the most difficult part of the structure solution.

The diffraction pattern of a crystal has its own symmetry (known as Laue symmetry), related to the symmetry of the structure, thus in the absence of systematic errors (particularly absorption), reflections with different, but related, indices should have equal intensities. According to Friedel's law,[34] the diffraction pattern of any crystal has a center of inversion, whether the crystal itself is centrosymmetric or not, that is, reflections with indices hkl and $\overline{hkl}$ ('Friedel equivalents') are equal. Therefore Laue symmetry is equal to the point-group symmetry of a crystal plus the inversion center (if it is not already present). There are 11 Laue symmetry classes. For example, if a crystal is monoclinic ($\beta \neq 90°$), then $I(hkl) = I(\overline{hkl}) = I(\bar{h}k\bar{l}) = I(h\bar{k}l) \neq I(\bar{h}kl)$. For an orthorhombic crystal, reflections hkl, $\bar{h}kl$, $h\bar{k}l$, $hk\bar{l}$ and their Friedel equivalents are equal. If by chance a monoclinic crystal has $\beta \approx 90°$, it can be mistaken for an orthorhombic, but Laue symmetry will show the error.

Friedel's law is valid only if every atom in the structure scatters X rays with the same phase change of 180°. However, if the frequency of the incident radiation is close to the natural absorption frequency of an atom, then an anomalous phase change occurs. Thus the atomic scattering factor, which has been regarded in equation (9) as a real number, is strictly a complex number of the form

$$f_j = f_o + \Delta f' + i\Delta f'' \tag{15}$$

where the real ($\Delta f'$) and imaginary ($\Delta f''$) correction terms are (unlike f_o) wavelength-dependent, but to a first approximation independent of θ (again unlike f_o). They are significant for heavy elements and particularly near the absorption edges, in which cases $I(hkl)$ and $I(\overline{hkl})$ of noncentrosymmetric crystals can be significantly different. Bijvoet was the first to show that this effect, known as anomalous scattering or anomalous dispersion, can be used to determine the absolute configuration of crystal structures and therefore of chiral molecules,[35] as well as to solve the phase problem for a noncentrosymmetric crystal.[36] The latter proved very useful for determining protein structures.[37] Since anomalous scattering is wavelength-dependent, so will be the reflection intensities of a protein crystal that contains anomalously scattering atoms naturally (e.g. Fe, Zn) or has them artificially introduced into the molecule (e.g. replacing Ca with Tb, S with Se). If the diffraction data at two or more different wavelengths are measured, phase angles can be determined either algebraically or by first locating the anomalously scattering atom by the anomalous difference Patterson method or second-generation direct methods. Although the idea of this 'multi-wavelength anomalous dispersion' (MAD) method has been suggested long ago,[38] it became widely practiced only in 1990s with the development of synchrotrons (where λ can be changed freely), as well as improved theory[39] and software.[40]

Anomalous scattering also occurs in neutron diffraction, several nuclei (^{113}Cd, ^{149}Sm, ^{151}Eu, ^{157}Gd, and ^{239}Pu) showing

a large wavelength-dependent effect. It also has been used to solve the phase problem by MAD technique.[41]

Another manifestation of the crystal symmetry are systematic absences, or ‘extinctions’, of reflections that apparently satisfy Bragg’s law. If the crystal lattice is not primitive, some reflections of the general type (i.e. with nonzero h, k, and l) are systematically absent. Specific absences along certain lattice directions indicate the existence of screw axes or glide planes in the crystal (Table 2). Systematic absences are valuable for determining the space group of a crystal. Because nontranslational elements of symmetry do not cause any systematic absences, only 63 out of 230 space groups can be unequivocally determined in this way. Additional information can be obtained from the distribution of reflection intensities, which is different for centrosymmetric and noncentrosymmetric structures, the former giving a relatively higher number of weak reflections than the former.[42] This method is fairly reliable but inconclusive, because of its probabilistic nature, and only a successful refinement of the structure gives the final proof of the correctness of the space group assignment.

2.2.3 *Effects of Thermal Motion*

The calculation of the structure factor in equation (8) assumes all atoms to be at rest in the positions corresponding to perfect crystal symmetry. In fact, atoms and molecules perform thermal vibrations and sometimes are statically disordered, that is, shifted from ideal positions, differently in different unit cells. Both effects disturb the long-range periodicity of a crystal and thus make it a poorer diffractor. Smearing of the electron distribution of an atom due to thermal vibration effectively reduces its scattering factor f_j, so that it drops faster with $\sin\theta/\lambda$ than the corresponding curve for a stationary atom (f_o), as shown in Figure 7. The decrease is described by an exponential temperature, or thermal, factor Q:

$$f_j = f_o Q = f_o \exp\left(-\frac{B\sin^2\theta}{\lambda^2}\right) \tag{16}$$

where B is related to the mean-square amplitude U of the atom’s vibrations

$$B = 8\pi^2 U \qquad U = \overline{u}^2 \tag{17}$$

Here the atom is assumed to vibrate with isotropic amplitude in all directions. As atoms in crystals seldom have isotropic environment, their displacements can be better approximated[43] by an ellipsoid, that is, a symmetrical tensor **U** with six independent components U_{ij}:

$$\mathbf{U} = \begin{pmatrix} U_{11} & U_{12} & U_{13} \\ U_{12} & U_{22} & U_{23} \\ U_{13} & U_{23} & U_{33} \end{pmatrix} \tag{18}$$

such that the mean-square amplitude of vibration in a direction of a vector **l** with components l_1, l_2, l_3 is

$$\overline{u}^2 = \sum_{ij} U_{ij} l_i l_j \tag{19}$$

In this case the temperature factor also becomes anisotropic, that is, reflections are weakened unequally in different direction. Historically, three different representations of anisotropic temperature factor have been used in the literature,[32,44] namely,

$$Q = \exp[-(h^2\beta_{11} + k^2\beta_{22} + l^2\beta_{33} + 2hk\beta_{12} + 2hl\beta_{13} + 2kl\beta_{23})] \tag{20}$$

$$Q = \exp[-1/4\{h^2B_{11}(a^*)^2 + k^2B_{22}(b^*)^2 + l^2B_{33}(c^*)^2 + 2hkB_{12}a^*b^* + 2hlB_{13}a^*c^* + 2klB_{23}b^*c^*)] \tag{21}$$

$$Q = \exp[-2\pi^2\{h^2U_{11}(a^*)^2 + k^2U_{22}(b^*)^2 + l^2U_{33}(c^*)^2 + (2hkU_{12}a^*b^* + 2hlU_{13}a^*c^* + 2klU_{23}b^*c^*)] \tag{22}$$

Parameters B_{ij} and U_{ij}, like the isotropic temperature factor, are expressed in Å^2, while β_{ij} are dimensionless. The accepted standard now is to report U for the isotropic model (U_{iso}) and U_{ij} for the anisotropic one.[45]

At ambient temperature, it is usually impossible to discern the smearing caused by thermal vibrations (averaged over time) from that caused by static displacements of atoms (averaged over the whole crystal), and the ‘vibrational parameters’ in fact account for both. Therefore it is now recommended to use the term ‘atomic displacement parameters’ (ADP) instead. A diffraction study of the same structure at different temperatures, however, will show the difference: the genuine thermal vibrations diminish on cooling, but the ADP due to static disorder (e.g. in ferrocene[46]) will remain large.

The mathematics of the temperature factor are described fully elsewhere.[32,43] Some notes of caution are necessary. The terms ‘temperature factor’ and ‘thermal vibration parameters’ are often used as synonyms. In fact, the former applies to diffraction intensities (and reciprocal space) and the latter to actual atomic motion (and direct space). Both are expressed by tensors/ellipsoids, but these are Fourier images of one another. It also must be emphasized that *separate* components U_{ij} have no physical meaning on their own and cannot be directly compared.[47] Graphically, ADP are usually presented in the form of a ‘thermal ellipsoid’, defined as a surface, inside which the vibrating atom’s center can be found with a certain probability.[48] Most commonly, the ellipsoids are drawn at a 50% probability level. Their shape provides a good visual indication of the anisotropy of thermal motion. The principal semiaxial lengths D of an ellipsoid are proportional to the root-mean-square displacement (RMSD) in the corresponding directions,

$$D_x = c\sqrt{\overline{u}_x^2},\ D_y = c\sqrt{\overline{u}_y^2},\ D_z = c\sqrt{\overline{u}_z^2} \tag{23}$$

(where $c = 1.5382$ for 50% probability), its dimensions in any other direction have no definite meaning. A surface

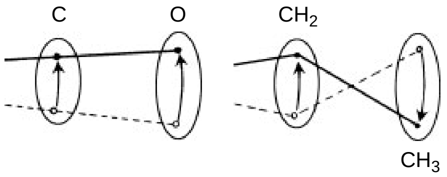

Figure 8 Vibrations of a rigid (CO) and a flexible (ethyl) groups: similar thermal ellipsoids can conceal different types of motion

duly representing RMSD components in all directions is not an ellipsoid but a quadric surface, resembling the shape of a peanut.[49] This presentation proved useful in analyzing thermal motion. A covalently bonded atom vibrates mainly in perpendicular direction to the bond. In a molecular crystals vibrations of a molecule as a whole are usually far more significant than intramolecular modes.

When atomic displacements are large, systematic errors can be introduced into the derived bond distances and angles associated with the strongly vibrating atom. Note that atomic motions discussed above are measured relative to the crystal lattice. Bragg reflections contain no information whatsoever about motion of atoms relative to each other. Knowing the ADP of two atoms, one cannot tell (without some external information) whether the atoms vibrate in phase or not (Figure 8). The measured bond lengths are in fact the distances between average positions of atoms. If, for example, atom A makes rotational oscillations (librations) around atom B as a center (Figure 9), its average position $\overline{A}$ lies inside the arc A′A″ and the bond AB is apparently shortened.[50] Although techniques[50,51] (and software[52]) for correcting these errors are available, they always require certain assumptions about correlations between atomic motions, that is, rigidity of the molecule or group under investigation. One must keep in mind that these assumptions originate from the model and not from the experiment.[53] Therefore the best way to avoid these systematic errors is to reduce the thermal motion itself, by carrying out the experiment at as low a temperature as possible. This is even more important in accurate electron density studies.[54,55] Only this way one can be certain that any anisotropy of electron distribution[56] is not caused either by inadequate corrections for all systematic errors or poor modeling of the displacement parameters.

2.3 Generation of X rays and Neutrons

2.3.1 Generation of X rays

X rays can be produced either (i) by sharp deceleration of fast-moving electrons, or (ii) by ionizing collisions of these electrons with atoms of a suitable (metallic) target. Process (i) gives a continuous 'white' spectrum (because the energy of a free electron is not quantized), whilst (ii) gives narrow *characteristic lines*. The latter occur when the energy

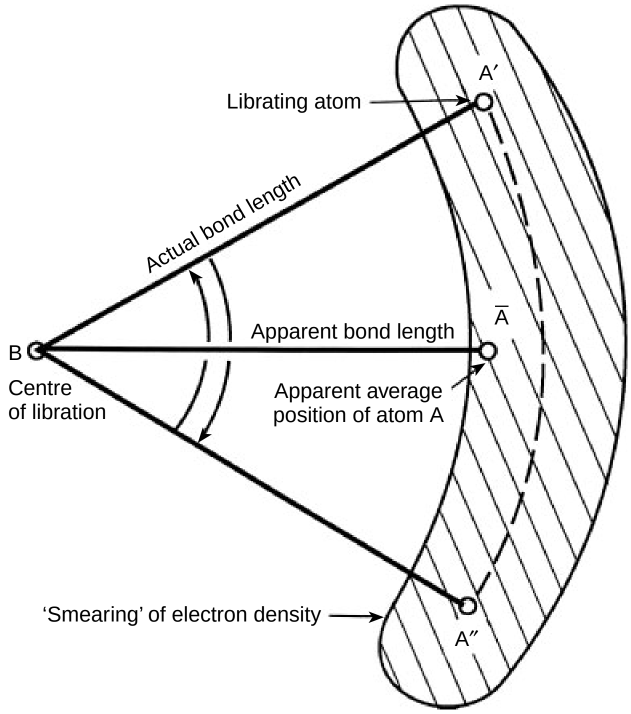

Figure 9 Apparent bond shortening in a librating group

of the colliding electron exceeds a certain limit (*threshold potential*), permitting it to knock another electron out of an interior electron shell of the atom. The vacancy created is then filled by a descent of an electron from a higher shell, and the released potential energy is emitted as nearly monochromatic radiation. The characteristic lines are called K, L, and M, after the electron shells (quantum numbers $n = 1$, 2, and 3) from which the electron is knocked out, with subscripts α or β indicating whether the vacancy is filled from the nearest shell or from the next higher one, respectively. Thus, the K_α line is emitted by a $L \rightarrow K$ transition and the K_β line by a $M \rightarrow K$ one. Because transition can occur from two electron configurations, slightly different in energy, both α and β lines are close doublets comprising $\alpha 1$, $\alpha 2$ and $\beta 1$, $\beta 2$ lines. The $\alpha 1$ line is about twice as intense as $\alpha 2$ and three to six times stronger than $\beta 1$, whilst $\beta 2$ is usually very weak. The characteristic wavelengths are constants of a given element. The lines commonly used in crystallography are Cu-K_α and Mo-K_α, with $\overline{\lambda}$ (the average λ of the $\alpha 1$–$\alpha 2$ doublet) of 1.54178 and 0.71073 Å, respectively. Radiations from Cr, Fe, Co, Ni, Ag, and W targets have limited application for special purposes.

The most common laboratory source of X rays is a sealed X-ray tube, that is, a glass (or ceramic) vessel with a metal base, in which under conditions of high vacuum a beam of electrons is created, accelerated by an electric potential of 30 to 60 kV and focused onto a target of one of the abovementioned metals, thereby producing X rays which leave the tube through a beryllium window. When electrons bombard the target, both

processes (i) and (ii) take place, producing an X-ray spectrum such as shown in Figure 10(a). X rays are emitted randomly in all directions; however, diffraction experiments require a parallel beam of monochromatic (unless Laue method is used) radiation, preferably focused. Neither can be achieved, as in light optics, by prisms, lenses, and so on, because refractive indices of X-ray radiation for all materials are very close to 1 and practically independent from the wavelength. X rays of a required wavelength (strictly speaking, of a narrow range of wavelengths) are selected using a crystal-monochromator or a β-filter. The former is a crystal, oriented in such way that the Bragg condition is met for the wavelength of the K_α line and the direction of the diffracted beam of a *very strong* reflection pointing toward the sample. This beam is then effectively monochromatic. The common monochromator for laboratory X-ray sources is a specimen of pyrolytic (textured polycrystalline) graphite, which can convert up to 54% of the incident K_α radiation into the monochromatic beam, corresponding to the (0 0 2) Bragg reflection. For *single* crystals of LiF, quartz or Si this parameter (efficiency, or reflectivity) is much lower, for example, 9.4% for LiF, but the monochromaticity of the resulting beam is much better than for graphite. Therefore single-crystal monochromators are used with synchrotron X-ray sources (see below), where some loss of intensity is not a problem. Unfortunately, a monochromator tuned to a wavelength λ will let through also any λ/n, of which $\lambda/2$ is present in X-ray tube radiation, $\lambda/2$ and $\lambda/3$ in synchrotron radiation (SR).

Filter is a thin film of a metal immediately, or closely, preceding the target element in the periodic table, for example, Ni for Cu target, Zr for Mo target. Thus the absorption edge of the filter metal falls between the K_α and K_β lines and effectively removes the latter, but not the white radiation. Filters lose very little of the K_α intensity compared to monochromators, but are inferior to the latter in spectral purity of the resulting beam.

To obtain a parallel beam, the monochromated X rays are passed through a *collimator*, a long metallic tube containing slits with pinholes, which reduces the divergence of the beam and prevents X rays scattered from other parts of the device (secondary scattering) from reaching the detector. Furthermore, only 0.3% of the power of the tube goes into the energy of X rays, the rest into heating the target. Removal of this heat (by circulating water) sets the limit to the power and brilliance of an X-ray tube. These can be improved by an order of magnitude if a stationary target is replaced by a *rotating anode*, a fast-revolving cylinder or cone constantly placing under the electron beam a new area. The anode is rotated by a shaft, entering the tube body through a vacuum seal, and cooled by water running inside the shaft; therefore such tube and (unlike a sealed tube) requires constant vacuum-pumping and frequent maintenance.

Note that collimator does *not* make divergent X rays parallel and hence utilizes only a small fraction of the emitted radiation. The efficiency can be improved, if divergent X rays are concentrated and directed toward the sample. This can be done by *bent* crystal monochromators, or by concave mirrors utilizing total external reflection of X rays at very small incidence angles ($<0.1°$), known as 'grazing incidence'. Both are commonly used with synchrotrons but seldom in laboratory devices. Recently this problem was addressed on a completely fresh basis, by means of polycapillary collimators, known also as 'X-ray lenses'.[57] An X-ray lens is composed of a large number (up to millions) of tapered capillaries (hollow fibers), gently bent to achieve grazing incidence of X rays, which by successive total reflections at the inner walls are guided along the capillaries with a very small energy loss. The curvatures of the capillaries can be arranged such that a divergent beam emitted by the tube is concentrated into a quasi-parallel incident beam of much higher flux. With better utilization of X rays, the focal spot can be made much smaller but also more intense (heat removal being faster from a small spot), drastically reducing the electric power required. Thus, a 60 W microfocal X-ray generator (Bede Microsource®[58]) with X-ray lenses achieves higher brilliance than a conventional sealed X-ray tube of 2 kW power.

The most powerful sources of X-ray radiation are synchrotrons,[59–61] that is, accelerators of charged elementary particles operating in s stationary (storage-ring) mode. Within the ring electrons (or sometimes positrons) circulate with ultrarelativistic (close to the speed of light) velocity along a closed-loop orbit inside an evacuated ring chamber. The electron beam is guided along the loop by *bending magnets* (magnetic dipoles) placed at equal intervals along the ring. A turning of the electron trajectory, like electron deceleration (i) mentioned earlier, generates SR directed tangentially to the trajectory (and therefore already highly collinear). Depending on the energy of the electrons, SR can vary from microwave to γ-rays, including the entire X-ray range. Between the bending magnets the electron beam moves by a straight line, here it is focused by magnetic lenses, that is, magnetic quadrupoles or higher-order multipoles.

Currently there are about 40 operating SR sources worldwide, with another 10 under construction. The circumference of the ring varies from 65 to 1436 m. For example, the European Synchrotron Radiation Facility (ESRF) in Grenoble (France), opened in 1994, has the circumference of 844 m with 64 bending magnets and 27 straight sections, and the working energy of 6 GeV. The first-generation synchrotrons, built in 1960s, were intended for high-energy particle physics research, X rays being a 'parasitic' by-product, and had the brilliance of 10^9 to 10^{12} photon s^{-1} mm^{-2} rad^{-2} (0.1% BW)$^{-1}$. Synchrotrons of the second generation (built in 1980s) were often specialized for SR production ('dedicated sources'). They achieved the brilliance of $10^{12}–10^{15}$, which in the third generation (1992–1999) was increased to $10^{18}–10^{23}$, thus exceeding the brilliance of conventional X-ray tubes by a factor of $10^8–10^{14}$. The straight sections of third-generation synchrotrons are equipped with special magnetic devices (undulators and wrigglers, jointly known as insertion devices),

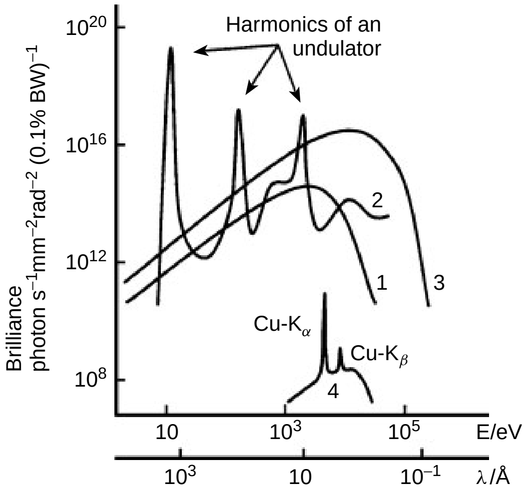

Figure 10 Spectral distribution of X-ray radiation generated by bending magnet (1), undulator (2) and wiggler (3) of a synchrotron and by a conventional X-ray tube with a Cu target. Brilliance and quantum energy are given on logarithmic scales. (Ref. 62. Reproduced by permission of Russian Academy of Science)

which cause the passing electrons' trajectory to oscillate, thus generating SR with enhanced characteristics. Particularly, the operational parameters of an undulator are chosen so as to achieve interference between the radiation emitted on adjacent curved sections of the electron trajectory. Consequently, the spectrum of undulator radiation shows a series of intensity maxima, known as undulator harmonics (Figure 10).

SR makes possible diffraction studies of much smaller or poorly diffracting crystals. It has also the advantage of easily tunable wavelength. However, owing to an imperfect vacuum inside the chamber, the electron beam, and hence the SR intensity, tend to decay with time (until a new portion of electrons is injected into the ring) and the observed reflection intensities must be corrected correspondingly.

2.3.2 Production of Neutron Beams

The practical neutron sources are nuclear fission reactors[62] and spallation facilities.[63,64] In the former, a thermal neutron is absorbed by a ^{235}U nucleus, which becomes excited and splits into medium-heavy nuclei with an emission of 2 to 5 fast neutrons, or on average 2.5 neutrons per fission, of which 1.5 are required to keep the chain reaction going. This leaves one usable neutron with the kinetic energy of about 2 MeV, while *ca.* 200 MeV are released as heat which has to be cooled away. For example, the High Flux Beam Reactor of the Institut Laue Langevin in Grenoble produces a flux density of approximately 1.5×10^{15} neutrons cm^{-2} at a thermal power of 62 MW. Usually the reactor operates in a 'steady state', producing a constant flux of neutrons, although some pulsed reactors have been constructed (IBR-2 in Russia).

Spallation is a process whereby a heavy metal target (of U, Ta or W) is bombarded by a stream of high-energy (typically 1 GeV) protons, accelerated in a proton synchrotron. A complex cascade of processes then yields ca. 20–25 neutrons per incident proton, besides other particles such as pions, muons, neutrinos, and protons. Most neutrons have energies of a few MeV, although for a small minority it can be as high as hundreds of MeV. While a spallation source is inferior to a fission reactor in the *total* output of neutrons, these are generated in a much smaller volume and therefore can give a more concentrated beam. Normally a spallation beam is pulsed (typical frequency 24 to 50 MHz) with the peak intensity comparable to that of a high-flux reactor. A continuous spallation source also exists (SINQ, Switzerland).

The energy E, wavelength λ and velocity v of a neutrons are related as

$$E = \frac{h^2}{2m\lambda^2} = \frac{C}{\lambda^2} \qquad \lambda = \frac{h}{mv} \qquad E = h\nu \tag{24}$$

where h is Planck's constant, m is the mass of a neutron (1.6749×10^{-27} kg) and $C = 81.799\,\mathrm{meV\,Å^{-2}}$. Neutrons are classified into cold ($E \le 10$ meV), thermal ($E \approx 25$ meV), hot ($E \ge 100$ meV), and epithermal ($E > 0.6$ eV). Diffraction experiments (and most other solid-state studies) require thermal neutrons, which have wavelengths of 1.5–2.0 Å (and $v \approx 2200\,\mathrm{m\,s^{-1}}$). Therefore neutrons emitted from a reactor or a spallation source must be slowed down in a *moderator*, where they are brought into thermal equilibrium through inelastic collisions with light atoms (e.g. H, D, or Be) and acquire an energy spectrum approaching Maxwellian distribution (Figure 11). The distribution can be shifted to lower or higher energies by using a low-temperature moderator (e.g. a vessel with liquid CH_4, H_2 or D_2) or a high temperature

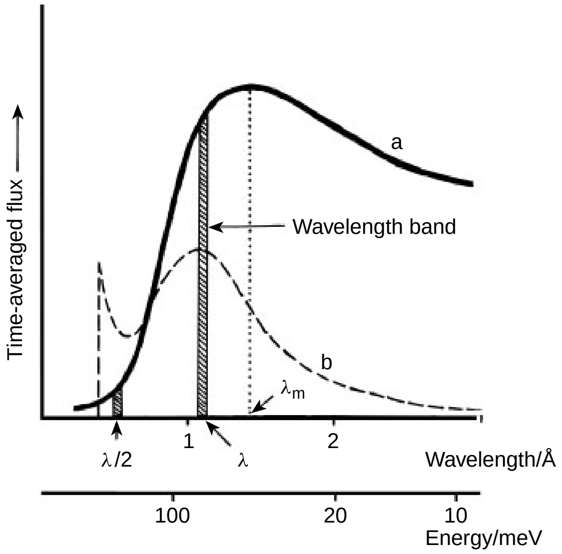

Figure 11 Spectral distribution of neutrons: (a) thermal neutrons from a moderator (showing the wavelength band isolated by monochromatization), (b) pulse spectrum in a TOF machine

one (e.g. a graphite block maintained at ca. 2000 K), known as ‘cold source’ and ‘hot source’, respectively.

Monochromatic neutron radiation is obtained using beryllium, copper or germanium single crystals as monochromators (in the same way as for X rays). Usually the wavelength extracted is chosen not at the intensity maximum (λ_m) but at $\lambda < \lambda_m$, in order to minimize $\lambda/2$ contamination (see Figure 11(a) and Section 2.3.1). In any case, monochromatization can utilize only 1% of thermal neutrons owing to their ‘white’, featureless spectrum; the rest are wasted. The alternative technique, similar to Laue method in X-ray diffraction, uses the widest possible range of λ, that is, the diameter of the Ewald sphere is varied to obtain a reflection. It requires distinguishing of neutrons of different wavelengths and knowledge of their spectral distribution, which is done in practice by sending short pulses of polychromatic radiation toward the sample by a long tube. As neutrons of different λ differ also in velocity (equations 24), they become segregated during the flight and can be identified according to the time of arrival to the detector. This method is therefore known as the ‘time-of-flight’ (TOF) technique.[63–65] The pulses can be obtained from a constant neutron source (a reactor) by interrupting the beam with a ‘chopper’, but the intrinsically pulsed (spallation) sources are most suitable for TOF experiments. In the latter case, the neutrons are moderated less (to avoid extending the time of the pulse) and retain a substantial higher-energy component (Figure 11(b)).

Neutron beams can be focused by mirrors or transmitted by long *curved* tubes (beam guides) using the effect of grazing reflection (see above) in both cases.

2.4 Detection of X rays and Neutrons

In a modern diffraction experiment it is necessary to measure both the directions of diffracted beams with the precision of a few hundredths of a degree *and* their intensities (which can vary by many orders of magnitude!) with the precision of about 1%. A good detector should have high spatial resolution, and be sensitive even to single quanta of diffracted radiation but also able to measure strongest reflections without ‘overflow’ or radiation damage. It should be a ‘proportional counter’, that is, with linear dependence between the beam intensity and the output signal in the whole range. This requires low inherent background (noise) and short dead time of the detector, whose behavior should be stable over time and uniform over its whole working area. Besides counting the *number* of radiation quanta, the detector should be able distinguish their energy (or λ), both to discriminate against parasitic radiation of different λ and to extract positive information in polychromatic methods (energy resolution, or spectral resolution). Finally, the output of a modern detector must be in electronic (digital) form, suitable for computer processing.

2.4.1 X-ray Detectors

The main classes of X-ray detectors are: (i) photographic films (plates), (ii) point detectors, and (iii) position-sensitive detectors (PSDs). AgBr based films react to X rays in much the same way as they do to light. They were used in the first X-ray diffraction experiment (1912) and remained the only practical means until the spread in 1960s and 70s of automated diffractometers equipped with scintillation detectors. A variety of X-ray methods (rotation, precession, and Weissenberg) and corresponding camera designs have been invented.[16–18] The reflection intensities were estimated by measuring the darkening of the film (optical density), at first visually and then by microdensitometers.[66] Photographic methods are slow and labor-intensive and have inherent problems of limited dynamic range and nonlinear response. Since ca. 1980, they have been used only for educational purposes and preliminary investigation of crystals, and recently have been superceded to a large extent even there by area detectors.

On the contrary, a point detector has a window $\leq 1°$ wide and therefore can measure diffraction intensity only in one direction (at a single point of the reciprocal space) at a time. Therefore, crystal and detector must be moved in a predetermined manner during the experiment. This is done by a four-circle diffractometer (Figure 12), an automated computer-controlled machine with four independently rotating axes (‘circles’). A goniometric head with the crystal attached is mounted on the shaft of the φ circle, whose carriage moves along the ring-like χ circle, the (imaginary) axis of which is always horizontal. This entire block is rotated on the vertical axis ω, while θ (or 2θ) axis moves the arm on which the detector is placed. All axes and the primary beam from the X-ray source intersect (with a precision of ≤ 0.02 mm) in the same point, called optical center of the diffractometer. The crystal, if properly aligned, remains centered in this point during any rotation. The ω and θ axes are driven by separate step-motors, while the φ and χ rotations are performed by one motor through two ring pinions located inside the χ circle and enclosing the φ shaft between them, so that an opposite rotation of the pinions spins the φ shaft and a similar rotation moves the φ carriage along the χ circle. All circles can be positioned with high precision, 0.01–0.02°.

In principle, rotations around *three* axis (one of them θ) would be sufficient to bring any lattice plane into an orientation satisfying the Bragg condition (see above) and to intercept the resulting diffracted beam with the detector. However, the fourth degree of freedom makes possible an ‘azimuthal scan’ of a reflection, during which the plane remains in a reflecting position but the crystal rotates around the normal to this plane (so-called ψ axis).

Alternatively, four-circle diffractometer can have a κ (kappa) geometry, in which the χ circle is replaced by two arcs, one of which (‘ω block’) rotates around the vertical ω axis and the other (‘κ block’) around the κ shaft, mounted on the ω block (Figure 12). The κ and ω axes always form the ‘magic angle’ $\alpha = 54°$. Note that in either geometry, every

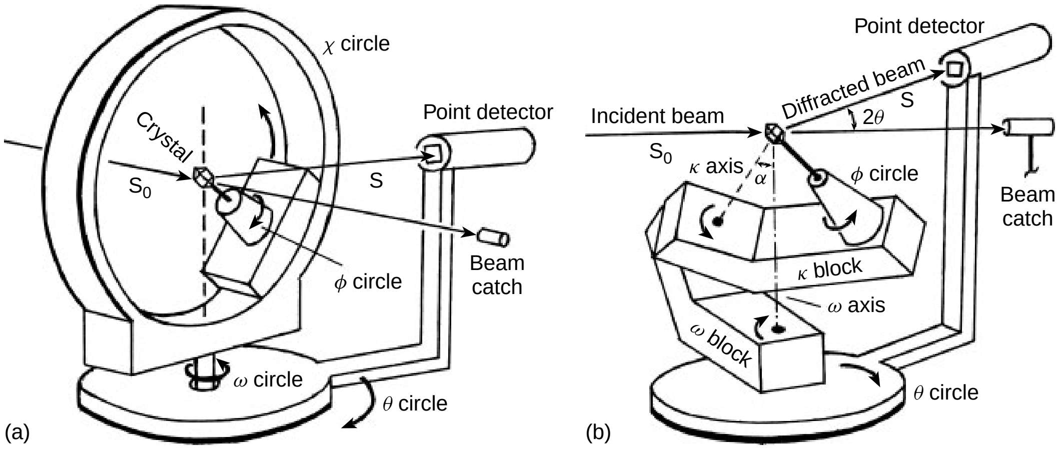

Figure 12 Scheme of a four-circle diffractometer: (a) conventional geometry, (b) κ (kappa) geometry

reflection must be brought into the horizontal (equatorial) plane, in which the counter moves.

Three successive generations of X-ray point detectors have been developed, namely,

- *Gas ionization counters* (classified into ionization chambers, proportional counters, and Geiger-Muller counters) consist of a chamber filled with gas (usually Ar or Xe) and containing a pair of electrodes with a potential difference. Ionizing the gas, X rays produce an electric discharge between the electrodes, proportional to the number and energy of the quanta. Historically the first point detector, which was mounted on a primitive hand-driven diffractometer, was used by Bragg in 1913. Ionization chambers are used today only for primary beam monitoring, being suitable for very high X-ray intensities.
- *Scintillation counters*, wherein X-ray quanta are absorbed in a fluorescent material (usually a Tl-doped NaI or CsI crystal, protected from outside by a Be foil) and converted into light (visible or UV) photons, which are converted into electric pulses and amplified by a photoelectronic multiplier tube, connected to the scintillator through a smear of optical grease. Their comprehensive description can be found in Reference.[15]
- *Solid-state (semiconductor) detectors* are similar in their operational principle to ionization chambers, with the gas replaced by a semiconductor crystal (e.g. silicon or germanium doped with lithium, high purity Ge, CdTe, or HgI_2) in which passing X-ray photons generate electron-hole pairs. This requires only a few eV (compared to tens of eV in a gas), hence such detectors have high sensitivity and energy resolution ca. 15 times higher than scintillation ones. They are closer to being ideally proportional counters than any other type.

Semiconductor detectors have supplanted all other point detectors during 1980s, soon to be superseded by *position-sensitive detectors* (PSDs) alias *area detectors*, which can measure simultaneously all diffracted beams reaching an extensive surface, thus combining greatly increased speed of the experiment with the visual obviousness of a diffraction photograph and the precision equal to (or higher than) that of a modern point detector. The earliest PSDs were developed (since 1970s) for neutron diffraction (see below)[67] and protein crystallography,[68] where respectively the scarcity of source time and the large size of unit cells (and hence of reflection numbers) made the slowness of measuring one reflection at a time particularly vexing. Operating a PSD requires much more complex data analysis and handy electronic storage of vast amounts of data, severely taxing the IT of the time. However, since the mid-1990s PSDs were applied increasingly to small-molecule X-ray crystallography and currently became standard laboratory devices, thanks to major advances in computer technology and recent tremendous decrease in data storage costs. Since the development impetus came from protein crystallography, all early X-ray PSDs were designed for Cu-K_α radiation, but in the last few years, instruments optimized for Mo-K_α radiation (which is normally used in inorganic X-ray crystallography) became commercially available.

The first practical PSDs were the multiwire proportional counter[69] and the television-camera area detector (TVD).[70] The former is a large flat gas-filled chamber, containing a planar anode sandwiched between two planar cathodes. The anode consists of an array of parallel wires, and one of the cathodes of similar wires at a right angle with the former. A passing X-ray photon ionizes the gas (Xe is used for Cu-K_α radiation) and causes an electric discharge between *certain wires*, whose intersection gives the place of its arrival. This method was never much used in X-ray chemical crystallography, but is important in neutron studies.

In a TVD, X rays are converted by a fluorescent phosphor (gadolinium oxysulfide or ZnS) into visible light, which is amplified by an image intensifier (essentially a second phosphor) and detected by the photocathode of a high

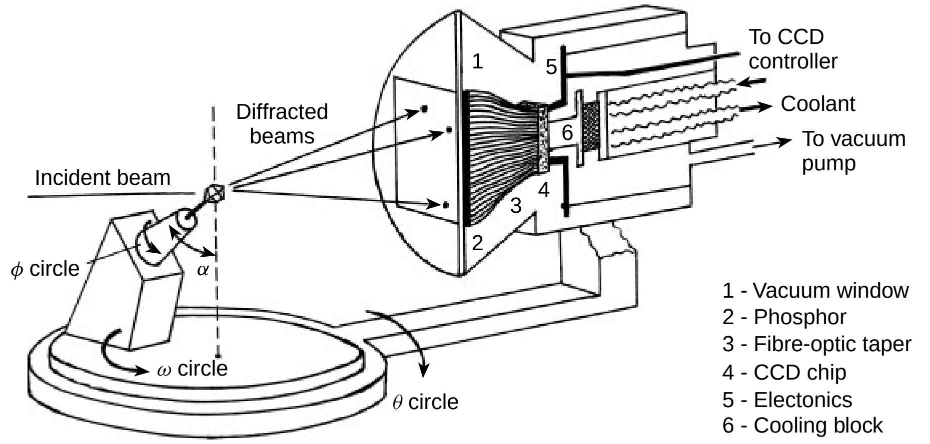

Figure 13 Scheme of a CCD area detector

sensitivity television camera. This scheme had been used in the single-crystal diffractometer FAST commercially manufactured by Enraf-Nonius in the 1990s, but was abandoned because image intensifiers proved expensive, delicate, and error-generating.

Today, two classes of PSD have proven their superiority and have practically replaced other detectors: imaging plates (IP)[71] and charge coupled devices (CCD).[72] IP's sensitive layer (ca. 150 µm thick) consists of a 'storage phosphor', that is, very fine particles (ca. 5 µm) of amorphous BaFBr or BaF(Br,I) doped with Eu^{2+}, bound by an organic binder. X rays 'photo-stimulate' the phosphor, by causing oxidation of Eu^{2+} to Eu^{3+}. The released photo-electrons are caught by halide vacancies and form color centers (so-called F-centers), which comprise a latent image of the diffraction pattern. This image can be displayed by irradiating the plate with a He–Ne laser beam, which causes an electron in a color center to reduce Eu^{3+} back to Eu^{2+}, with an emittance of blue (390 nm) fluorescent light (so-called poststimulated luminescence).

IPs possess all the advantages of photographic films, that is, high quantum efficiency, good linearity, and (being integrating devices) no dead time limitations. They are available in large sizes and relatively inexpensive. The spatial resolution (which depends on the size of the phosphor grains) is better than that in any other device currently available. The latent image can be stored for fairly long periods of time ($t_{1/2} \approx 10$ h), but usually the plate is processed immediately. In a read-out device, an IP is scanned, in a record-player like manner, by a fine laser beam and a photosensitive reading head. The image is then digitized and stored in computer memory. Then the IP is 'erased' by white light and is ready for repeated use. IPs are used with diffraction cameras, similar in geometry to the photographic ones, but the exposure time is incomparably shorter, usually seconds (although the reading-out process takes minutes).

CCD is a high-photosensitivity semiconductor chip, in which visible-light photons generate electron-hole pairs; the electrons are trapped in potential wells and then read out as electric current. CCDs were originally developed for astronomic observations and similar devices are now used in video cameras. The front of an X-ray CCD detector (Figure 13) is a thin protective layer of beryllium metal; behind it lies the phosphor of Tb-doped Gd_2O_2S, which transforms X rays into light photons. The light from different points of the phosphor sheet is conducted through a taper of optical fibers to the CCD chip of smaller area ('demagnification'). This process inevitably introduces spatial distortions, which must be calibrated on installation and whenever any alterations are made in the detector. In the latest generation of CCD detectors the taper is eliminated and the chip is connected directly to the phosphor. In the first commercially available X-ray CCD detectors, the chip had 1024×1024 sensitive points (pixels). Later this number was increased to 4096×4096. These detectors have efficient recording, a high dynamic range, and a read-out time measured in seconds. However, the CCD has high intrinsic noise owing to thermal excitation of electrons (even in the absence of any incident radiation) and therefore must be operated at low temperature (typically, 193 to 228 K) to achieve a low noise level. The next few years are likely to see the introduction of so-called 'pixel arrays', another form of solid-state detectors which should be able to record X rays directly, that is, without conversion into visible light, and over a larger area.

The use of area detectors requires much less crystal movement to access all reflections, hence the four-circle diffractometer geometry is no longer necessary. Thus, a CCD detector is usually mounted on a 2θ arm of a three-circle diffractometer, the χ circle is eliminated which inter alia gives considerably more freedom for attachments like low-temperature devices or high-pressure cells. Instead the φ block is mounted rigidly on the ω circle, so that the φ axis forms the 'magic' angle (54°) with the vertical. During a data collection, the reciprocal space is scanned by rotating the ω axis by a small constant steps (commonly, 0.3°), while other circles remaining stationary. During each step the detector

accumulates the signal, which is then stored on a computer disk as a 'frame'. The procedure ('run') can be repeated with the φ (and possibly 2θ) circle repositioned. The entire accessible area of the reciprocal space can be covered by a few such runs. When the crystal is mounted in a capillary (see below), it is preferable to perform φ scans while keeping the ω circle stationary.

2.4.2 Neutron Detectors

Neutrons are extremely penetrating and therefore both dangerous to personnel and difficult to detect. Neutron instruments are designed on broadly the same principles as their X-ray counterparts, but are of much greater size and bulk. This is largely due to the need of extensive shielding, in order to stop or slow down the fast neutrons and γ-rays. For shielding, the same materials are used as those employed in moderators or detectors. Cadmium metal captures neutrons very efficiently, but unfortunately produces equally dangerous γ-radiation in the process.

Unlike X rays, neutrons can be detected only by being 'killed', hence the detectors exploit certain neutron capture reactions. The early type of point detector was a gas-filled proportional counter containing pressurized ^{3}He or BF_3 enriched with ^{10}B, in which the absorbed neutron produces charged particles that ionize the gas. The emitted electrons are accelerated and in turn ionize more gas.[15,62] The charge obtained at the high-voltage anode wire is proportional to the reaction energy, which makes these counters extremely efficient for detecting thermal neutrons and discriminating against γ-radiation.

Scintillation detectors are composed of a glass or a plastic front plate loaded with ^{6}Li and ZnS. These absorb neutrons and in so doing create electronic excitations which decay through emitting light photons. The latter are channeled by light guides into photomultiplier tubes. Although they were originally introduced as point detectors, large scintillation detectors can be used as area detectors; with fast electronics, high count rates can be accommodated.[67b] This type of detector is particularly suited for neutron time-of-flight experiments with a pulsed source, and has found application at the ISIS neutron facility (Rutherford and Appleton Laboratory, Chilton, UK).

As already mentioned, area (or position sensitive) detectors were first developed for neutron crystallography, since neutrons are scarce and expensive and it is important both to shorten the experiment and to use all neutrons scattered by a sample in various directions, rather than waste all but one reflection at a time. Besides 2D scintillation detectors, there are 'banana' 1D multiwire detector[67b] and 2D detectors with two mutually perpendicular sets of parallel wires. The latter design is useful for time-of-flight experiments because of ideal time resolution: once an ionization discharge induces current in one or more wires, we instantly know both the place *and* time of its arrival.

3 APPLICATIONS OF THE TECHNIQUES

3.1 Choice of the Technique

The major decisions to be taken are the choice of single-crystal versus powder technique, of the radiation type, and of temperature. Of course, in practice this is often a matter of expediency rather than choice. Thus, all the techniques described above require single crystals. Obviously, if none are available but only microcrystalline powders, a powder diffraction method seems the only route to follow. Although significant advances are being made in solving crystal structures *ab initio* from powder data[73] (*see* ***Solids: Characterization by Powder Diffraction***), this route is much more expensive in human and computer time, limited in terms of the complexity of the structure (i.e. number of independent atoms) that can be solved, and less certain in outcome than the single-crystal technique, and should be resorted to only after all attempts to obtain a single crystal have failed.

Since neutrons are an infinitely more expensive and limited resource than X rays, all neutron beam allocation committees normally require that an X-ray determination of the structure has already been completed and that the experiment represents one of those tasks that can be solved *only* by neutron diffraction, such as

1. locating hydrogen atoms with precision, especially in the presence of heavy atoms (e.g. in transition metal hydrides);[74]
2. distinguishing between real crystal symmetry and pseudosymmetry created by the arrangement of heavy atoms;[75]
3. distinguishing between heavy elements with close atomic numbers;
4. studying magnetic properties of the materials (neutrons have a magnetic moment);[76,77]
5. studying structural dynamics, using inelastic scattering of neutrons (the latter exchanging energy with the structure);[77,78]
6. real-time studies of transient phenomena, for example, solid-state chemical reactions, phase transitions, and morphology transformations, and particularly of thermally stimulated processes ('thermo-diffractometry').[62,64]

Tasks 1–3 rely on the fact that neutron (unlike X-ray) scattering does not correlate directly with the atomic number and therefore heavy atoms no longer dominate the diffraction pattern; 4 and 5 also depend on intrinsic properties of thermal neutrons, but require special experimental settings, distinct from ordinary diffraction studies. Task 6 requires a combination of a high-flux neutron source *and* a PSD, so that a complete (powder) diffraction pattern can be recorded simultaneously within minutes.

In 1970s and 1980s, neutron diffraction was regarded an indispensable step in a charge density study, but this is no

longer the case (see below).[52,54] Neutron radiation is also used for powder diffraction and Rietveld analysis[77] (*see* ***Solids: Characterization by Powder Diffraction***).

Another limitation of the neutron technique is that it generally requires much larger single crystals than X-ray studies, which are not always possible to grow. However, this is changing with the introduction of new generation of neutron area detectors.

X-ray SR, because of its high intensity, enables crystallographers to obtain meaningful data from samples which are too small or weakly diffracting to be studied with a laboratory source. However, synchrotron beamtime is also a scarce resource.

The choice of X-ray wavelength λ is guided by a number of (often conflicting) considerations. In laboratory conditions, this choice is usually restricted to two characteristic wavelengths, from X-ray tubes with Cu-anode (1.54178 Å) and Mo-anode (0.71073 Å). The intensity of X-ray scattering is proportional to λ^3 (equation 7), hence the former will give 10 times more diffracted intensity from the same sample. On the other hand, long-wavelength X rays are almost always absorbed more strongly than short-wavelength (except in the rare cases when the latter wavelength falls under the specific absorption band of some sample element). Not only does this reduce the overall intensity of the recorded reflections, but the *relative* intensities are distorted, sometimes drastically (if the crystal shape is very anisotropic and heavier elements are present). The latter can seriously hinder structure solution and refinement. Furthermore, the absorbed X-ray energy goes into heating the crystal and may cause its chemical deterioration.

A longer λ is preferable when unit the cell parameters are very large, in order to facilitate the resolution of adjacent reflections. This is one of the reasons why Cu radiation is preferable in protein crystallography, where the unit cell dimensions are generally large. In inorganic chemistry this problem seldom occurs, except for some metal clusters, which are unsuitable for Cu radiation anyway, owing to its strong absorption. On the other hand, the shorter the wavelength, the more reflections will appear on an area detector of a constant size, and the higher order of reflections can be measured with the same experimental setting.

Anomalous X-ray scattering (Section 2.2.2) is a specific property, but generally it increases with λ and with atomic number Z. The difference may be significant if an absolute configuration of the compound is to be determined. With Mo radiation, it is hopeless to attempt such determinations unless atoms with $Z \geq 15$ are present in the sample. With Cu radiation, even anomalous scattering of oxygen is sometimes sufficient to effect discrimination.

Finally, X rays of a certain λ can specifically excite X-ray luminescence of the sample. Thus, Cu-K_α line will excite iron atoms, and Mo-K_α those of yttrium, producing a strong parasitic background which (unlike Bragg scattering) *does not* decrease with the increase of the Bragg angle – a most unwelcome complication.

As for the choice of temperature, it is always preferable to collect X-ray diffraction experiments at as low temperature as possible, unless the sample undergoes a phase transition on cooling, resulting in its destruction or serious deterioration of quality. The advantages of low-temperature experiment[79] are numerous, including:

- it decreases the atomic vibrations, which both reduce diffraction intensities (especially at high Bragg angles) and cause systematic errors in observed bond distances (see Section 2.1.3);
- it reduces the thermal diffuse scattering (TDS) and extinction – sources of systematic errors in F_{hkl};
- it makes possible data collection from most crystals which would be unstable at room temperature, owing to radiation damage, chemical decomposition (even without irradiation), reactions with air and moisture, or solvent loss;
- it allows both positional (static) and thermal (dynamic) disorder to be more readily identified and modeled.

3.2 Nonambient Conditions

3.2.1 Low Temperatures

The standard device for maintaining the low temperature of the crystal during an X-ray diffraction experiment is an open flow nitrogen gas cryostat, which is required (i) to produce a stream of cold N_2 gas with constant temperature and flow rate, (ii) to convey it to the crystal without obstructing movements of the diffractometer circles, and (iii) to prevent ice forming upon the contact between the N_2 and warm outside air. The ice is highly undesirable, as it provides X-ray reflections of its own, and can damage the crystal and sometimes even the hardware.

In early designs of cryostats,[80,81] the cold gas was obtained by evaporating liquid nitrogen (by a boiling resistor) inside a pressurized Dewar vessel, transferred by an insulated pipe, and delivered through the nozzle placed within <1 cm from the crystal. Inside the pipe (usually just before the nozzle), there are an electric heater to regulate the stream temperature and a thermo-couple to measure it. Although such low-temperature attachments to X-ray diffractometers (Syntex, Enraf-Nonius) were produced since 1970s, smooth running thereof required constant efforts and engineering skills, and was done routinely only in a few laboratories. The main sources of trouble were fluctuations of the flow rate, frequent ice blockages, high consumption rate of liquid N_2 ($2-3\,\mathrm{l\,h^{-1}}$) and impossibility to refill the supply tank without interrupting the experiment. Furthermore, since the N_2 gas was warming up by 20 K or more in the long transfer pipes, the base temperature was impossible to achieve.

These problems were largely eliminated by the principally new Cryostream device,[82] which became commercially available in 1990 from Oxford Cryosystems. In it, liquid

N_2 was pumped from an unpressurized Dewar tank into an electric evaporator, converted there into nitrogen gas, cooled in a heat exchanger by a counterflow of liquid N_2 and delivered to the sample through a very short pipe. This device proved extremely reliable. The consumption of liquid N_2 is low ($0.6\,l\,h^{-1}$) and the supply tank can be refilled without stopping the experiment. Using a stream heater, the temperature can be regulated between 80 and 375 K with a stability of 0.1 K. Icing is efficiently prevented by surrounding the cold N_2 nozzle with an outer warmer one, which conveys dry air at room temperature. However, it is very important to avoid any turbulence between the two streams and between the cold stream and the crystal mount.

Since the Cryostream nozzle is stationary, the angle between the stream and the crystal mount changes as the diffractometer circles move. For a long time such an arrangement was regarded as highly undesirable, because it was a source of systematic errors. Therefore, in the low-temperature attachments to the Syntex (later Bruker) four-circle diffractometers, the nozzle is fixed to the χ circle and remains coaxial with the φ axis, whatever the circle movements. The gas is conveyed to the nozzle through a system of Dewar glass pipes with swivel joints, which provide reasonably free movement about all goniometer axes (but not as free as without them!). To prevent icing, an electrically heated conical deflector is placed below the crystal. However, it has been proven by experience that the advantages of the latter design are not substantial, and hardly compensate for the restricted circle movements and for the loss of cold at each of the swivel joints.

Most importantly, with the new cryostats the sample temperature can be regulated at will (while for the first generation, any alteration of the setting was most undesirable). Combined with the new means of fast and visual monitoring of the diffraction pattern, this opens unprecedented opportunities for in situ, real-time studies, for example of phase transitions.

Using these cryostats, it is possible to grow and study single crystals of substances which are liquid, or even gaseous, at room temperature.[83] The liquid/gas is sealed into a Lindemann tube, which is attached to a goniometric head. The sample is flush-cooled and freezes into a polycrystalline mass, then warmed up to the melting point, until all of it melts except a single powder grain, then very cautiously cooled again. Now the surviving grain serves as the nuclei, from which a single crystal is grown. Such experiments still require more-than-average dexterity and patience, but have been greatly simplified by new cryostats and area detectors.

3.2.2 *Ultralow Temperatures*

The absolute lower limit of cryostats using N_2 is its boiling point of 77 K. Lower temperatures can be obtained using helium as a cryogen, in the following two principally different schemes.

- Closed-circuit cryostats, for example, of the Displex type, were originally introduced for neutron diffraction studies,[84] but later were successfully applied for X-ray studies as well.[85] The crystal is enclosed by three successive thin-walled cans of beryllium metal, the interior of which is evacuated. Circulating He cryogen cools the copper block, on which the crystal is mounted upon a heat-conducting fiber, and hence the crystal itself. Temperatures down to 9 K have been achieved and maintained with high stability.[85] However, the device is large and heavy (several kg) – and it has to be mounted on the χ circle of a diffractometer. This does not matter for neutron diffractometers (which have to be massive anyway), but have precluded wide use of the closed-circuit scheme in X-ray diffractometry. Besides this, the beryllium metal of the cans (i) contributes strong parasitic diffraction, (ii) in nontransparent, hence the crystal has to centered 'blindly' according to the diffraction pattern, and (iii) is highly toxic.
- Open-circuit He cryostats work on the same principle as N_2 cryostats, that is, a stream of cold He gas is blown upon the crystal and then dissipated into the atmosphere.[86] The high cost of He made this scheme unthinkable until the duration of X-ray experiments was drastically reduced by the advent of area detectors, as well as made the access the sample easier (by eliminating the need for the χ circle). The first commercial device (Oxford HeliX, from Oxford Cryosystems) has recently emerged from the prototype stage.[87] It allows experiments at temperatures down to 30(1) K (Figure 14), while successfully addressing the problem of icing. It has the advantage of using He gas (ca. $2\,l\,h^{-1}$ at 200 bar) rather than liquid He, which is very expensive and difficult to handle. The cryostat comprises a small closed-cycle helium refrigerator which is used

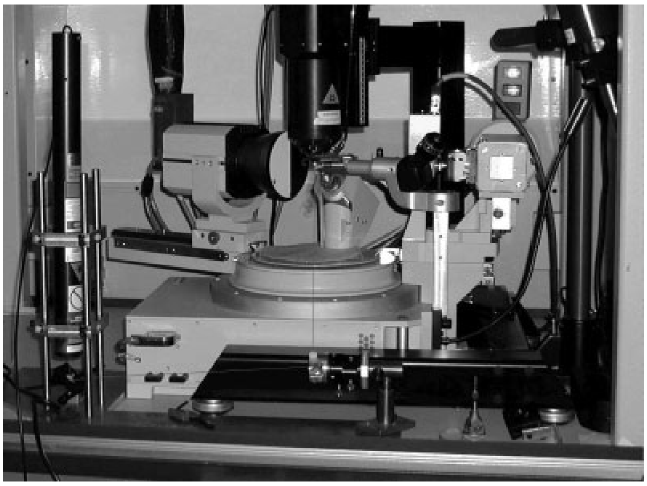

Figure 14 An experimental setting for single-crystal X-ray diffraction study at 30 K, showing a Bruker three-circle diffractometer with a SMART 1000 CCD area detector, a laser device for crystal irradiation and a HeliX open flow helium cryostat in action

to cool down a heating stage. He gas flowing around this stage is cooled down and finally released through a specially designed nozzle onto the sample.

The lowest possible temperatures are essential for

- charge density studies (Section 3.2.8);
- the studies of superconducting material, for most of which the T_c is well below 77 K.

Generally, access to the widest possible temperature range is vital for the study of new materials, where the detailed structure is unknown at certain critical temperatures directly related to changes in physical properties.

3.2.3 High Temperatures

High-temperature crystallography[81,88,89] is a very specialized area of research and will not be discussed here in detail. In the past decade, a large number of novel sophisticated single-crystal heaters[88,89] and corresponding crystal holders[90] have been described. Generally, single crystals can be heated up to ca. 900 °C using gas-flow heaters (either resistance- or combustion-heated) and above that limit by radiative heaters or laser heaters. Moderately high temperatures (up to 500 K) can also be achieved with standard nitrogen cryostats, which permit heating of the N_2 stream.

3.2.4 High Pressures

High-pressure crystallography generally, and diffraction studies (with both X rays and neutrons) particularly, is a nonroutine and traditionally highly specialized area of research, developed by several research groups around the world and (in part) closely associated with industrial, aerospace, and defense applications. X-ray diffraction studies began in 1935 with a modest pressure of 1 kbar (0.1 GPa) achieved between quartz anvils.[91] The real breakthrough came with the development of the diamond anvils cell (DAC)[92] which increased the pressure limit to 1 Mbar, and subsequently to 3 Mbar (300 GPa),[93] thus approaching the ultimate strength of diamond (gem grade). Although high-pressure diffraction is more often carried out on powders, highly sophisticated single-crystal techniques[93,94] have also been developed. In recent years this field has undergone explosive growth, owing to the new possibilities offered by better methods of generation and detection of X rays, and increasingly attracts the interest of the wider crystallographic community.

The operating principle of a DAC is elegantly simple (Figure 15). A gasket of metal foil (usually steel, W or Re) is placed between the diamond anvils. A hole drilled in the center of the gasket contains the sample immersed in a hydrostatic liquid. The anvils are mounted on beryllium (for X-ray transparency) back-plates, to which force is applied by an inflatable membrane, a level-arm mechanism or just by tightening screw-bolts. Thus a hydrostatic compression is achieved. Such cells can be operated also at high and low temperature, and are also suitable for spectroscopic studies, since diamond is an ideal transmitter of heat and of all types of radiation.

Unfortunately, the scale of the DAC is limited by the size of natural diamonds (which are also expensive and are prone to crack during loading). Hence, the higher the pressure, the smaller the volume to which it can be applied, which in the megabar range is already of the order of 0.001 mm^3. Furthermore, metallic parts of the cell greatly reduce the accessible part of the reciprocal space. Finally, both the incident and the diffracted beams have to pass through the whole thickness of the diamond, which both absorbs X rays

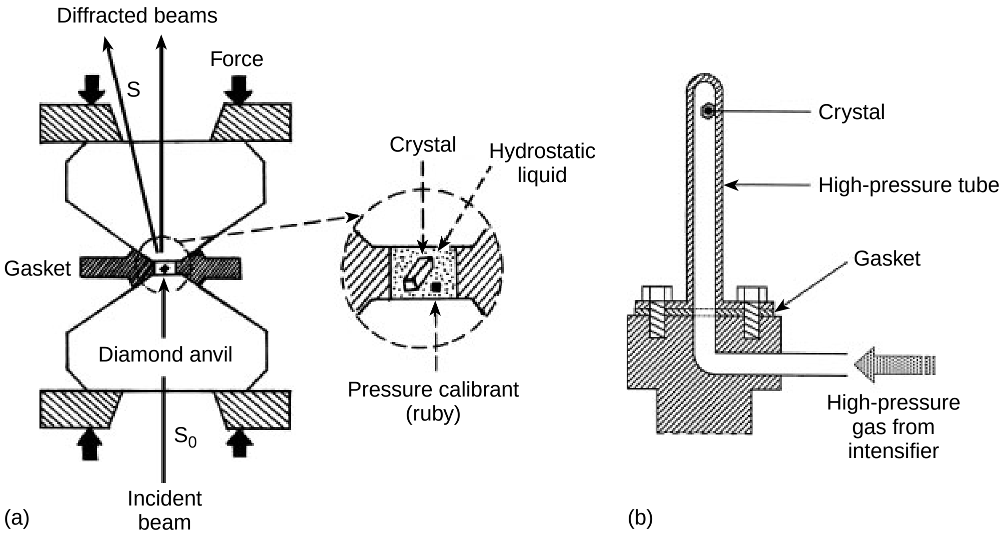

Figure 15 High-pressure cells for single-crystal X-ray studies: (a) diamond anvil cell, (b) gas pressure cell

and (being a single crystal) contributes *very* strong reflections of its own. Thus the experiment is far from trivial[95] and requires a strong X-ray beam and specialized software. In this respect, much can be expected from the novel sharp-focused Microsource X-ray sources (see Section 2.3.1).

The DAC is unsuitable for an ordinary neutron experiment, because the latter requires much larger samples. Alternative means of compression, such as liquid- and gas-pressure cells,[94] or even sapphire anvils (specially designed for use with He cryostats),[96] are but poor substitutes in the magnitudes of pressure. However, encouraging results[97] have been obtained by using DACs in conjunction with high-power neutron sources and optimizing the diffraction instrument itself.

Single-crystal diffraction studies at moderate pressures (2–3 kbar, with 5 kbar in prospect) can be carried out with a gas pressure cell, that is, a thin but strong tube of X-ray transparent material, for example, a laminated carbon composite (Figure 15). Such a cell is small enough to be mounted on an ordinary goniometer head, yet can accommodate much larger (and more easily mounted) crystals than a DAC. A similar device is being developed at the ISIS facility for neutron diffraction experiments.[98]

3.3 Conducting an X-ray Diffraction Study

A sufficiently detailed practical guide on this subject would run into many volumes, hence only the main points are summarized in this section, together with some 'hints' not always included into main textbooks. A routine X-ray crystallographic study comprise the following major steps:

1. grow good quality crystals;
2. select a suitable crystal, mount it on a diffractometer and optically center;
3. assess its 'X-ray quality' and find the (preliminary) crystal lattice;
4. choose measuring strategy and collect the intensity data;
5. reduce intensity data to structure factors F_{hkl};
6. solve the phase problem and find a model structure;
7. refine this model against observed structure factors;
8. calculate geometrical parameters of the structure and interpret them;
9. prepare the results for publication and/or deposit them at one of the databases.

It is noteworthy that area detectors require somewhat different strategies than point detectors; the differences are discussed below.

3.3.1 Growing Crystals

This step is surprisingly overlooked, in a sense 'lost' between crystallographers and synthetic chemists. One cannot emphasize too strongly that crystallographic results can be only as good as the crystals. Ii is also unfortunate that details are seldom published of exactly how the crystals were obtained, as this often requires much ingenuity or a lucky hit upon the right conditions. The remark 'suitable crystals were obtained by slow evaporation' is of no help to the reader.

Optimally, X-ray crystallography requires single crystals of a few tenths of a millimetre in size, which are not intergrown and which have grown *slowly* (they are usually of better quality). Neutron experiments generally require larger crystals; a decade ago ca. 5 mm^3 was considered a standard size, but recent improvement of the technique make considerably smaller samples acceptable ($\leq$1 mm^3).

In fact, extremely valuable information about different crystallization techniques can be found in the chemical literature.[99] Good crystals can be grown from gas phases (sublimation), melts, gels[100] and liquid solutions, the latter being by far the most common. Crystallization comprises two major stages, namely (a) nucleation and (b) growth of the resulting crystal seed into a substantial crystal. Nucleation is usually endothermic, hence it is better achieved by slow evaporation at elevated temperature than by slow cooling. It is often helped by ultrasound (that is the reason why scratching at the glass of the vessel may help) and affected considerably by mere traces of impurities (which may act both as inhibitors and accelerators). Hence extremely clean, or brand new, vessels are preferable.

On evaporation the solvent often creeps up the walls of a glass vessel, because the silicate OH-groups make glass hydrophilic. Therefore nucleation occurs outside the solution; this never gives good crystals and can be avoided by using polypropylene or Teflon vessels.

Note that *very few* seeds are required to grow good single crystals, and that massive seeding gives a crash precipitation of powder or poor crystals. Therefore it is advisable, after spontaneous crystallization sets in, to redissolve almost all the seeds and to leave the remaining few to grow, as close as possible to the point of thermodynamic equilibrium, beyond which the nuclei redissolve. Therefore crystallization from too concentrated solutions, that is, good solvents, should be avoided. It is better to use a solvent, or a mixture of solvents, in which the solute is less soluble.

It is helpful to avoid, as far as possible, the solvents (especially dichloromethane) and anions (e.g. perchlorate or triflate) that show a tendency to be disordered in the crystal structure.

3.3.2 Choosing and Handling the Crystal

Selection of the crystal is the crucial step of the whole study and the time spent on it is well spent. During data collection the crystal should remain within that inner part of the incident beam which has a uniform intensity distribution. Its diameter is smaller (80% at best) than the nominal diameter of the collimator. Thus in X-ray diffractometry a good working norm is for all dimensions of the crystal to be $\leq$0.5 mm, and preferably as uniform as possible. For neutron experiments,

the samples must be larger by one or two orders of magnitude, but the following comments concerning crystal quality apply to them also. With area detectors this requirement is not as strict with point detectors, if a sufficient redundancy of the data can be ensured to perform an empirical correction of the reflection intensities (see below). Larger crystals must be cut to size by a sharp scalpel blade (special diamond or sapphire blades are used for hard crystals). If thereupon they crumble and fall apart, they are probably aggregates of microcrystals that had grown deceptively into more or less 'regular' shape, but these will not give usable diffraction patterns. The way in which a (true) single crystal cleaves reflects its internal packing. For this reason, some crystals which grow as long thin needles or plates, respond to any attempt to cut them by cleaving in all directions except the necessary one. These have to be used as they are, or reduced by dissolving parts of them in a solvent.

On the other hand, the crystal must be big enough to provide sufficiently strong diffraction, but this depends also on the beam intensity, detector sensitivity, and crystal composition, and has to be learned by the rule-of-thumb. Thus, a crystal smaller than 0.001 mm^3 and containing no atom heavier than oxygen seldom gives good data, while this size may be ideal for a crystal of a heavy metal cluster. Other things being equal, a crystal with larger unit cell dimensions diffracts more weakly, the density of lattice points in the Bragg plane being lower. If the crystal is strongly absorbing the X rays, its optimal diameter would be the inverse of the linear absorption coefficient μ, for example, if $\mu = 10\,\text{mm}^{-1}$, the maximum optimal diameter would be 0.1 mm.

The crystal should have well defined faces and straight edges, with no reentrant angles and must be transparent, unless very darkly colored. The time-depending darkening or clouding of once shiny crystal faces, the loss of transparency, surface pitting, and 'auto-crumbling' are indicators that the crystal is chemically unstable toward air oxygen or moisture. Alternatively, many crystal structures incorporate solvent molecules, the gradual loss of which has a similar effect, that is, the crystal deteriorates in quality and finally turns polycrystalline or amorphous.

Several techniques exist for handling air-sensitive crystals. The highly sensitive ones are handled inside a laboratory glovebox (filled with a dry, inert gas) and sealed into a Lindemann tube, that is, a thin-walled glass capillary made of low-density, nonsilicate glass (which thus gives minimum parasitic X-ray scattering). In this case, careful preinspection of the crystal is almost impossible and its quality must be investigated subsequently using X-ray diffraction.

Crystals that are only moderately unstable can be handled using the 'oil drop' method,[101] which became popular in the last decade. This method is extremely convenient and easy, obviating the need for glove boxes and other complicated mounting devices. The crystals are prepared in a Schlenk vessel which is connected to an inert gas (N_2 or Ar) line, creating an excess pressure inside. Then it is possible to open the vessel without letting the air in and to reach the crystal with a spatula carrying a drop of the inert oil (polyfluorinated polyesters). The oil, which has exceptionally high surface tension, will coat the crystal and become an effective atmospheric seal. Then the crystal (under an oil drop) can be studied visually on a microscope slide (with the possibility to be cooled by dry ice), mounted onto a holder and thus transferred to the diffractometer, which is operating with a low-temperature device. On cooling, the oil, which solidifies at -30 to $-40\,^{\circ}$C, will act as a glue.

Neither the inert atmosphere nor the oil, will prevent the crystal from losing any solvent of crystallization. In such a case, the crystal should be stored under its mother liquor and sealed into a Lindemann capillary together with a small amount of mother liquor, to maintain a high local vapor pressure of the solvent.

A number of 'home-grown' and commercially produced mounting devices exist,[79a] which allow manipulations of sensitive crystals under a stream of dry, possibly cold, N_2 gas, or even their transportation in a small Dewar vessel with liquid N_2 and direct transfer into the cold stream of the diffractometer cryostat.

The quality of a transparent crystal can be very efficiently checked using a polarizing microscope.[11] When the crystal is placed between two polarizing prisms with perpendicular polarizing directions, the background and all noncrystalline matter will remain dark, but the crystal itself will be illuminated owing to its birefringence. If the microscope slide is rotated, the crystal will be 'extinguished' every 90°. If parts of it do not extinguish simultaneously, or not at all, we are dealing with more than one crystal grown together. Note that crystals of trigonal, hexagonal, and tetragonal symmetry viewed along the major axis, and cubic crystals in any direction, behave like optically isotropic (amorphous) matter, that is, remain dark.

After a suitable crystal has been selected, it must be fixed securely (e.g. with epoxy resin) inside a Lindemann tube, or on the end of a glass fiber several mm long, which in turn is glued into a metal pip, which fits into the well at the top of a goniometer head. During the experiment the whole mounting must remain perfectly rigid lest a wandering crystal play havoc with the reflection intensities. Therefore one should avoid adhesives which do not set quickly and firmly. The glass fiber must be thick enough not to wobble during circle rotations or under the pressure of the N_2 stream, but its thickness and the amount of glue should not be excessive, because both will contribute to parasitic X-ray scattering and absorption. At low temperature, a human hair 2–3 mm long is preferable to glass fiber.

The goniometer head is mounted on the φ circle of the diffractometer. The head has three mutually orthogonal micrometric screws, which permit optical centering of the crystal in the center of rotation of all diffractometer axes. The crystal must not appear to precess at all when viewed through the telescope (or a video camera) mounted on the

diffractometer, that is, it must not move away from the optical center when rotated around any axis. Good optical centering is often difficult with crystals mounted inside capillary tubes, or when working at low temperatures as ice starts to form on the crystal, the fiber, and the tube. Here the true center can be deduced from the X-ray scattering results.

3.3.3 Preliminary X-ray Investigation

With a point detector, it is impractical to scan the whole of the reciprocal space; X-ray intensity is measured only in the areas where the reflections are expected. Hence it is impossible even to begin data collection until the parameters of the crystal lattice *and* its orientation are known with precision. To determine them, a few sectors of the reciprocal space are scanned in a 'random search mode'. Once a high intensity is detected, the setting angles of the reflection are optimized by an iteration procedure, with the precision of 0.01° in ω, 0.04° in χ. Alternatively, the preliminary angles of a reflection can be determined from a Polaroid diffraction photograph and then refined. After 20 to 50 reflections (lattice points in the reciprocal space) are thus obtained, the autoindexing program will search for a set of three shortest vectors (reciprocal lattice translations, see Section 2.1) describing all these points.

Now we have two different coordinate systems. One, known as the 'laboratory axes', comprises three orthogonal axes of unit length, the directions of which are uniquely defined with respect to the axes of the diffractometer circles and the direction of the primary beam (although these conventions vary from one diffractometer type to another). A point in these coordinates is described by a vector **x**. The other system comprises three principal vectors of the reciprocal crystal lattice (see Section 2.1). In this system, a Bragg reflection is expressed by a vector **h** whose coordinates are the Miller indices *hkl* (Section 2.2.1). The relation $\mathbf{x} = \mathbf{Ah}$ between the two systems is defined by the *orientation matrix* (OM) **A**,

$$\mathbf{A} = \begin{pmatrix} a_x^* & b_x^* & c_x^* \\ a_y^* & b_y^* & c_y^* \\ a_z^* & b_z^* & c_z^* \end{pmatrix} \qquad (25)$$

The OM is pivotal to the data collection, because from it one can calculate diffractometer angles for each reflection.[102] After the autoindexing, the unit cell parameters and the OM are refined by least squares[103] against the setting angles of all available reflections. Then the lattice is transformed to the standard Bravais lattice in the standard setting. It is now possible to measure the intensity of any reflection in its precalculated position. A common approach is to find another 20 to 50 strong reflections with higher Bragg angle, and re-refine the unit cell and OM against them, with higher precision.

The real crystal, even of the best quality, is not the perfectly ordered array described in Section 2.1, but an assembly of microscopic crystalline 'blocks', the orientations of which differ by a small angle known as its 'mosaic spread'. Equation (2) is not satisfied for all of the blocks simultaneously, but under slightly different conditions. The same, of course, applies to the monochromator crystal, hence the λ in equation (2) is not a single value but varies in a certain range. The incident beam is not absolutely collinear, and the sample has finite size. Because of these and other factors, each reflection is not a geometrical point but a three-dimensional feature in the reciprocal space. The quality of the crystal can be assessed by scanning the profiles of several reflections. There are many different types of scans,[104] corresponding in fact to different directions in the reciprocal space (Figure 16). For example, if the ω circle (i.e. the crystal) is rotated by a certain angle while the 2θ circle (i.e. the counter) is simultaneously rotated by twice that angle (so-called $\omega/2\theta$ or $\theta/2\theta$ scan), the reflection is scanned along the line connecting its center with the lattice origin. If the ω circle is rotated and the counter remains stationary ('ω scan'), the reflection is scanned along an arc, the center of which is the origin. This scan, whereby blocks are passing through the Ewald sphere in succession, gives the most explicit indication of the crystal quality. A 'good' crystal must have a symmetric peak in any cross section (scan). A split peak indicates two slightly misoriented (intergrown) crystals, an exceedingly wide peak indicates a crystal of poor quality or one in the process of decomposition.

If the autoindexing fails, it is usually because (i) the reflections are too few, and more of them should be found

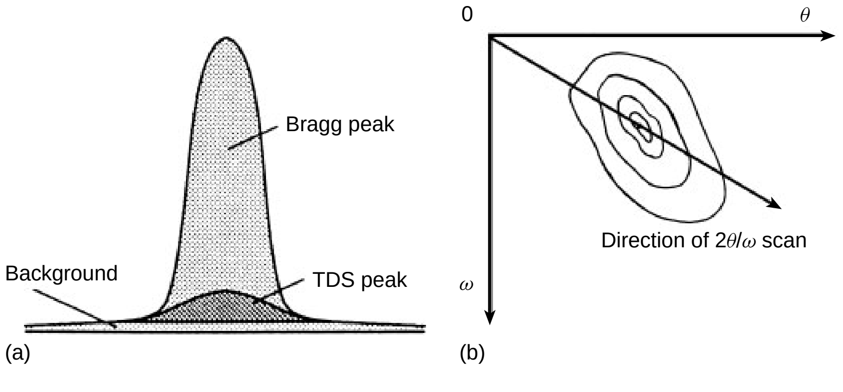

Figure 16 Schematic of a diffraction peak profile in one (a) and two (b) dimensions

and centered, (ii) the reflection set does not define a 3D picture, for example, all reciprocal lattice point lie in one plane, or (iii) the reflections belong to more than one crystal, grown together in the sample. In the latter case, autoindexing can apparently ‘succeed’, yielding a unit cell with unreasonably large dimensions (>50 Å). It is sometimes possible to ‘deconvolute’ the reflection set, that is, to identify which reflections belong to each of the crystals and index them separately. Nevertheless, determining the structure from such crystal is a task difficult and uncertain in outcome, which should be undertaken only if no truly single crystals can be obtained.

This illustrates the principal drawback of the point-detector instrument, that is, the operator cannot see the whole diffraction pattern but can only probe it at different points. For example, if the structure contains one outstandingly heavy atom with the coordinate $x = 0.5$, all reflections with the even index h will be systematically stronger than those with odd h. In this case, a random search may miss the latter reflections altogether and the cell parameter a that is found by the autoindexing will be half the value of the real one. The data collection routine based on such parameters will miss half of the reflections, without which it will be impossible to determine the structure.

With an area detector, the data collection consists of scanning all the accessible reciprocal space or a large part thereof, and we do not need the OM or any other information to begin it. However, it is always advisable to investigate the crystal quality at this stage, rather than risk wasting valuable instrument time on collecting worthless data. In this case, the autoindexing routine includes

- scanning through three narrow sectors of the reciprocal space, in mutually perpendicular directions;
- identifying strong reflections (peaks of intensity) and determining their weighted centers;
- finding the lattice vectors fitting the positions (setting angles) of these reflections;
- performing the least squares refinement of the lattice parameters and OM.

The unit cell thus obtained will be the smallest one fitting all the reflections, that is, a primitive triclinic one. The software will automatically investigate whether (i) the shape of the lattice does not correspond to a higher system (i.e. orthorhombic if all the unit cell angles are close to 90° within experimental errors) and (ii) the primitive lattice can be transformed (by linear combinations of the lattice vectors) into a centered lattice of higher symmetry, corresponding to one of the Bravais types. However, the suggested symmetry is based solely on the *shape* of the unit cell (which can be deceptive) and must be verified by comparing the intensities of the (supposedly) symmetrically related reflections, which are not yet available on this stage.

A failure of the autoindexing routine happens for the same reasons as described above and can be treated in a similar manner. The great advantage of the area detector is the possibility of constant visual monitoring of the *whole* diffraction pattern, as each frame is processed and displayed on a computer screen in real time, and previously recorded frames are stored in memory and can be recalled rapidly. The crystal quality can be assessed by investigating peak profiles in various directions. In this case, each peak is recorded as a *three-dimensional* intensity map, as it covers a number of CCD pixels in each frame (this gives two dimensions, x and y) and usually is present in a few adjacent frames (the third dimension, z). The software also can calculate the expected reflection positions on the detector and to compare them with the actual intensity at the spot; this greatly reduces the risk of mis-characterising the lattice.

Generally, an area detector permits one to check the sample quality much faster and more conclusively, because of easier visualization. Thus if a supposed single crystal gives a set of powder diffraction rings or an amorphous-state halo, the operator will see this immediately; it would take a lot of time and expertise to extract this from the results of a random search!

In any case, the unit cell found must be considered with common sense. It must always contain an integer number (Z) of formula units, and Z is related in certain ways to the crystal symmetry. Thus a triclinic crystal with the space group $P\bar{1}$ may have $Z = 1$ if the molecule lies at an inversion center, $Z = 2$ if the molecule has no crystallographic symmetry, $Z = 3$ for the (most unlikely) combination of the first two options, and $Z = 2n$ if there are n symmetrically independent molecules in the structure. Note that while (molecular) crystals with $n = 2$ are very common, those with $n > 4$ are extremely rare.

Thus it is easy to check whether the cell volume is compatible with the expected molecular formula, allowing 18 Å^3 per nonhydrogen atom. This rule is valid for a surprisingly wide range of organic, organometallic, and coordination compounds, although adjustments can be made for special cases (down to 14 Å^3 for fluorine and some highly condensed aromatics, up to 22.5 Å^3 for some organosilicon compounds). It is useful to check at this stage whether the structure has not been already determined, by searching the relevant database (see Section 4) for similar unit cell parameters.

The experiments with N_2 cryostats are usually run at temperatures between 100 and 170 K; the desire for the lowest possible temperature is balanced by the necessity to avoid icing. Such temperatures are almost always sufficient to prevent both the chemical (or photochemical) decomposition of the sample and the solvent loss. The choice between rapid (flash) and slow cooling depends on the nature of the sample. When the thermal expansion coefficient is likely to be high, as is usually the case with conformationally flexible molecules, slow cooling is preferable if the crystal stability permits it. On the other hand, flash-cooling is the only technique possible for protein crystals, because slow cooling will allow the crystallization water to form ice crystals,

whereupon the protein itself will lose crystallinity.[105] In fact, most crystals survive sharp cooling, that is, being placed instantly under the cold stream of N_2. If the crystal cracks, turns polycrystalline (and opaque) or falls off the mount at this moment, this is usually because it has undergone a phase transition on cooling. During a transition into a phase of lower symmetry, a single crystal often becomes a twin (see Section 3.37) while remaining apparently intact; thus the sample that looked perfect during preliminary investigation (at room temperature!) gives an unindexable diffraction pattern. In such cases, one should determine the transition temperature (by a slow cooling) and perform the data collection at a slightly higher temperature, unless the transition itself is the object of the study.

3.3.4 Data Collection

Data collection on a point-detector diffractometer consists of scanning the reflections (at predetermined positions) in succession, by one of the scan modes described above, as well as measuring the background on both sides of every reflection. The $\omega/2\theta$ scan mode is preferable for good crystal with sharp peak profiles, ω mode for poorer quality crystals. In neutron experiments, a compromise $\omega/x\theta$ scan is used, where x equals 1 or it is variable. In order to attain the same statistical accuracy (e.g. 1%) for all reflections, weaker reflections are scanned more slowly than the strong ones. For a good structure determination, the diffraction data should extend at least to $\sin\theta/\lambda = 0.6\,\text{Å}^{-1}$, that is, a complete set of reflections with $\theta_{\max} \geq 25°$ for Mo-K_α radiation, or $\theta_{\max} \geq 68°$ must be collected. Light-element molecular crystals at room temperature seldom diffract much beyond this limit, but minerals do. Cooling the sample tremendously increases high-angle diffraction, especially for molecular materials. Often only symmetrically independent ('unique'), rather than all reflections within the θ limit are measured, in order to shorten the experiment. The risk inherent in this strategy is that if the lattice symmetry has been overestimated on the previous step, for example, a monoclinic lattice with $\beta \approx 90°$ has been mistaken for an orthorhombic, the experiment will yield only a fraction (in this case, about half) of the real unique set. Such data is completely useless, and there is no way to repair the blunder except repeating the whole experiment.

The duration of the data collection is roughly proportional to the number of unique reflections, that is, basically to the volume of the asymmetric part of the unit cell. For a well-diffracting sample, a modern four-circle diffractometer can measure 80–150 reflections per hour, although the speed can be considerably lower for a weakly diffracting sample. Thus the whole experiment can take several days for a moderately complex structure. Data collection is highly automated; a small group of strong reflections (standard, or check reflections) is remeasured at regular intervals throughout the experiment, thus monitoring the possible radiation source instability, movement/misalignment of the crystal or its chemical or radiation decay. If the latter occurs, reflection intensities are corrected by scaling them against the intensities of the standard reflections.[104b]

With an area detector, the data collection time is proportional to the volume of the reciprocal space scanned (no matter how many reflections are present there) and hence independent of the unit cell size. The scan speed must be optimized according to the intensity of diffraction for each sample. Since all reflections, with widely varying intensities, are scanned with the same speed, it has to be a compromise speed. With too fast speed, weak reflections may have unacceptably low signal-to-noise ratio. With too slow speed (or too large crystal), the strongest reflections may overflow the charge-accumulating wells of the CCD, and their intensities will be underestimated. In this case, the offending frame has to be remeasured at a faster rate.

A standard data collection with a CCD does not exceed 6 to 10 h, or 1 day for the extremely weakly diffraction samples. Therefore, crystal decay is much less of a problem, it can be monitored by rescanning the first several (up to 50) frames at the end of the data collection and comparing the intensities of duplicate reflections.

With less time-pressure, it became the common strategy to collect much more than one unique set of data; often a full sphere of the reciprocal space is scanned. Having several symmetrical equivalents of each reflection, it is possible to make empirical corrections for absorption and some other systematic errors, and to obtain more realistic estimates of the estimated standard deviation (esd's) for individual reflections (important in crystallographic calculations). In fact, a high-redundancy data set usually gives much better results even without explicit corrections. It has been proven by experience that a given amount of diffractometer time is always better spent on measuring more unique sets than on measuring a single set slower.

3.3.5 Obtaining Structure Factors

The data needed for structure solution and refinement are moduli of the structure factors F_{hkl}. To obtain these from the raw intensity measurements, we need to

1. integrate the intensity over an entire reflection peak and subtract the background;
2. correct the integrated intensities I_{hkl} for the Lp factor (Section 2.2.2) and various systematic errors;
3. calculate $|F_{hkl}|$ as square roots of I_{hkl} and bring them to the absolute scale.

Step (a) is illustrated in Figure 16. In a reflection, the Bragg peak is superimposed upon the lower, but broader, peak of TDS which peaks at the same position, and the incoherent scattering which varies slowly and not periodically through reciprocal space. The latter can be subtracted, in the first approximation, as an averaged flat background, provided we know where

the peak ends and the background begins! In one dimension (i.e. with point detectors), this is done either by assuming a constant width for all reflections, or by optimizing the width of each individual reflection by the following technique.[104c] The routine starts with an overestimate of the peak width and reduces it by successive steps, each time calculating the ratio of I integrated within the peakwidth to $\sigma(I)$ integrated outside it. The maximum $I/\sigma(I)$ corresponds to the 'true' width. A 3D equivalent of this procedure can be applied to area detector data.

A correction for TDS, that is, the inelastic phonon scattering,[44] is a difficult problem not yet satisfactorily solved. A proper correction can only be made[106] if the elastic constants of the crystal are known, although an empirical method has been suggested.[107] TDS is inversely correlated with the bulk modulus, thus for soft molecular crystals at room temperature it can be as high as 20–30% of the Bragg intensity, while a much smaller percentage for hard inorganic solids. The effect of no correction is to underestimate the ADP.[108] For neutrons, the problem is even more complicated since the TDS correction will depend on the neutron velocity relative to the velocity of sound in the crystal.[15,22,109]

Other systematic errors include absorption, extinction, and multiple reflection. *Absorption* effects and the required corrections are well understood. When a monochromatic beam of X rays or neutrons with incident intensity I_o passes through a crystal, the intensity is reduced exponentially

$$I = I_o \exp(-\mu t) \qquad (26)$$

where t is the beam path length (mm or cm) inside the crystal and μ is the linear absorption coefficient (measured in mm^{-1} or cm^{-1}), which can be calculated from the individual atomic absorption coefficients of the elements of the sample.[25] These coefficients are element-specific and depend on the wavelength λ, in different ways for X rays and neutrons.[110] In general, all mass atomic absorption coefficients (μ/ρ) are smaller for neutrons than X rays, which is fortuitous given the large samples required for the neutron diffraction experiments. In the range of λ used in crystallography, (μ/ρ) is the sum of two terms: (i) true absorption, due to the photoelectric effect for X rays and to nuclear capture processes for neutrons, and (ii) apparent absorption, due to both coherent and incoherent scattering. For X-ray diffraction the former predominates, while for neutrons the capture absorption varies with λ and can be less than the apparent absorption. The values for true absorption, as well as the incoherent absorption cross sections required to calculate (μ/ρ) for neutrons and tables of (μ/ρ) for X rays can be found elsewhere.[25,110]

Absorption correction can be based on an accurate description of the crystal shape in terms of Miller planes (faces), so that the t can be calculated for each incident and diffracted beam. The total absorption is then given by equation (27), where A is the absorption factor.

$$I = I_o \frac{1}{V} \int_v \exp(-\mu t)\,dv = I_o A \qquad (27)$$

In the analytical method of absorption correction,[111] the integration required by equation (27) is performed by representing the crystal as a combination of several tetrahedra, but the standard technique is numerical or Gaussian integration.[112] When the crystal faces cannot be measured or the absorption coefficient is not well known, empirical or semiempirical methods can be used. On a four-circle diffractometer, it is possible to perform a 360° azimuthal scan of several reflections. The variation of intensity during the scan will define the dependence of absorption on the ψ angle,[113] which can then be applied to all data. With an area detector the azimuthal scan is impractical, but instead there is (due to high data redundancy) a sufficiently large number of Laue equivalents or even of identical reflections repeatedly measured, to derive a polynomial function describing absorption factors in various directions.[114] The latter method has an advantage of simultaneously correcting for the absorption by things other than the crystal (e.g. the glass fiber, glue, capillary) indeed, for any direction-dependent systematic error (e.g. due to parts of the crystal projecting out of the beam). It can be applied to strongly absorbing crystals *after* a numerical correction. A rather controversial program DIFABS is also styled as an 'empirical' absorption correction.[115] In fact, this program adjusts the observed data to minimize the angle-dependent differences between these and the model, during least squares refinement of the structure.

To assess whether an absorption correction is necessary, one should calculate the minimum and maximum μt values from the minimum and maximum crystal dimensions. If $\mu t_{\text{max}} < 2$, absorption is unlikely to be a problem. If $\mu t_{\text{max}} > 5$ or $\mu t_{\text{max}} - \mu t_{\text{min}} > 2$, an absorption correction is necessary, or there will be significant errors in U_{ij} (Section 2.1.3). For $\mu > 20\,\text{mm}^{-1}$, absorption correction is necessary even when the crystal shape is highly isotropic, indeed spherical, for although in a spherical sample t does not depend on the ψ angle, it does depend on θ. The traditional technique for very strongly absorbing materials (e.g. Pb, Hg, or W containing minerals) is to collect the data from a crystal which has been ground into a sphere. Absorption corrections for a sphere have been calculated analytically and tabulated once and for all.[32]

Extinction (see Section 2.2.2) is the phenomenon that reduces the observed intensity of the incident or diffracted beams by internal scattering and backscattering parallel to the incident beam direction. *Primary extinction* is assumed to take place when the different crystal blocks (domains) are sufficiently mutually misoriented that the reduction in intensity takes place only within each block. In *secondary extinction*, the size of the blocks is assumed to be so small that loss of intensity within each block is negligible. Instead, the reduction takes place by adjacent blocks scattering and rescattering the

passing beam. It is an effect most commonly observed in strong X-ray reflections at low Bragg angle from crystals with low mosaic spread. An increase in mosaicity (i.e. deterioration of the crystal quality!) reduces any extinction effects. This can happen as a result of irradiation or of a thermal shock, that is, flash-cooling of the crystal, in which case the strong reflections will appear to increase in intensity relative to other reflections. However, the changes in intensity at lower temperatures are likely to mask this effect. Zachariasen's theory (1967)[116] has formed the basis for most extinction correction programs in common use.[117] These corrections are applied on the stage of structure refinement and not of data reduction, like most other corrections. Extinction effects are less with smaller crystals and shorter wavelengths, but such apparent 'remedies' are usually impractical or counterproductive.

Multiple reflection, or the Renninger effect,[118] occurs when more than one reciprocal lattice point simultaneously cross, or come very close to, the surface of the Ewald sphere. In this case, the once-scattered beam can be rescattered by the other plane(s) with a decrease of intensity. On the other hand, this process ('umwegangregung') can also enhance intensity, such that a reflection will appear to be present even when it should be forbidden by space group symmetry. This is a common enough source of ambiguity in space group determination from systematic absences, which can be resolved by measuring the same reflection (or its equivalent) at a different ψ angle where the multiple reflection will not occur. This effect is observed more frequently in high-symmetry lattices. In routine analyses it is largely ignored, although it can be corrected[119] when very accurate data are required, for example, in charge density studies.

To calculate equation (14) correctly, the structure factor magnitudes must be expressed on the absolute scale, that is, relative to the scattering factor of a single electron under the same conditions. In practice, the observed I_{hkl} and hence $|F_{hkl}|_{obs}$ values are on an arbitrary scale, depending on the crystal size, primary beam flux, photon-multiplying effect of the counter, and so on, which are in practice impossible to estimate. The scale factor K, required to bring $|F_{hkl}|_{obs}$ to the absolute scale, can be found by means of a so-called Wilson plot,[120,121] which gives also the overall temperature factor B (see below) of the structure

$$\ln\left(\frac{\Sigma|F_{hkl}|^2_{obs}}{\Sigma f^2}\right) = \ln K - 2B\frac{\sin^2\theta}{\lambda^2}, \qquad (28)$$

since

$$K|F_{hkl}|^2_{obs} \approx \Sigma f^2 \exp\left[-2B\frac{\sin^2\theta}{\lambda^2}\right] \approx |F_{hkl}|^2 \qquad (29)$$

The scale factor so obtained is very approximate; it is used only in the early stages of the structure solution and it is then refined, among other structural parameters, in the least squares procedure.

3.3.6 Structure Solution and Refinement

These, essentially computational, steps of the crystallographic study are treated extensively in many excellent textbooks and are only summarized here.

The phase problem can be solved, that is, phases of the scattered waves determined, either by Patterson function[122] or by direct methods.[121,123] The Patterson function P is a 'self-convolution' of the electron density ρ, and its magnitude at a point u, v, w can be obtained by multiplying $\rho\ (x, y, z)$ by $\rho\ (x+u, y+v, z+w)$ and summing these products for every point of the unit cell. In practice, it is calculated as

$$P(u, v, w) = \frac{1}{V}\sum_h\sum_k\sum_l |F_{hkl}|^2 \cos 2\pi(hu + kv + lw) \qquad (30)$$

This summation, known as the Patterson synthesis, has the same form as equation (14) for the electron density, but it contains no phase angle. Its coefficients are $|F_{hkl}|^2$, so that the unknown phases of F_{hkl} are irrelevant. When the structure contains two atoms (with atomic numbers Z_1 and Z_2) connected by a $[u, v, w]$ vector, the Patterson map has a peak at u, v, w, whose height is approximately proportional to Z_1Z_2. Thus the only prominent peaks correspond to the vectors connecting heavy atoms (this applies only to X ray and not neutron diffraction!), whose coordinates can be deduced from the peak positions, using the knowledge about various symmetry operations in the given space group. Even a single heavy atom, if it comprises a large fraction of the total scattering power, is sufficient to determine phases for a large number of the measured structure factors. It is quite common for more than 80% of the phasing to be correct, based only on one metal atom possessing 10% of the total scattering power. The Patterson method had only very limited application for structures of similar (light) atoms, so that in the past, heavy atoms (e.g. Br) had to be introduced into organic molecules to make the structure solution possible.

Fortunately the phases of structure factors are not independent but have certain relations to each other and to the magnitudes $|F_{hkl}|$, all of them being the consequences of the same electron density distribution. Therefore the phases can be derived from the magnitudes by mathematical techniques, collectively known as the *direct methods*. They rely on certain 'constraints' on the electron density, especially its being everywhere nonnegative and comprising discrete peaks (atoms). These assumptions were the basis of the Harker-Kasper inequalities,[124] from which the philosophy of the direct methods has grown.[125] All phase relations in the direct methods are essentially probabilistic (except those imposed by the space group symmetry, which are strict) and were originally based also on the assumption of equal atoms randomly distributed in the unit cell.[126] Direct methods first of all revolutionized the crystallography of light atom (organic) structures, making unnecessary the toil of 'heavy-atom' substitution. Today, the vast majority of crystal structures are solved by powerful 'descendants'[127] of these

early ideas, including cluster-type organometallic complexes which are a far cry from the concept of 'equal atoms'.

Generally, direct methods require better data quality than the Patterson method, because phases of some reflections are used to derive other phases, and a single bad reflection can do much harm. Early direct methods used only the stronger reflections in the phasing equations; modern versions rely heavily on weaker data, which therefore must be measured carefully and not neglected, as has been the case quite often in the past. It can happen that not all necessary Bragg reflections are available, owing to poor crystal quality, restricted 2θ maximum, and so on. In this case, simply ignoring the missing reflections, that is, assuming them to have zero intensity, may generate false patterns. Since 1990s, the concept of maximum entropy[128] has been applied to this problem, with very impressive results.[129]

The Patterson or direct method solution will give a number of electron density peaks which can be identified as atoms of certain types. This is still a very crude model of the structure, which should be optimized by the *least squares* (*LS*) *refinement*[130,131] in the following way. Spherically symmetrical Hartree-Fock atoms are placed at the positions of the peaks and the coordinates (Section 2.2.2) and displacement parameters (Section 2.2.3) of these atoms are altered so as to minimize the function

$$M_1 = \Sigma w(|F_o| - |F_c|)^2 \tag{31}$$

$$M_2 = \Sigma w(F_o^2 - F_c^2)^2 \tag{32}$$

where F_o are the observed structure factors and F_c are those calculated from the current model according to equation (9), and weights w account for the fact that different reflections have been measured with unequal precision. The crystallographic community is still divided as to whether equation (31) or (32) represents a better way of refinement, and both (as well as refinement against I) are used in various software packages, but with good data the outcome is not substantially different. The commonly used and quoted single-value measures of how well the model fits the observations, are the so-called R-factors, or discrepancy factors. There are several forms of these, for example,

$$R = \frac{\Sigma||F_o| - |F_c||}{\Sigma|F_o|} \tag{33}$$

$$R_w = \frac{\Sigma w^{-1/2}||F_o| - |F_c||}{\Sigma w^{-1/2}|F_o|} \tag{34}$$

$$wR = \left\{\frac{\Sigma[w(F_o^2 - F_c^2)^2]}{[w(F_o^2)^2]}\right\}^{1/2} \tag{35}$$

R is traditionally established as *the* R-factor and accorded a (greatly exaggerated) reverence as the most important indicator of quality; R_w is known as the weighted R-factor and *wR* as the 'generalized R-factor' (also referred to as R' and R_g). For a good routine structure analysis, R value is expected to be 0.02 to 0.05 (2 to 5%); values between 5 and 10% may be acceptable but the model must be scrutinized carefully for possible errors (see below); $R > 10\%$ indicate serious problems. Note that *wR* is roughly twice the magnitude of R for the same data and model, simply because squares of any numbers differ more than the numbers themselves.

LS refinement is an iterational procedure, repeated in 'cycles' until the shifts of refined variables during the last cycle become insignificant. If the model is still incomplete (not all atoms have been located), an electron density map is calculated according to equation (14), atoms assigned to the revealed peaks and the refinement is repeated. In fact, a more revealing technique is to calculate not the full electron density map, but a 'difference' one, from which the already known atoms have been subtracted. The electron density map calculated after the final LS refinement, is known as the *residual density* map. For a good quality data sets and an adequate model, this map should be relatively featureless. For Period 2 elements the highest peaks should not exceed 0.2–0.3 eÅ^{-3}, although they can be higher for heavier elements.

Other variables refined in the LS procedure are the scale factor K (Section 3.3.5) always, atomic site occupancies in the cases of disorder and/or nonstoichiometric composition and the absolute structure parameter for noncentrosymmetric structures.[132] If the sample contains atoms with sufficiently strong anomalous scattering, the latter parameter indicates whether the assumed absolute structure of the crystal is right or wrong.

Modern programs for LS refinement[133] reached high degree of sophistication, permitting various types of constrained refinement (e.g. treating methyl or phenyl groups as rigid bodies), intelligently dealing with disorder, and so on. Work is currently in progress in several centers on the development of a new generation of truly intelligent, interactive programs. Nevertheless, there are many possible sources of errors in LS refinements (for practical advice see[131]), for example,

1. Insufficient data. A 'good' LS refinement requires at least 5, and preferably 10 reflections per refined variable. Each refined atom contributes three coordinates and 1 or 6 displacement parameters (in isotropic or anisotropic refinement, respectively);
2. Too weak data: background noise is comparable in intensity with the reflections;
3. Errors in the model, for example, attempting to refine an atom as a wrong element;
4. Unrecognized or incorrectly modeled disorder;
5. Wrong symmetry/space group;
6. Twinned crystal;
7. Modulated or incommensurate structure.

Twinning is one of the most common causes of failure in structure determinations. It is estimated that ca. 10% of all crystals submitted for X-ray analysis are twinned, and the proportion is much larger for high-symmetry structures (trigonal/hexagonal, tetragonal, and cubic). Twin[10,134] is a combination of two (or occasionally more) crystals, grown together

in such way that they are related by some symmetry operation. This element ('twin law') is usually a rotation around some rational lattice direction in the direct space or in reciprocal space (the latter amounts to a reflection in a mirror plane in the direct space). The twin law may be such that the *positions* of all reflections from the two crystals coincide, so that the diffraction pattern seems 'normal' at the first glance (merohedral twin). However, as the reflection intensities are affected, the model cannot be found, or even if found, cannot be refined properly. Often R-factor cannot be reduced below 15–20%, even as the structural parameters are chemically meaningful, if imprecise. In the case of nonmerohedral twin, only some of the reflections coincide, or the overlap is imperfect.

Twinning usually occurs for good structural reasons, that is, when the symmetry of the crystal lattice (or its superlattice) is higher than the symmetry of the structure (e.g. when a monoclinic lattice has $\beta \approx 90°$) and the bonding interactions across the twin boundary are competitive in energy with those within a single crystal. Therefore twinning usually tends to affect *all* crystals of a given phase. Until recently, determining the structure of a twinned crystal was a highly specialized area, almost an art. In the last decade, it has been greatly facilitated through introduction of area detectors (visualizing the diffraction pattern is crucial here!) and development of efficient software,[135,136] specially designed for dealing with twins. This requires (i) indexing the diffraction patterns of a twinned crystal, (ii) determining the twin law, (iii) integrating the reflection intensities for each crystal separately, (iv) finding out, how the reflections overlap, and (v) refining the structure with the relative contributions of the components to the observed reflections refined among other LS variables.[137]

Modulation[138] is a perturbation of the crystal lattice which, unlike random perturbations due to thermal motion and static disorder, has regular character and therefore creates sharp diffraction peaks, usually as 'satellites' of ordinary reflections. The diffraction vector can be then expressed as (cf. Section 2.2.1)

$$Q = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^* + m\mathbf{q} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^* + m(\alpha\mathbf{a}^* + \beta\mathbf{b}^* + \gamma\mathbf{c}) \tag{36}$$

The modulation is called commensurate if the coefficients α, β and γ are all rational, and incommensurate[138] if at least one of them is irrational. Effectively the crystal has two different periodicities. Since its discovery of this effect in 1927,[139] it remained one of the most difficult (and specialized) areas of diffraction studies. Recently it also experienced remarkable progress of understanding[140] and development of efficient programs.[141]

3.3.7 Charge Density Studies

In all the calculations described above, it has been assumed that the electron density in the crystal is well described by the superposition of isolated, ground-state (spherically symmetrical) atoms, and that the maxima of electron density coincide with the nuclear positions. This assumption, known as the independent-atom model (IAM) is, of course, only an approximation, albeit a remarkably good one. In the actual structure the atoms form chemical bonds, bear net electric charges, and lose spherical symmetry (e.g. through hybridization). Is it possible to go beyond the IAM and determine the actual distribution of electron density (ED), also called charge density? In principle, the possibility has been envisaged by Debye as early as 1915,[142] and practical attempts have been made since 1950s.[143] However, in practice the X-ray crystallography had neither experimental accuracy nor mathematical apparatus to deal with the problem until the 1970s. Since then, only a few hundreds of ED studies have been published, compared to hundreds of thousands of IAM structures – a clear indication of the difficulty of the task. It is not possible to give more than the briefest outline of this subject. For an introduction the reader is referred to the article by Coppens[144] and for a detailed description of the technique (for a practitioner) to two recent books.[55,145] Chemical applications of X-ray ED analysis[146] and ED studies of silica and silicates[147] have been reviewed extensively.

An ED study requires a complete set of intensity data, measured to a much higher Bragg angle ($\sin\theta/\lambda > 1.1\,\text{Å}^{-1}$, sometimes[148] up to $1.77\,\text{Å}^{-1}$) than is required for an IAM study, and with much more accuracy and precision. It is necessary to measure all symmetrical equivalents of each reflection, carefully address all possible sources of systematic errors, especially extinction and TDS. With a point detector, the data collection required many weeks or even months, but with an area detector (especially using SR) this time has been reduced to a few days, without any loss in precision.[148] There is an intrinsic difficulty to distinguish between the ED distribution of a stationary atom and an apparent 'smearing' of its ED from thermal motion, therefore the data must be collected at as low a temperature as possible.[79,85]

The results can be represented in different ways. The earliest approach was to calculate by a Fourier synthesis the total ED distribution and then to subtract from the latter the ED of the *promolecule*, that is, of isolated atoms, centered at the atomic nuclei positions. The latter can be determined directly by neutron diffraction (X–N method) or from high-order X-ray reflections (X–X_{ho} method). The latter technique, which by now has practically supplanted the X–N method, makes use of the fact that valence electrons scatter X rays mainly at lower Bragg angles ($\sin\theta/\lambda < 0.7$ or $0.8\,\text{Å}^{-1}$) and thus the high-angle reflections are due mainly to the inner (core) electron shells, which remain unaffected by chemical bonding. The resulting *deformation electron density* maps give a rather crude picture of the chemical bonding, which can be made more informative if we subtract a correctly preoriented atom in a correct state of hybridization rather than a spherically symmetrical atom. The main disadvantage of this approach is that the ED map can be only as accurate as the assumed phases

of the structure factors which are very difficult to determine, especially for noncentrosymmetric structures.

Alternatively, the deformation ED can be described by a series of multipoles, that is, spherical harmonic density functions, the parameters of which can be refined by the LS technique. The core ED is described as spherically symmetrical, using the so-called κ formalism. The κ parameter expresses the isotropic expansion ($\kappa > 1$) or contraction ($\kappa < 1$) of a valence shell as a whole. The higher-order multipoles describe the deviations of the ED from spherical symmetry.

Chemically relevant information can be obtained by the topological analysis of the ED distribution and of its Laplacian (second gradient),

$$\nabla^2\rho(\mathbf{r}) = \frac{\partial^2\rho(\mathbf{r})}{\partial x} + \frac{\partial^2\rho(\mathbf{r})}{\partial y} + \frac{\partial^2\rho(\mathbf{r})}{\partial z} \qquad (37)$$

Such analysis can reveal bond paths (lines of maximum ED linking two atoms), exact location of the bond critical points, bond ellipticity (deviation from cylindrical symmetry), and so on. The 'real' atomic boundaries can be found and the effective atomic charges integrated.

The X-ray ED formalism, which is closely connected to the theory of atoms in molecules,[149] is still evolving and there are some unsolved problems. Thus, it appears that in simple inorganic structure the multipole model may be nonunique.[150]

4 INTERPRETATION OF THE RESULTS

4.1 Reading a Crystallographic Paper

The complete results of an ordinary (IAM) crystal structure determination comprise:

1. lattice type and symmetry, space group, and unit cell dimensions with the errors, that is, the esd's, of the latter;
2. other details of the structure itself and of the experimental technique, known (together with 1) as *crystal data*;
3. fractional coordinates of all atoms (with esd's);
4. ADP with esd's;
5. bond distances, bond angles, and torsion angles (with esd's);
6. observed and calculated structure factors.

Most papers in the chemical, biological, and material science literature reporting the results of crystal structure analyses include a section (or a footnote) listing the crystal data, which should indicate the quality of the crystal, the form of the experiment, the accuracy of the measurements, and the precision of the results. The journals all have slightly different requirements for the contents of this section; the list presented in Table 3 conforms to the most rigorous requirements of the International Union of Crystallography (IUCr) and its journal *Acta Crystallographica*. On the other extreme, the *minimum minimorum* of the structural information comprises 1 and 3. Parameters 5 can be always calculated from 3, although the esd of 5 can be only approximately estimated from those of 3.

In earlier years, all the parameters 1–6 were published for each crystal structure. With the exponential growth of the number of structures, the publication of structure factors has been discontinued about 1975, and today they are requested only by *Acta Crystallographica* and that only for refereeing purposes. ADP soon followed, unfortunately just at the time when their calculation was at last becoming reliable (see below). Then many journals resorted to deposition rather than publication of extensive tables of 3 and 5. With the recent development of the Internet, all data except 6 began to be published as electronic supplementary information. The archiving of crystallographic information has been greatly facilitated by the development (by IUCr) of the Crystallographic Information File (CIF) with its standardized, yet flexible, format.[151]

To read a structural paper intelligently, one must be able to appreciate various measures of the precision (i.e. the level of random errors) and accuracy (the absence of systematic errors) of a structure and be able to spot the warning signs that it may be incorrect.[131] There are three principal ways of assessing the structure 'quality' viz.

1. From the internal consistency of the X-ray data itself,[152] for example, the agreement between the intensities of symmetrically related reflections, which must be equivalent by definition. Also, the number of data should be sufficiently large (at least 5, or better 10 times the number of refined variables) for a stable LS refinement.
2. From various measures of agreement between observed and calculated data.[153] Of the overall 'residuals', or single-value measures of agreement, the most popular are various R-factors (equations (33–35)) and especially the traditional one expressed by equation (33). It is frequently the case that the R value is the only criterion taken into account by a nonspecialist. Unfortunately, it (and other R-factors) can be deceptive. In the first place R can always be reduced by omitting some part of the data (not necessarily of inferior quality!), but this can simultaneously increase the esd's in the positional and displacement parameters. Indeed, the latter can provide a complementary measure of quality. All R-factors can be manipulated to a considerable degree by changing the weighting scheme. A good additional indicator is the 'goodness of fit',

$$S = \left[\frac{\Sigma w(|F_o| - |F_c|)^2}{(m-n)}\right]^{-1/2} \qquad (38)$$

where m is the number of observed reflections and n is the number of parameters refined. Theoretically S should equal 1 for a perfect structure with absolute weights

Table 3 Crystal data required by *Acta Crystallographica*, with additional explanatory comments

Formula	Refers to the molecule or the smallest chemical formula unit in continuous solids
Formula weight, M (a.u.)	Molecular weight for the formula above
Crystal system and space group	E.g. orthorhombic, *Pbca*
Unit cell dimensions	1 to 6 of the parameters a, b, c (Å), α, β, γ (°). How many depends on the crystal system, from cubic (1) to triclinic (6). Esd's are given in parentheses
Volume of unit cell, V (Å^3)	Calculated from cell parameters
Z	Number of formula units per unit cell
Measured density D_m	If measured, details of the method should be given, e.g. 'by flotation in . . . '
Calculated density, D_x (g cm^{-3})	In Mg m^{-3} (= g cm^{-3}), calculated as $D_x = 1.661MZ/V$
Radiation type and wavelength	E.g. Mo-K_α, $\overline{\lambda} = 0.71073$Å; mean $\overline{\lambda}$ is given for the α_1/α_2 doublet
Number and θ range of reflections used to determine lattice parameters	E.g. 20, $10° < \theta < 20°$. Tens of reflections are usual for point-detector experiments, hundreds or thousands for area detectors
Linear absorption coefficient, μ	In mm^{-1}, not cm^{-1}; if large, absorption correction is necessary
Temperature of measurement, T	In K
Crystal shape, color, and size	E.g. Dark red, rectangular prism, $0.50 \times 0.34 \times 0.28$ mm
Diffractometer used	E.g., Bruker SMART 6000 CCD area detector diffractometer
Scan mode	E.g. ω scans
Standard reflection measurements	E.g. 3 standard reflections every 97 reflections, intensity decay: 5%; N/A to area detectors
Absorption correction applied	E.g. analytical, numerical, empirical via ψ-scans; max. and min. transmission factors T must be specified, $0 < T_{min} < T_{max} < 1$
Number of reflections	Total number of measured reflections; no of unique (independent) reflections after merging symmetrical equivalents; no of 'observed reflections' and the criterion for 'observed'; e.g '6896 measured refls., 4323 unique, 2544 observed refls. with $I > 2\sigma(I)$'
R_{int}	Discrepancy factor from merging equivalent reflections; expect ≤5% for good and ≤10% for weak data; if higher, absorption correction or crystal symmetry may be wrong
Maximum Bragg angle, θ_{max}	$\theta_{max} \geq 25°$ for Mo-K_α, 68° for Cu-K_α required for a routine study
Range of indices h, k, l	E.g. $0 \leq h \leq 7$, $0 \leq k \leq 15$, $-18 \leq l \leq 18$; check for consistency with crystal symmetry (this corresponds to monoclinic), θ_{max} and a, b, c parameters
Type of refinement	On F, or F^2, or I
Numbers of reflections and variables in LS	Number of reflections in least squares refinement (≤ number of unique reflections) must be ≥10 times the number of refined variables (in exceptional cases, ≥5 times)
Weighting scheme in LS refinement	E.g. $w = 1/[\sigma(F_o^2) + (0.045\text{P})^2]$ where $\text{P} = (F_o^2 + 2F_c^2)/3$
Treatment of hydrogen atoms	E.g. H-atom parameters constrained
Shift-to-error ratio, $(\Delta/\sigma)_{max}$	Must be small in the last cycle of LS refinement, for example, 0.001; if ≥ 1, the refinement is unfinished or does not converge at all (disorder? wrong symmetry?)
Final values of R	Various R-factors are in use, typically quoted in *Acta Crystallographica* are the R (equation 33) for 'observed' data and *wR* (equation 35) for all data used in LS
Goodness of fit, S	According to equation 38; ideally ≈ 1, usually 0.8 to 2.5
Residual electron density, $\Delta\rho_{max,min}$ (e Å^{-3})	Largest peak and 'hole' in the residual electron density map e.g. 0.25, −0.18; $\Delta\rho_{max}$ should not exceed 0.2–0.4 for light elements, 1 for heavy ones, higher values indicate disorder, uncorrected absorption, twinned crystal

and without errors; in practice S varies from 0.8 to 2.5. More sophisticated indicators include the χ^2 distribution, normal probability plots, significance testing, and so on. They are particularly important in charge density studies. A 'noisy' residual electron density map also indicates disagreement between the data and the model.

3. From the absolute values and internal consistency of ADP, visualized as 'thermal (or displacement) ellipsoids'. These parameters, especially in anisotropic approximation, tend to act as 'sinks' for all kinds of random and (neglected) systematic errors. Thus, for a strongly absorbing crystal (in the absence of intensity correction) the thermal ellipsoids of all atoms will approximate the Fourier image of the crystal's outer shape. An unreasonably small or large ADP often indicates a wrongly assigned atomic type, with a too small or too large atomic number, respectively. Exceedingly elongated thermal ellipsoids usually signify static disorder rather than thermal vibrations, certainly so if the data has been collected at low temperature. Often, such disorder can be better approximated by two or more partially occupied positions for the atom in question. Covalent bonds usually remain 'rigid' (undeformed) during thermal vibrations, and in molecular crystals the vibrations of a molecule as a whole are far more important than intramolecular modes. Hence thermal ellipsoids are usually elongated in the direction perpendicular to the bonds, and the ellipsoids of adjacent atoms are similar (correlated). If this does not happen, or if anisotropic

ADP are 'non-positive definite', that is, they do not define an ellipsoid at all but an open surface, this usually indicates grossly erroneous data (e.g. due to twinning) or a wrong space group (e.g. a centrosymmetric structure is refined as noncentrosymmetric).

4. From comparison of the structure with chemically similar ones, that is, by spotting unusual bond distances or intermolecular contacts. An excellent standard for such comparison is provided by the tables of bond distances in organic[154] and inorganic or coordination[155] compounds, which have been compiled using the Cambridge Crystallographic Database (see below). These tables are also reproduced verbatim elsewhere.[32,156]

4.2 Crystallographic Databases

Today, the number of crystal structures in the public domain runs into hundreds of thousands, so that the traditional literature search has long since become impractical. Fortunately, a number of crystallographic databases are available,[8] which store all the published and some unpublished structures and provide very efficient access to this wealth of information.

The Cambridge Structural Database (CSD)[156,157] is the oldest (established in 1965) and probably the most widely used database for chemical crystallography, run by the Cambridge Crystallographic Data Centre (CCDC), Cambridge, UK. Although it stores only the structures which contain at least one 'organic' carbon atom (except biopolymers), in fact only about 50% of its contents are organic compounds proper. The rest are organometallic compounds (including transition metal carbonyl clusters), metal complexes with organic ligands (but without direct metal–carbon bonds) or even the structures of purely 'inorganic' molecules or ions with organic counterions or solvent molecules. Thus it is eminently relevant for inorganic structural chemistry.[158] Besides X ray and neutron single-crystal structures, the CSD includes powder diffraction studies which yield 3D atomic coordinates at least for all nonhydrogen atoms. The November 2004 release of the CSD contained 325 709 entries (cf. 109 000 in 1994) with ca. 24 000 added annually.

The CSD provides powerful search-and-retrieval methods,[159] which can be formulated in terms of

- text and numerical data items;
- two-dimensional chemical (sub)structures (chemical connectivity);
- an extensive range of three-dimensional geometrical parameters.

The results are presented in terms of bibliographic and chemical text, 2D chemical diagrams, 3D structure diagrams at the molecular or extended crystal structure levels, and also as tables of geometrical parameters for each located substructure or chemical fragment. The search query is via a menu-driven graphical interface and the graphical results obtained for any hit can be manipulated interactively too. The tables of user-defined geometrical parameters for a set of retrieved fragments can form the basis for a variety of data analysis methodologies. These can range from simple descriptive statistics,[160] that is, the mean values, medians, and estimated standard deviations, through correlation and regression methods, to the multivariate numerical techniques of principal component and clustering analysis.[161] These latter are designed to reduce the dimensionality of the problem and enable the user to locate and classify the configurational subgroups.

Besides its most obvious utility as a bibliographic source, the CSD enabled researchers to investigate many problems relevant to the nature of the chemical bonding and chemical reactivity. Thus, the so-called method of structure correlations[9,162] uses the geometries of a given chemical fragment in different environments within many crystal structures as static 'snapshots' of a chemical transformation, such as nucleophilic substitution, and thus to provide insight into the structural changes accompanying a chemical reaction. Principal component analysis has been used to show correlations between the structural parameters of the same molecular fragment in many different molecules. These structural results can be combined with kinetic information (vibrational force constants, activation energies, etc.) to model the energy surfaces involved in the formation and breaking of bonds in a reaction sequence. While accuracy is not crucial for the mapping of reaction pathways in which the changes in structure are much greater than the experimental errors, it is of considerable importance in structure–reactivity relationships. Here very small differences in structure can relate to large changes in activation energies and high precision structural data are essential. The structural data stored, and the molecular patterns extracted from them, are used in force field calculations and subsequent molecular mechanics procedures. Molecular modeling software relies upon the parameters so derived and 'modeling' has become a powerful predictive tool in many aspects of chemical research, finding wide applications in the pharmaceutical and agrochemical industries.

Another major area of CSD-based research is the supramolecular structural organization and crystal engineering,[163] and particularly the role of hydrogen bonding[164] in the solid state. Although the initial incentive came from biomolecular chemistry, the results are equally important for inorganic, organometallic, and polymeric materials.

Various more specific structural-chemical problems addressed successfully with the use of the CSD are too numerous to list. Inter alia, it was possible for the first time to clarify the stereochemistry of less common (and less regular) types of metal coordination, for example, with coordination numbers five[165] and seven.[161,166]

The Inorganic Crystal Structure Database (ICSD),[167] originally established at the University of Bonn and currently

run by the Fachinformationszentrum, Karlsruhe (Germany), covers inorganic and mineral structures (64 848 structures in 2003, with ca. 3000 added annually). There is a small area of overlap between the CSD and ICSD, comprising 'molecular inorganics'. The methods of search, retrieval and analysis[168] in ICSD are similar to those of the CSD, except that in continuous (inorganic) solids it is inherently more difficult to define clearly the geometrical form and connectivities than in molecular crystals.

The Metals Crystallographic Data File (CRYSTMET)[169] covers metals, alloys, and intermetallides (77 242 entries in 2003, ca. 2500 added annually). It was started in 1960 in Los Alamos (USA), in 1974 has been transferred to the National Research Council of Canada and since 1996 is managed by Toth Information Systems (Ottawa, Canada). CRYSTMET contains the bibliographic and crystallographic data categories similar to CSD and ICSD, but formal connectivity is not applicable.

Biopolymer structures are stored at the Protein Data Bank (PDB),[170] founded in 1971 at Brookhaven National Laboratory (USA), and the Nucleic Acid Database (NDP),[171] both currently operated by Rutgers, the State University of New Jersey (USA). As of April 2004, the PDB contained 25 176 structures and NDP had 2379 structures.

Additionally there is the Crystal Data Identification File (CDIF), maintained by the US National Institute of Science and Technology, which stores unit cell parameters and crystal class information (determined by either single-crystal or powder diffraction) for all types of substances. The CDIF does not store any information on atomic positions, indeed it does not require the full structure to be known. Nevertheless, it provides a very useful preliminary check at the start of a 'new' structure analysis. Currently the CDIF contains ca. 237 000 entries, with a large backlog.

5 CONCLUSIONS

Since the first edition of this Encyclopedia (1994), the technique of single-crystal X-ray diffraction experiment underwent a major revolution, comparable to that occasioned by the replacement of diffractometers for photographic cameras about 1970. A routine X-ray data collection, which took many weeks with photographic films in 1965 and several days with a 4-circle diffractometer in 1970–1995, is now reduced to several hours. Furthermore, area detectors made feasible many experiments altogether impossible before, through higher sensitivity and the recording of the whole pattern. The technology for nonambient conditions has greatly improved; experiments at liquid nitrogen temperatures have become routine and those at liquid helium temperatures and at high pressures have ceased to be exotic. The improvement of software and computer facilities has greatly facilitated structure solution (particularly by direct methods) and charge density calculations; efficient programs for dealing with twinned crystals and incommensurate phases are being developed.

1 INTRODUCTION

Metals and metal–metal bonding hold a fascination for all chemists. Dimers are the simplest units that incorporate metal–metal bonds. They represent the next step in chemical complexity in going from monomers to clusters (*see* ***Polynuclear Organometallic Cluster Complexes***) and ultimately to surfaces as shown in equation (1).

$$\underset{\text{monomer}}{ML_n} \longrightarrow \underset{\text{dimer}}{L_nM\text{–}ML_n} \longrightarrow \underset{\text{cluster}}{(L_nM)_x} \longrightarrow$$

$$\underset{\text{surface}}{\cdots \begin{matrix} L & & L & & L & & L & & L & & L \\ | & & | & & | & & | & & | & & | \\ M & - & M & - & M & - & M & - & M & - & M \end{matrix} \cdots} \qquad (1)$$

All the complexes shown in equation (1) can undergo reactions such as ligand substitution (*see Ligand Substitution*) or oxidative addition (*see Oxidative Addition*), which reflect the character of the individual metal–ligand bonds. For metal–metal bonded complexes, reactions can occur at the following sites: (1) reaction at the coordinated ligand; (2) reaction at the metal–ligand bond; (3) reaction at the metal–metal bond.

The presence of a metal–metal bond not only introduces possibility (3) but can also modify the reactivities (1) and (2). The influence of metal–metal bonds on these types of reactivity is still being investigated, and this review is meant to be an illustrative introduction to metal–metal bonding in inorganic and organometallic dimers. Since the metal–metal bond of a dimeric complex provides the fundamental unit of more complex architectures, some discussion of clusters is also included.

2 RECENT DEVELOPMENTS AND NEW DIRECTIONS

The basic themes of metal–metal bonded dimers were established years ago and have remained largely unchanged. However, new aspects of metal–metal bonding have been discovered and in addition, application of metal–metal bonded complexes in other areas has grown. Important contributions in emerging fields such as nanomaterials, fullerene (*see* ***Carbon: Fullerenes***) chemistry, combinatorial catalytic research, molecular recognition, and dendrimers have all utilized metal–metal bonded complexes.

2.1 Electrical Conductivity and Related Physical Properties

An increasing area of interest and utilization of metal–metal bonded complexes is the area of electrical conduction at the molecular level. A prototypical complex is shown in Figure 1, which incorporates a diphosphine-bridged Pt^{I}–Pt^{I} dimer[1] spliced to two linear acetylenic linkages terminated by ferrocenyl (*see Ferrocene*) groups as endcaps.

Electronic communication is deemed to be high in this complex, but much lower in a related gold-bridged system. The exact nature of what controls 'conductivity' or 'electronic communication' at the molecular level is far from being understood. Inroads in that area have been made as well, as discussed later, but advances in synthetic and structural chemistry continue to lead the way, as demonstrated by the complexes highlighted in this section.

The cluster $Ir_4(CO)_8(PMe_3)_4$ reacts with excess C_{60} to yield a square planer core of four Ir atoms.[2] Two of the Ir atoms in the Ir_4 fragment are linked simultaneously to the faces of two C_{60}'s, as shown in Figure 2.

In addition to electrical properties, the optical properties (*see* ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds***) of the metal–metal bonded unit have also received increased attention. 'Luminescence tribochromism' – light emission that occurs with mechanical grinding – has been displayed by a Au–Au dimeric complex where the monomeric unit with a Au–Au separation of 2.8797 Å arranges in a helical structure with alternating longer Au$\cdots$Au distances as shown in Figure 3.[3]

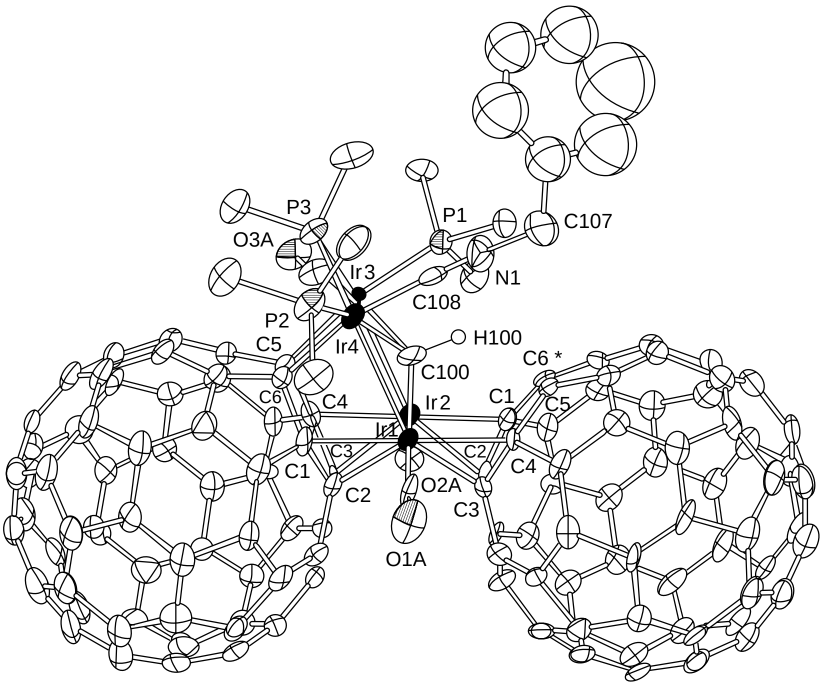

Figure 2 Coordination of two C_{60}'s to an Ir–Ir fragment, allowing a 'wide passage for interfullerene electronic interaction'.[2] (Reprinted with permission from Ref. 2. © 2003 American Chemical Society)

2.2 Supramolecular Complexes, Molecular Engineering, Dendrimers, Nanoparticles

Nanotechnology has seen an upsurge in development and in this area as well, metal–metal bonded complexes find a role. Manganese phosphide (*see* ***Phosphides: Solid-state Chemistry***) nanocrystals have recently been prepared utilizing $Mn_2(CO)_{10}$.[4] In this application, metal–metal bonded complexes are used as precursors to novel materials. A number of applications in which supramolecular architectures have

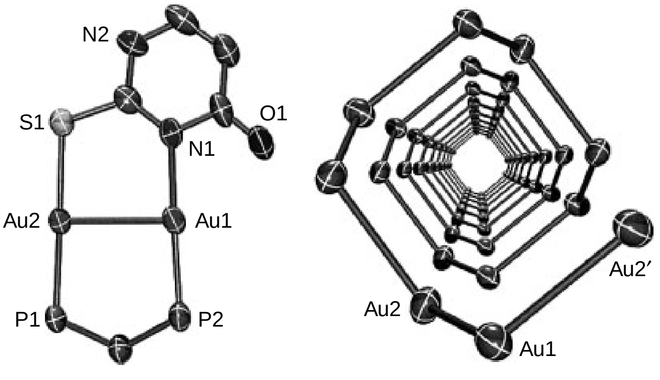

Figure 3 Au–Au dimeric unit[3] that crystallizes, producing a helical arrangement conducive to 'luminescence tribochromism'. (Reprinted with permission from Ref. 3. © 2003 American Chemical Society)

been assembled that incorporate, as part of the assembly, a metal–metal bonded subunit. The ability of these subunits to interact and the extent of these interactions remains an area of open investigation. Aspects of polymer formation incorporating metal–metal multiply bonded dimeric units have been explored and reviewed for one-dimensional polymers[5] and as supramolecular arrays.[6] Dimeric ruthenium complexes have been prepared that crystallize in square arrays, each containing four paramagnetic Ru–Ru dimers, as shown in Figure 4.

The entire crystal structure displays a supramolecular structure that is tetragonal, as shown in Figure 5.

Square-shaped channels in the crystal are occupied by solvent molecules. Further illustration of continued utilization of metal–metal bonded complexes in 'molecular engineering' type of applications is the dendrimer-like complex in Figure 6.

A novel one-dimensional helical polymer resembling DNA and composed of heterodinuclear subunits containing $Pt^{II} \rightarrow Ag^{I}$ dative bonds has been synthesized.[9] The design and utilization of supramolecular metal–metal bonded assemblies such as those shown above can be expected to be an area of intense research effort in the future (*see* ***Semiconductor Interfaces***).

2.3 Multiple Bonded Main Group–Main Group and Transition Metal–Main Group Complexes

A general resurgence in main group inorganic chemistry has led to a number of spectacular developments including

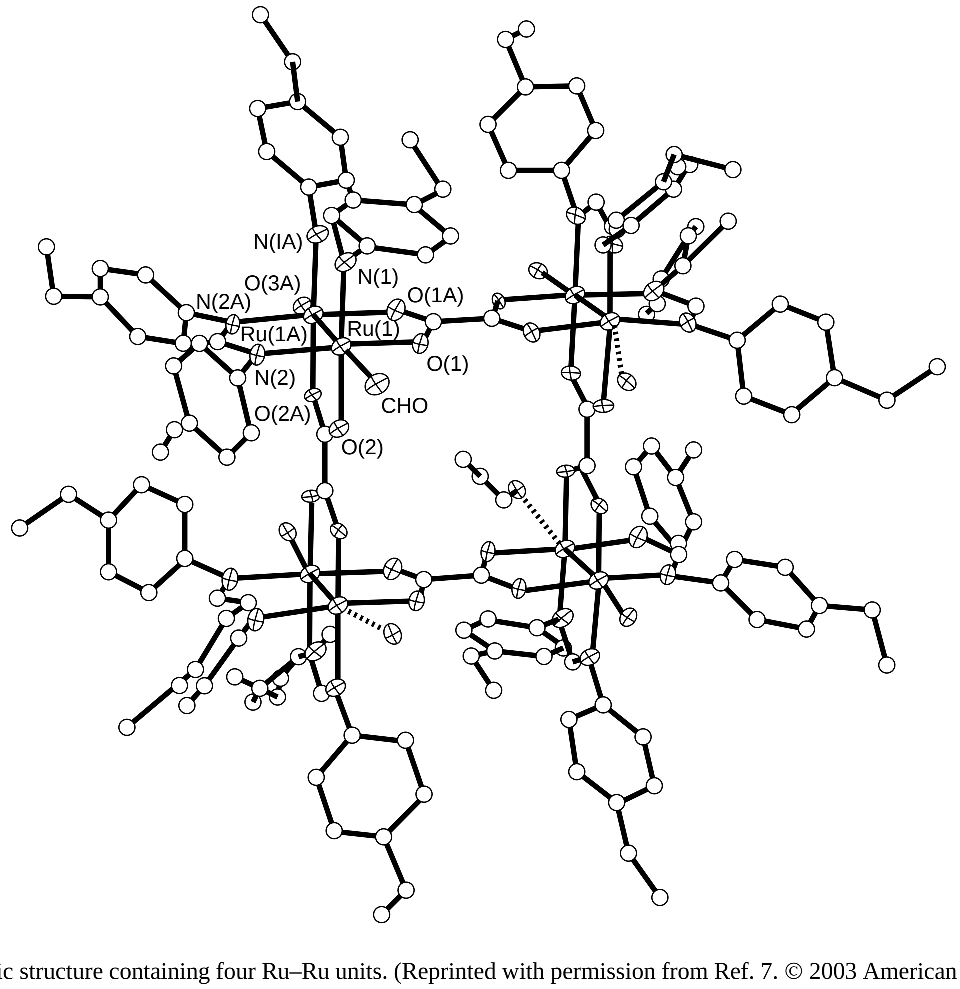

Figure 4 Tetrameric structure containing four Ru–Ru units. (Reprinted with permission from Ref. 7. © 2003 American Chemical Society)

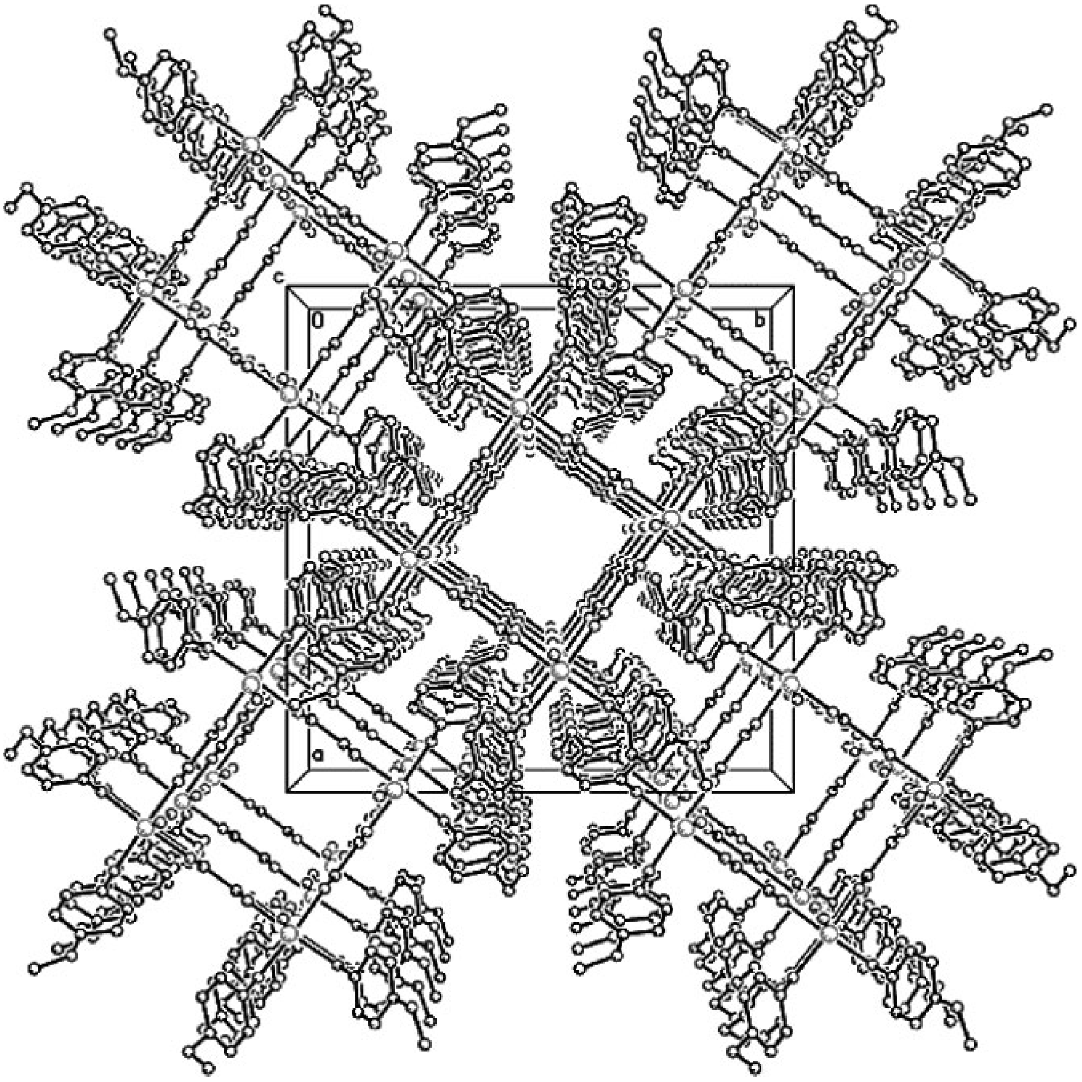

Figure 5 Figure showing supramolecular stacking of Ru–Ru complex from Figure 4. (Reprinted with permission from Ref. 7. © 2003 American Chemical Society)

synthesis of multiply bonded metal complexes. The concept of 'metalloaromaticity' and 'antiaromaticity' has been introduced for some of these complexes and is an area of current theoretical debate.[10] In addition to main group–main group multiple bonding, main group metal–transition-metal complexes with metal–metal bonds have also been prepared, as shown in Figure 7.

2.4 Theoretical Advances

The rapid advances in synthetic and structural chemistry of the metal–metal bond have inspired detailed theoretical investigation. Unlike main group elements such as carbon, transition metals can form a quadruple bond between two metal atoms. The quadruple bond consists of a single σ bond (overlap of two $d_{z}2$ orbitals), two degenerate π bonds (overlap of two d_{yz} orbitals and two d_{xz} orbitals), and a δ bond (overlap of two d_{xy} orbitals). The existence of a quadruple bond between two metal atoms was first recognized in 1964 when Cotton and coworkers[12] isolated the compound $[Re_2Cl_8]^{-2}$. Since then, many other compounds have been found containing a quadruple bond (such as $[Mo_2Cl_8]^{-4}$).

The bonding between two metals that contain a quadruple bond is largely due to the σ and π bond interactions. The δ bond contribution to the quadruple bond is small and is illustrated by the fact that the removal of a δ bond typically results in a bond lengthening of only 3%.[13] Also, in the compound $[Re_2Cl_8]^{-2}$ whose bond strength is $85 \pm 5\,\text{kcal mol}^{-1}$, only approximately $6\,\text{kcal mol}^{-1}$ is assigned to the δ bond[14] (which is comparable to a hydrogen bond). The strength of a δ bond depends on the amount of overlap existing between the two d_{xy} orbitals of the metals. Orbital overlap of the δ bond depends on a twist angle

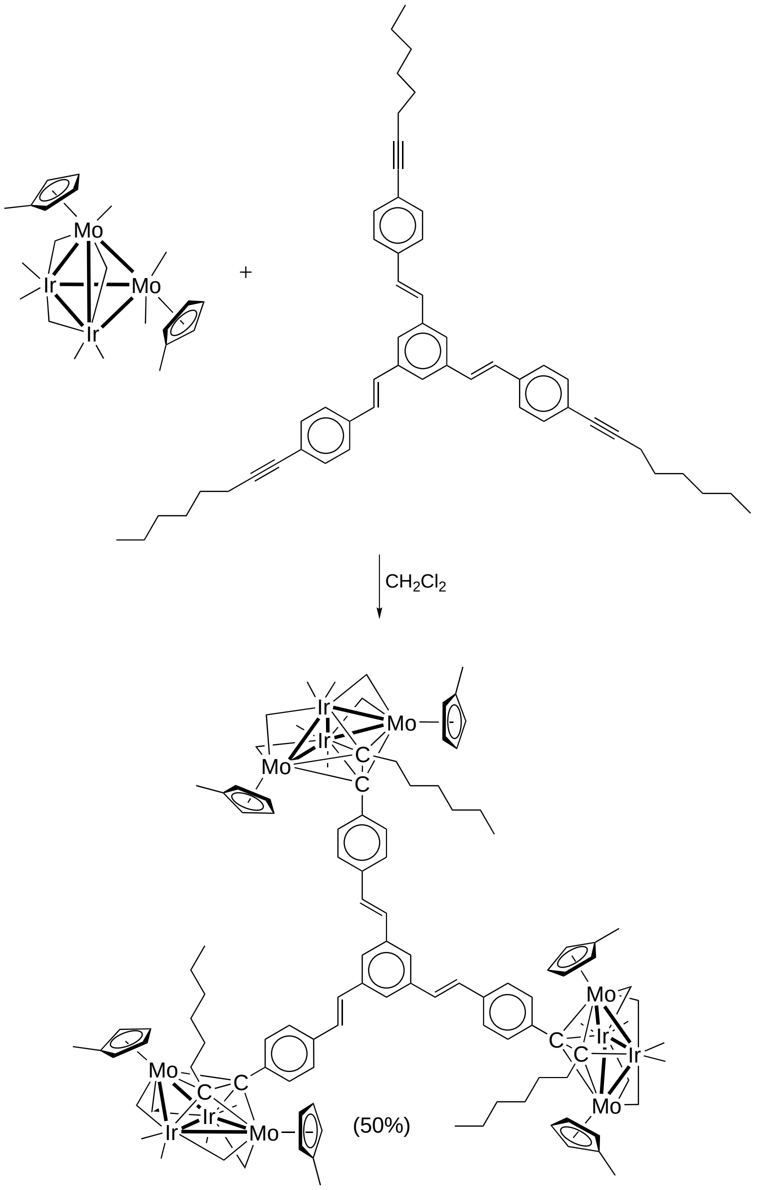

Figure 6 Preparation of bridging acetylene dendrimeric metal–metal bonded complexes. (Reprinted with permission from Ref. 8. © 2003 American Chemical Society)

between the two metals and can be varied because of steric factors of the ligand substituents. The weakening of the δ bond can be observed in several ways, such as by the lengthening of the M–M bond distance or by a decrease in the $\delta \rightarrow \delta^*$ transition.[15] It seems clear that a nearly continuous variation of bond orders can be developed for the M–M bond.[13,15–20]

3 HISTORICAL BACKGROUND

Although the first transition metal complex that we now know contains metal–metal bonds[21] was reported as early as 1844, the concept of metal–metal bonding became widely accepted only more than a century later, during the 1960s. The development of the chemistry of organometallic compounds with metal–metal bonds is intimately connected with metal carbonyl chemistry (*see* ***Carbonyl Complexes of the Transition Metals***) and homogeneous catalysis.[22–24] The first organometallic compound, which would later be shown to have a metal–metal bond, was $Co_2(CO)_8$, discovered by Mond in 1910. The successful use of this complex as the starting catalyst in hydroformylation (*see Hydroformylation*) was developed by Roelen in 1938 and would later have a tremendous impact on this area. The pioneering work of Hieber and his group during the 1930s led to the synthesis of numerous

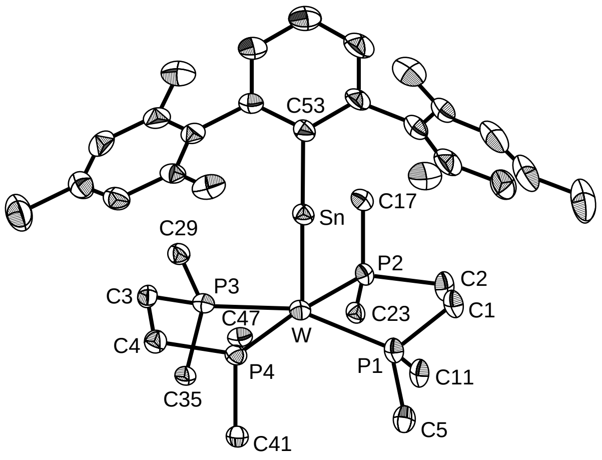

Figure 7 Complex with proposed Sn≡W bond. (Reprinted with permission from Ref. 11. © 2003 American Chemical Society). There is a long history of transition metal–main group–metal dimers, but multiple bonding between main group metals and transition metals is a new area

landmark complexes whose structures and chemistries would only later be shown to have metal–metal bonds.

The earliest structural proof[25] of a metal–metal bond in a complex was that of Hg_2Cl_2 in 1926, but this structure was considered something of an anomaly. The Swedish chemist Brosset published the structure of $K_3W_2Cl_9$ in 1935, and it showed clear evidence of a W–W bond.[21] The first organometallic complex proven to have a metal–metal bond was $Fe_2(CO)_9$. Its structure, determined in 1939 and reinvestigated more recently by Cotton,[26] shows an Fe–Fe distance of 2.46 Å. Since the metal–metal bond is supported by three bridging carbonyl ligands, it did not give definitive proof of the metal–metal interaction. The synthesis and later structural determinations of the complexes $Re_2(CO)_{10}$, $Mn_2(CO)_{10}$, and $[Cp(CO)_3Mo]_2$ provided the first unequivocal structural proofs of metal–metal bonding unsupported by bridging ligands (For leading references to these and related complexes, see Ref. 1 and also Ref. 27).[27]

The slow evolution of metal–metal bonding was greatly accelerated when Cotton and coworkers[12] published the X-ray structure of $Re_2Cl_8{}^{2-}$ in 1964. This complex with its quadruple metal–metal bond remains a landmark complex, and recently, its electronic structure and orbital energies in the gas phase were confirmed experimentally for the first time.[28] The first organometallic complexes showing multiple metal–metal bonds were prepared and characterized only a few years later by King and Bisnette.[29] The oil crisis in the mid-1970s induced a flurry of interest in homonuclear bimetallic transition metal complexes because of their potential application as catalysts or catalyst precursors. The concept of combining the activity of heterogeneous catalysts with the selectivity of homogeneous systems motivated the development of this chemistry. More recently, considerable interest has focused on the synthesis and chemistry of heteronuclear catalysts, in particular, early–late bimetallics. It is hoped that such complexes containing hard and soft metal centers in close proximity can activate organic substrates by combining the different reactivity of the two metal centers. Understanding the nature of the metal–metal bond has been a motivating factor for pure research in this area from the beginning. In spite of the large amount of work, the chemistry of metal–metal bonded complexes remains a vast frontier. In a review of this length, it is only possible to highlight principle features.

Transition metal complexes with metal–metal bonds have been divided into two general classes by Cotton and Wilkinson:[30] (1) high-valent halide complexes, such as $Re_2Cl_8{}^{2-}$ and (2) low-valent organometallic carbonyl complexes, such as $Mn_2(CO)_{10}$. This division held precedent for a long time since the groups of people working were largely different and used different approaches. In addition, the chemistry itself seemed to have different qualities. This distinction is no longer clear. Many researchers have made contributions to both classes, none more than Cotton himself. For example, the complex $[Re_2Cl_8]^{2-}$, one of the first halide types prepared, has an organometallic analog $[Re_2Me_8]^{2-}$ that was prepared some 14 years after the halide complex. According to all definitions, $[Re_2Me_8]^{2-}$ qualifies as an organometallic complex since it has direct bonds between organic groups and a metal. On the other hand, $Re_2(CO)_{10}$ is viewed in some strict definitions as not being organometallic since CO is 'inorganic carbon'. These semantic problems mask the more subtle questions of which complexes most resemble each other. The reactivity patterns of these compounds are a varied mosaic that crosses all boundaries. This review will focus on what are traditionally viewed as organometallic complexes but, where appropriate, inorganic complexes will be discussed as well. Related articles are also available to the reader (*see* ***Polynuclear Organometallic Cluster Complexes***; and ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***).

The development of organic chemistry has been organized largely around the idea of 'functional groups'. Certainly, the metal–metal bond is one of the more important functional groups in inorganic chemistry. However, it must be recognized that there may be little in common between, for example, an iron–iron or a niobium–niobium bond. In addition, even for a given element, there is a range of oxidation states that display metal–metal bonding. For a given metal and a given oxidation state, variation of the ligand arrangement can be expected to cause changes in the character or, even possibly, the chemical reactivity of metal–metal bonds. Metal–metal bonds may show a continuous variation of reaction patterns, but at the time of writing this review, the principles guiding this field are still not completely known. Three quotations from the literature make this clear. The first is from a review of this field by Vahrenkamp[31] in 1978 regarding what is known about metal–metal bond complexes: 'So much that compounds containing metal–metal bonds have already been

treated in about 70 reviews and monographs cited in this article. The other answer is: So little that the significance of metal–metal interactions is still uncertain even in the simplest compounds...'. The second is from a later review by Chisholm:[32] 'Are there simple chemical tests available to distinguish between M–M quadruple, triple, and double bonds based on reactivity? Some 20 years after the discovery of the M–M quadruple bond, the answer is still no!' The final quotation is taken from Cotton, Murillo, *et al.*[7] and points to the future: 'In short with the synthesis of **1**, **2**, and **3**, we have opened the door to the possibility of magnets and conductors built with metal–metal bonded subunits'.

This refers to complexes such as that shown in Figure 5. It shows both how much progress has been made in metal–metal bonded complexes and how much remains to be discovered.

4 ILLUSTRATIVE EXAMPLES OF METAL–METAL BONDED COMPLEXES

The range of metal–metal bonding as a function of ancillary ligands and oxidation state can be best illustrated by specific examples. The given examples are chosen primarily from molybdenum chemistry, but are indicative of general classes of metal–metal bonded complexes. With the possible exception of dinuclear ligand-bridged complexes of iron, there are probably more characterized metal–metal bonded dimers of molybdenum than of any other element. The reactions shown are meant to be illustrative of different methods of obtaining metal–metal bonds but may not represent optimum synthetic procedures. For detailed coverage, the next section provides additional review articles and monographs. The relation of some of these complexes to $Mo(CO)_6$ is shown in Scheme 1.

The present section begins with examples of metal–metal bonding in the absence of external ligands (gas-phase dimers, the solid state, and surfaces). These are covered since they represent metal–metal bonding in its simplest form. Study of the addition of organic ligands to these structures is an area of ever-increasing research activity. It continues on to complexes that are representative of broad classes of organometallic metal–metal bonding dimers.

4.1 'Naked Dimers', Mo_2 (g)

The simplest metal–metal bonded dimers occur in the gas phase in the absence of ligands. Pyrolysis of molybdenum metal at high temperatures in vacuum produces Mo (g) that is in equilibrium with the gas-phase dimer Mo_2 (g) (equation 2).

$$\cdots\text{Mo–Mo–Mo–Mo–Mo}\cdots \longrightarrow \underset{1.93\,\text{Å}}{\text{Mo=Mo(g)}} \rightleftharpoons 2\text{Mo} \qquad (2)$$

The internuclear distance of 1.93 Å, is the shortest Mo–Mo distance observed to date. The net bond strength of 97 kcal mol^{-1} in this molecule[33] probably represents an upper limit for the Mo–Mo interaction in any environment. It seems unlikely, but not impossible, that some type of additional bridging ligand could be found to further strengthen/shorten this bond. To date, it does not appear to have been accomplished. This highlights the fact that, in spite of their importance, metal–metal bonds, even multiple ones, are not generally of exceptional strength.

In view of the tremendous amount of gas-phase chemistry that has been done with metal atoms and ions, the use of these 'naked dimers' as precursors to ligated metal–metal bonded complexes seems to be a field that could expand (equation 3).

$$\text{Mo=Mo} + n\text{L} \longrightarrow \text{L}_n\text{Mo=MoL}_n \qquad (3)$$

Only scattered reports of studies of gas-phase reactions of dimers, such as that shown in equation (3), have appeared. There have been several reports in metal-atom chemistry of formation of dimeric complexes, but the mechanism of dimer formation is not known.

4.2 Metals, Colloids, Surfaces, and Mo(s)

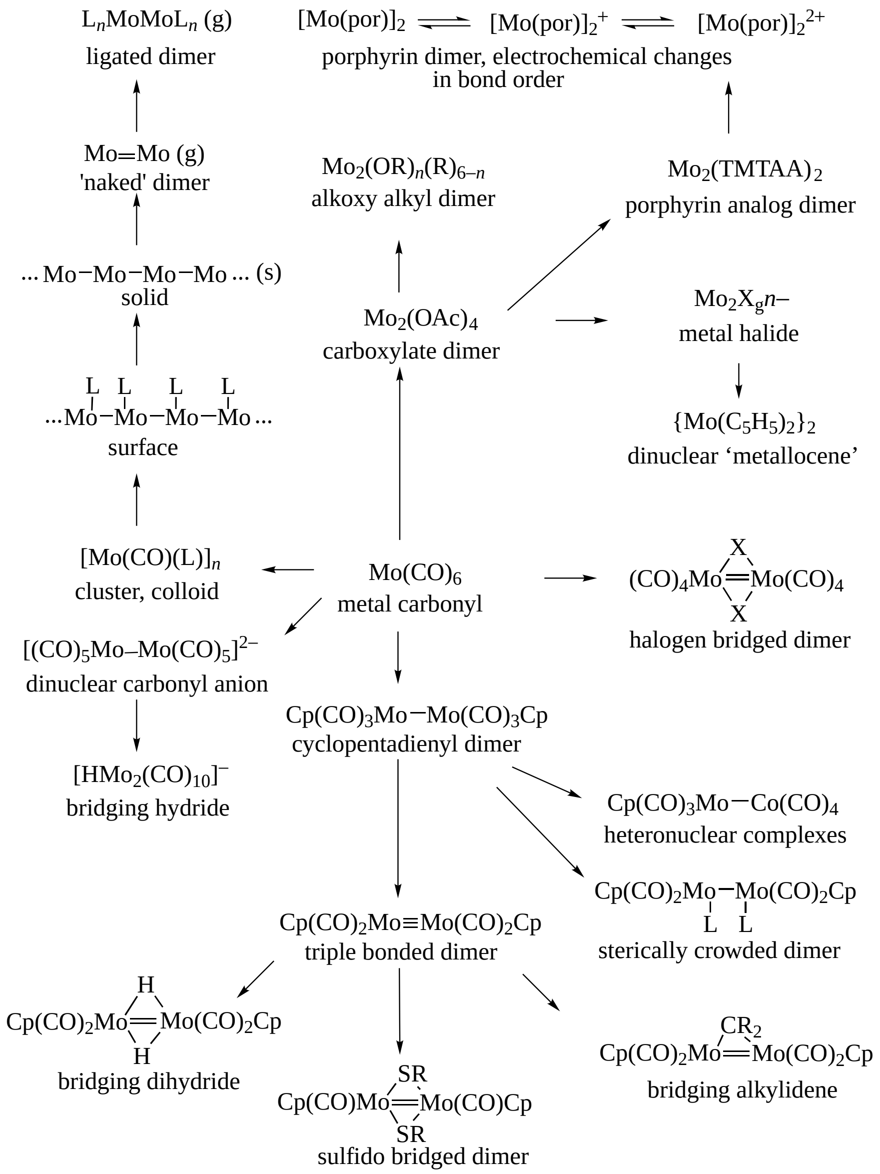
Solid metals provide a benchmark for judging metal–metal bond distances and a rough guide to energetics and bond strengths. This is true, even though the metal–metal bond in bulk metals is best understood in terms of solid-state theory (*see* ***Surfaces*** and ***Electronic Structure of Solids***). The metal–metal bond in dimers and clusters is often cited as a model for metal–metal bonding in bulk metals or on surfaces. The reverse should also be considered: observations from surface and cluster chemistry could provide insight and perspective for dimers. There is probably a smooth transition in the nature of the metal–metal bond as the number of neighboring metal atoms increases. Recent results in the study of metallic colloids appear to indicate that when the cluster size begins to exceed 50 to 60 atoms, the electronic properties of some of the atoms in the center begin to approach those of bulk metals.

Work on metal dimers has been aimed at understanding the effects of adding or withdrawing electrons from the metal framework. In some cases, either addition or subtraction of electrons has been shown to apparently strengthen the bond. These, and related studies, could provide the framework for understanding bonding effects in more complex systems once allowance is made for the additional constraints placed on the system by the total lattice energy and framework.

For comparison to the properties of dimeric complexes, it is worth noting that the Mo–Mo distance in the bulk metal is 2.76 Å. The enthalpy of atomization of molybdenum is 157 kcal mol^{-1} (equation 4).

$$[\cdots\text{Mo–Mo–Mo–Mo–Mo}\cdots](\text{s}) \longrightarrow n\text{Mo(g)} \qquad (4)$$

Molybdenum metal exists as either body-centered cubic (bcc) or hexagonal close-packed allotropes. In the bcc form,



Scheme 1 Flow chart for metal–metal bonded molybdenum complexes

it has a coordination number of eight. If a localized bond structure were imagined for this system, complete destruction of the lattice could correspond to breaking four bonds per metal atom, corresponding to an average value of approximately 40 kcal mol^{-1} for a single molybdenum–molybdenum bond. Whether such an approximation is valid or not, this is a reasonable estimate for the single bond strength in organometallic dimers of molybdenum (see Section 4.3). It is also nearly the same as the Mo–CO bond strength in $Mo(CO)_6$. The metal–metal bond strength (in the absence of steric repulsion) is often on the order of the metal–carbon monoxide bond strength for low-valent metals. For that reason, metal–metal bond cleavage is often competitive with ligand dissociation.

A second insight regarding bond strengths can be gained by comparing the enthalpies of atomization of Cr = 95, Mo = 157, and W = 203 kcal mol^{-1}. Metal–metal bond strengths in dimeric complexes also increase when going from Cr to Mo to W. To date, information appears to support this trend for all transition metals.

In spite of considerable study, the effects of ligands on metal–metal bonding in dimeric complexes is not fully understood. Nevertheless, binding of bulky ligands in dimetallic complexes normally decreases the metal–metal bond strength for both enthalpic and entropic reasons. This would correspond in metal surfaces to the coverage of two adjacent sites at the metal, as shown in equation (5).

$$2L + \cdots Mo-Mo-Mo-Mo-Mo\cdots \longrightarrow \cdots Mo-Mo(L)-Mo(L)-Mo-Mo\cdots \quad (5)$$

A recent monograph on the energetics of metal surfaces has appeared,[34] but at this time, it does not appear that the influence of ancillary ligands to either increase or decrease metal–metal bond strengths is well understood. In several cases now, it has been established in 'molecular wire' type complexes that mild oxidation or, in some cases, reduction can influence the M–M bond distances and strengths.[35] The goal in these complexes is to increase the metal–metal bond strength; however, in heterogeneous catalysis with metals, the goal might be to weaken the metal–metal bond. It, therefore, seems possible that at local kinks and ledges of a heterogeneous metal, changes in bond order may occur during surface redox reactions. This illustrates that principles learned from both disciplines (solid state and surface chemistry on the one hand and homogeneous discrete systems on the other) may be symbiotic.

Understanding the types of bonding involved in metal colloids (intermediates between surfaces and dimers) has been enhanced by a range of physical techniques. For example, EXAFS studies[36] of $Au_{55}(PPh_3)_{12}Cl_6$ indicate that the Au–Au distance is 2.803 Å, smaller than that found in bulk gold (2.878 Å). Thus, in this case, surprisingly, binding of ligands appears to shorten the metal–metal bonds in a surface-like environment. Several groups, most notably Schmidbauer, have extended the knowledge of the 'aurophilic' Au···Au interaction. (*see* ***Gold: Organometallic Chemistry***).

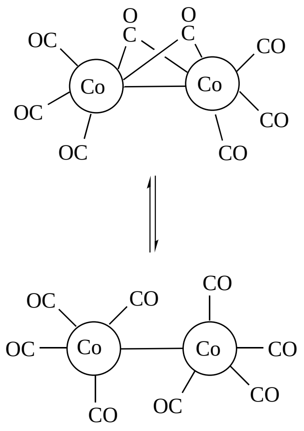
4.3 Metal Carbonyl Dimers, $Mo_2(CO)_{10}^{2-}$

One of the broadest and historically most important areas of dimetal chemistry is that of the simple carbonyl complexes (*see* ***Carbonyl Complexes of the Transition Metals***). As mentioned above, $Co_2(CO)_8$, $Fe_2(CO)_9$, and $Mn_2(CO)_{10}$ were among the first metal–metal bonded complexes characterized. To this day, these complexes continue to be involved in new chemistry, for example, $Co_2(CO)_8$ found recent use in a one-pot synthesis of 'tricyclic δ-lactones'.[37] In the case of molybdenum, the zerovalent carbonyl is monomeric; however, reduction gives a dinuclear metal carbonyl dianion in which the metal is in the [−1] oxidation state (equation 6).

$$Mo(CO)_6 \xrightarrow{K} K_2[(CO)_5Mo\text{–}Mo(CO)_5] \quad (6)$$
$$d(\text{Mo–Mo}) = 3.123\,\text{Å}$$

There are a number of metal carbonyl clusters, many of them anionic in nature. They range in size from dinuclear complexes, such as that shown above, to very large clusters and even charged colloidal particles.

In many cases, particularly for first-row metals, the metal–metal bonds are supported by bridging carbonyl ligands. The simplest case is $Co_2(CO)_8$, which exists as an equilibrium mixture of bridged and unbridged forms (equation 7).



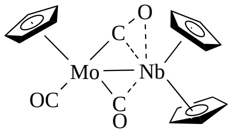
(7)

More complicated forms of CO bridging, which involve bonding through both the C and O atoms, also appear in metal–metal bonded compounds. For example, while $Mn_2(CO)_{10}$ does not have bridging CO ligands, substitution by the chelating phosphine ligand dppm (bis-diphenyl phosphino methane) proceeds as shown in equation (8). In this reaction, the phosphine-substituted metal–metal bonded dimer reversibly loses CO to produce a structure, which escapes coordinative unsaturation by having a π-CO interaction across the metal–metal bond.

$$Mn_2(CO)_{10} + 2\text{dppm} \longrightarrow Mn_2(CO)_6(\text{dppm})_2 \underset{+\,CO}{\overset{-\,CO}{\rightleftharpoons}} Mn_2(CO)_4(\mu\text{-CO})(\text{dppm})_2 + CO \quad (8)$$

A related reaction is shown for the molybdenum–niobium complex (equation 9). As described in a review by Horowitz and Shriver[38] on bridging carbonyl ligands, this complex is a rare example of a structure containing terminal, bridging, and π-bridging CO ligands. All such complexes, of necessity, include metal–metal bonding.

$$Cp_2Nb(BH_4) + Et_3N + RMo(CO)Cp \longrightarrow$$



(9)

This two-site binding of ligands is one of the great potentials of dimetal complexes. The π-bridging CO in the complex cited above shows significant lengthening of the carbon–oxygen bond. The goal of such chemistry is activation or cleavage of CO. The binding interactions in such dimers are complex

and not easily analyzed. For example, even if one knew the enthalpy of binding of the π-bridging CO, this value would be difficult to interpret since it involves at least four bonding interactions: weakening of the carbon–oxygen bond along with formation of metal–carbon and metal–oxygen bonds as well as changes in metal–metal bonding character. Clearly, delocalized molecular orbital theory is the best approach to understand the nature of bonding in such complicated situations.

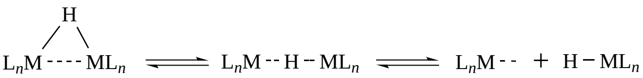
4.4 Hydrido-bridged Carbonyls, $HMo_2(CO)_{10}^-$

An important class of metal–metal bonded dimers is the hydrido-bridged carbonyls (*see* ***Hydrides: Solid State Transition Metal Complexes***). These can be obtained through a number of reactions, most commonly, through protonation and direct reaction with hydrogen. Protonation of the metal carbonyl dianion $Mo_2(CO)_{10}^{2-}$ yields the complex shown in equation (10).

$$Mo_2(CO)_{10}^{2-} + H^+ \longrightarrow HMo_2(CO)_{10}^- \qquad d(\text{Mo–Mo}) = 3.41\ \text{Å} \tag{10}$$

Complexes of this type are found for anionic, neutral, and cationic metal carbonyl dimers. It is difficult to determine the extent of metal–metal bonding in these structures. The Mo–Mo bond distance in the protonated complex is quite long, almost beyond the limit of what is reasonable for metal–metal bonding. This complex is best viewed in terms of a three-center, two-electron bond similar to that found in B_2H_6 and other bridging borohydrides. Some metal–metal bonding character may be implied. The related complex, $H_2W_2(CO)_8^{2-}$, has a W–W bond length of 3.1 to 3.2 Å, which is indicative of a stronger W–W interaction.

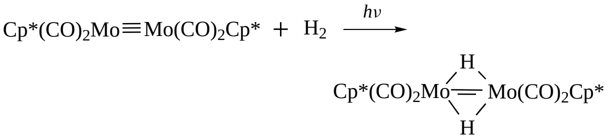
In complexes of this type, the potential energy surface is probably 'soft', with the interplay of metal–metal, metal–hydrogen, and three-center forms of bonding close in energy. Thus, opening of the bridging structure to a linear bridging hydride is probably a low-energy process and could be the precursor to dissociation to a mononuclear metal hydride and a coordinatively unsaturated complex (equation 11).



(11)

It should also be considered that, due to the high mobility of the H^- ligand, linear hydrido-bridged species might readily transform to transition states involving hydrido-bridged metal–metal bonded complexes.

In a novel use of photolytic addition of H_2 across the metal–metal multiple bond, the two-H-atom-bridged double-bonded complex[39] shown below has been prepared (equation 12).

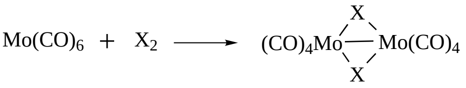


(12)

For the analogous cyclopentadiene(*see Cyclopentadienyl*) derivative, prepared by a different route, the complex is unstable in solution and is believed to dissociate back to H_2 and the Mo–Mo triple-bonded complex. In view of the fact that many catalytic cycles utilize hydrogen, these types of complexes are important models. Interactions of dihydrogen leading to cleavage of the metal–metal bond are discussed in Section 7.1.4.

4.5 Halogeno-bridged Carbonyls, $[XMo(CO)_4]_2$

While bridging carbonyl and hydrido ligands are often present in metal–metal bonded dimers, halogens are probably the most common bridging ligands. Oxidation by halogens under controlled conditions leads to the Mo^I-bridged dimers as shown in equation (13).



(13)

X = Cl, Br, I

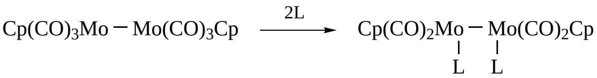
In complexes such as $[XMo(CO)_4]_2$, where the metal–metal bond is held together by the equally strong or stronger bridging halide system, it is difficult to assess the strength of the metal–metal bond. The importance of metal–metal bonds in this type of complex is still disputed.

4.6 Cyclopentadienyl Metal Carbonyl Dimers, $Cp(CO)_3Mo–Mo(CO)_3Cp$

Aside from the carbonyl group, the Cp ligand and its analogs are probably the most common ligand systems in organometallic chemistry. This is also reflected in the large number of cyclopentadienyl metal carbonyl dimers and their derivatives that have been studied. For molybdenum, direct reaction of molybdenum hexacarbonyl and dicyclopentadiene is one of several routes to $[CpMo(CO)_3]_2$ (equation 14).

$$C_{10}H_{12} + Mo(CO)_6 \longrightarrow Cp(CO)_3Mo\text{–}Mo(CO)_3Cp \qquad d(\text{Mo–Mo}) = 3.235\ \text{Å} \tag{14}$$

A number of derivatives of this complex have been prepared (*see* ***Multi-Heme Cytochromes & Enzymes***). Substitution of carbonyl ligands by other donors, such as that shown in equation (15), gives rise to a wide range of complexes.



(15)

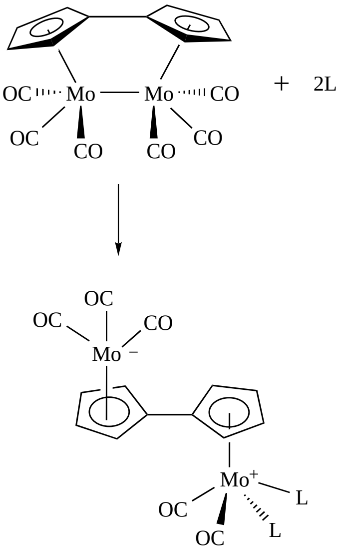
In addition to substitution of the carbonyl groups, changes in the cyclopentadienyl ring have also been extensively studied. The use of pentamethylcyclopentadiene led to formation of some of the first organometallic multiply bonded complexes as discussed in Section 4.8. The tris(pyrazolyl)borate ion (Tp^-, *see Tris(pyrazolyl)borates*) is a Cp analog.[40] It reacts with $Mo(CO)_6$ to yield the $TpMo(CO)_3{}^-$ anion. Oxidation yields the paramagnetic radical that shows no tendency to form a single metal–metal bond. Decarbonylation yields a triply bonded structure. These reactions are summarized in equation (16).

$$Tp^- + Mo(CO)_6 \longrightarrow TpMo(CO)_3{}^- \longrightarrow TpMo(CO)_3 \longrightarrow [Tp(CO)_2Mo]_2 \qquad (16)$$

$$d(\text{Mo–Mo}) = 2.507\,\text{Å}$$

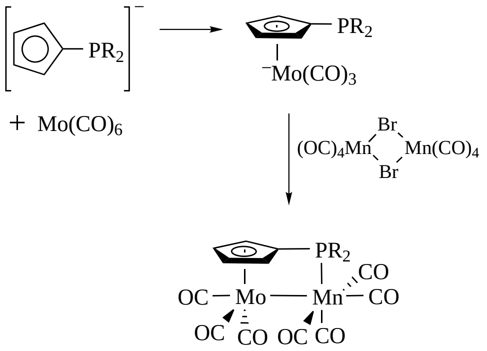
4.7 'Tethered' Bridges, $[(Fulvalene)Mo(CO)_3]_2$, and Related Complexes

A number of ligands have been tethered to a cyclopentadienyl ring to prepare unique chelating ligands. In some cases, these have been extended to metal–metal bonded complexes. A good example is the work of Vollhardt and coworkers on fulvalene systems.[41] Complexes of this type are often more flexible than halide-bridged complexes; that is, the bridging ligand keeps the metal fragments in close proximity so that the metal–metal bond can be readily broken and reformed. Cleavage of the metal–metal bond will not result in disruption of individual metal–ligand bonds, as would be the case for many bridging ligands. One interesting reaction of the fulvalene–molybdenum complex produces the novel zwitterionic (*see Zwitterion*) structure shown in equation (17).



(17)

In addition to fulvalene complexes, other bridges such as the bis(dimethylsilylclopentadienyl) ligand have been used to bridge dinuclear complexes.[42] Other pendant groups have been attached to the cyclopentadienyl ligand, and these can lead to interesting complexes as well. The cyclopentadienyl phosphine system[43] shown in equation (18) is but one of the numerous examples.



(18)

4.8 Multiple Bonded and 'Unsaturated' Dimers, $(C_5R_5)(CO)_2Mo{\equiv}Mo(CO)_2(C_5R_5)$

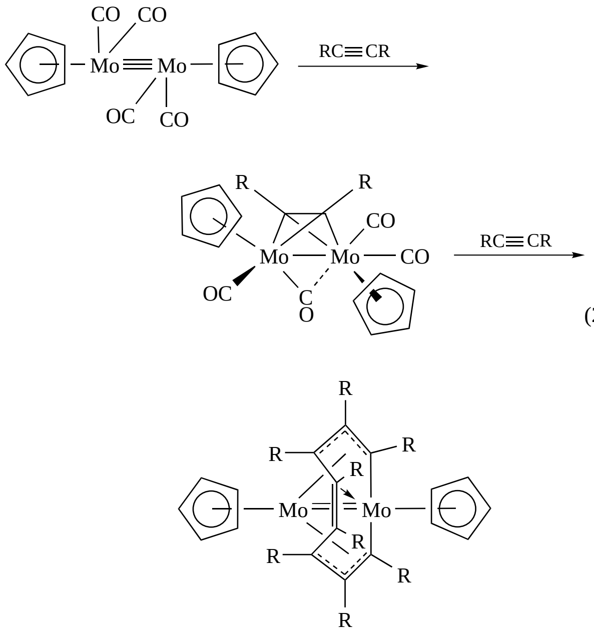
Some of the most interesting metal–metal bonded complexes contain multiple bonds. A good example[44] of this, and one of the first multiply bonded complexes formed, is the reaction of pentamethylcyclopentadiene with molybdenum carbonyl (equation 19).

$$Mo(CO)_6 + C_5Me_5H \longrightarrow Cp^*(CO)_3Mo{-}Mo(CO)_3Cp^* \underset{+2CO}{\overset{-2CO}{\rightleftharpoons}} Cp^*(CO)_2Mo{\equiv}Mo(CO)_2Cp^*$$

$$(Cp^* = \eta\text{-}C_5Me_5) \qquad (19)$$

Heating the single-bonded dimer causes loss of two moles of carbon monoxide to yield the triple-bonded dimer in a fully reversible reaction. Owing to the fact that the carbonyl groups in the triply bonded dimer are semibridging (*see Semibridging Carbonyl Ligand*), there can be some question about the true bond order in this dimer. A wide range of reactions are displayed by this and other 'coordinatively unsaturated' metal dimers (*see Coordinative Saturation & Unsaturation*). While the complex does obey the eighteen-electron rule (*see Effective Atomic Number Rule*) by adopting the triple bond and/or semibridging structure, the multiple metal–metal bond is relatively weak. Thus, it is somewhat like mononuclear complexes that have a vacant site at the metal, which is protected by an agostic

bond (*see Agostic Bonding*). The operational difference here is that it is a two-center site, and thus capable of more complex reactions. A good example of this is coordination of acetylenes as well as the interconversions shown in equation (20).[45]



(20)

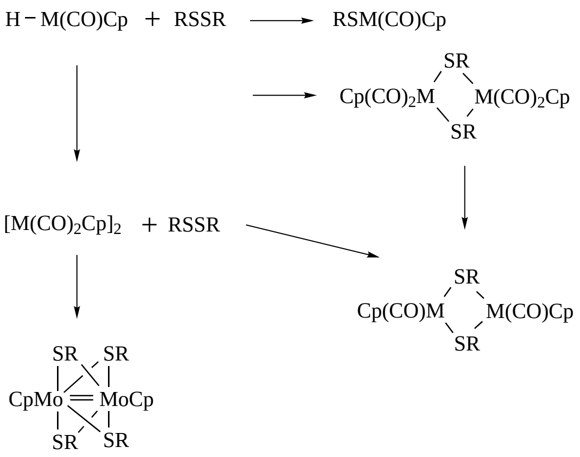
Some coordinatively unsaturated metal dimers are not proposed to contain multiple bonds, for example, $CoRh(CO)_7$. This complex can be viewed as an analog of $Co_2(CO)_8$ in which one CO ligand has dissociated from the complex and the heavier congener Rh has replaced one of the Co atoms. The degree of interaction between the two metals is not clear in spite of the known structure. This complex can fragment,[46] but can also undergo addition reactions at the metal–metal bond, as shown in equations (21) and (22) respectively.

$$CoRh(CO)_7 + CO \rightleftharpoons CoRh(CO)_8 \qquad (21)$$

$$CoRh(CO)_7 + \tfrac{1}{2}H_2 \longrightarrow HCo(CO)_4 + \tfrac{1}{4}Rh_4(CO)_{12} \qquad (22)$$

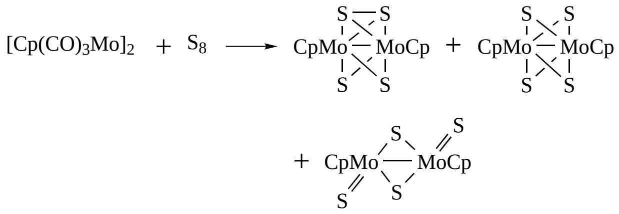
4.9 Sulfur- and Selenium-bridged Dimers, $[CpMo(ER)_2]_2$

In addition to halogen-bridged dimers illustrated above, chalcogen-bridged dimers are another major category of organometallic metal–metal bonded dimers. For example, the complexes shown in equation (23) have been prepared and studied by several groups.



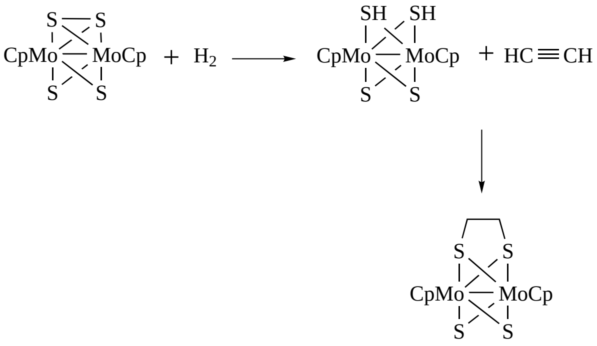
(23)

In addition to thiolate-bridged dimers, sulfido complexes containing metal–metal bonds show related chemistry. Of particular interest are the products of reaction between $[(C_5R_5)(CO)_3Mo]_2$ and sulfur (equation 24). In complexes such as these, the ability to assign bond orders is no longer simple. The internuclear distances are supportive of metal–metal bonds for a majority of the complexes, but the exact bond orders are uncertain in some cases.



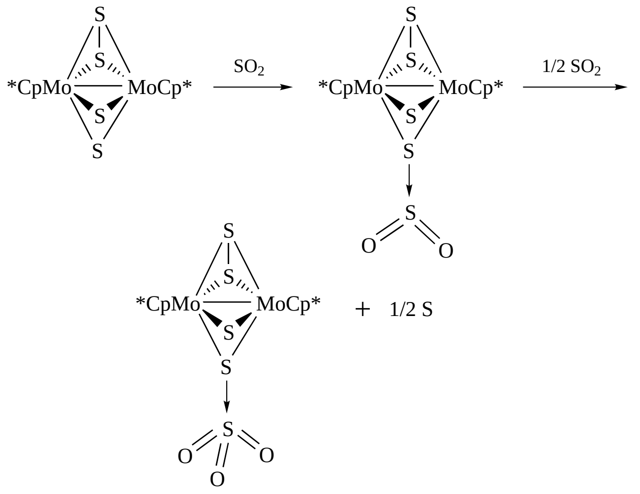
(24)

Bridging ligands are normally 'innocent' or 'spectators' and do not play an active role in chemical reactions. This is not always the case, however, particularly for coordinated sulfur. For example, reaction of the sulfur-bridged metal–metal bonded complexes with hydrogen, followed by reaction with acetylene, occurs at the sulfur, as investigated by Rakowski Dubois (equation 25).[47]



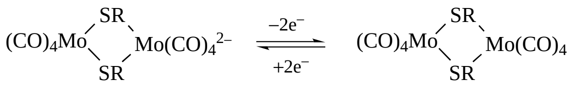
(25)

Kubas[48] discovered reactions of the Cp∗ dimers, which are part of a catalytic cycle for the hydrogenation of SO_2 (equation 26). The net reactions involve the coordinated sulfur and may or may not involve the metal atoms, which may be the true 'spectators' in this chemistry. This opens the possibility that the metal–metal bond serves to stabilize the reacting fragment without direct involvement in the chemistry. However, reaction could also occur at the metal–metal bond followed by transfer to the sulfide ligands. These types of multiple interactions give an added dimension, but also an added complexity, to metal–metal bonded chemistry with bridging functional ligands.



(26)

An interesting example[49] of sulfur-bridged systems is shown in equation (27). The disulfur-bridged dianion does not contain a metal bond. Chemical or electrochemical oxidation generates the neutral species that does have a metal–metal bond. This process of electrochemically induced changes in bond order will be discussed below for porphyrin complexes as well.

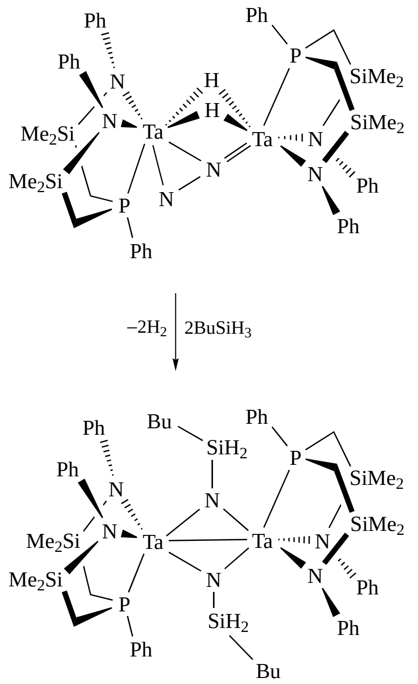


(27)

Increasingly, heavier congeners of sulfur have been investigated. For example, Adams has recently reported preparation, structure, and reactions of $CpMoMn(CO)_5(\mu\text{-}Se_2)$,[50] which contains a doubly bridging diselenido ligand in the heteronuclear Mo–Mn bonded complex.

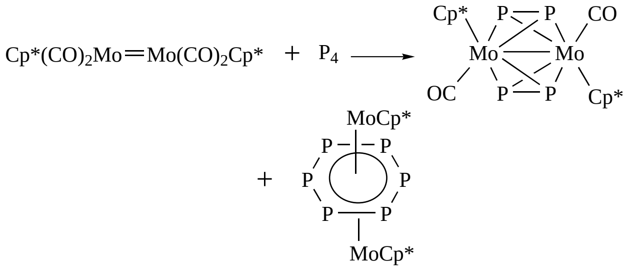
4.10 Phosphorus and Nitrogen Ligand-bridged Dimers

There are a range of nitrido, phosphido, carbido, and related complexes with metal–metal bonds (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***). They are not as common as the halogen- and chalcogen-bridged species described above. Carbido complexes are generally associated with higher-level clusters and are not discussed here (*see* ***Carbides: Transition Metal Solid-state Chemistry***). Reaction of the coordinated dinitrogen complex, shown in equation (28), with butylsilane results in cleavage of the nitrogen–nitrogen bond and in the formation of a bridged Ta–Ta bonded complex.[51]



(28)

A range of chelating phosphine ligands with small 'bite' size have been shown to stabilize metal bonds. In addition to chelates, metal phosphido, amido, and even polyelemental derivatives exist. A range of truly novel complexes are known, such as the two products isolated in low yield in equation (29). The dimers retain metal–metal bonding and stabilize the coordinated P_2 and P_6 fragments.[52]

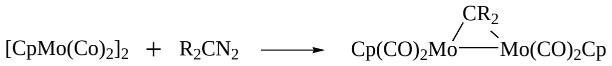


(29)

4.11 Hydrocarbon-bridged Metal–metal Bonded Dimers

Carbide-type ligands often hold together clusters of higher order but not dimers or trimers. However, a number of dimeric complexes are bridged by hydrocarbon ligands. These can

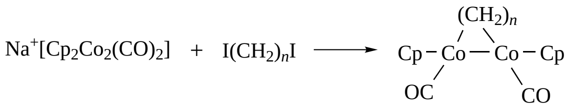
be viewed as dimetallacycloalkanes or as bridging alkenes and more complicated species. The simplest form would be the metal–metal bonded complexes with bridging alkylidene (*see Alkylidene*) ligands. Several reviews have appeared regarding these complexes.[53] Reaction with diazoalkenes and the triple-bonded complex, shown in equation (30), leads to formation of bridging carbene (dimetallacyclopropane) structures.



(30)

Saturated alkanes can also bridge metals. Reaction of metal carbonyl anions[54] with dihaloalkanes has been widely investigated since the report of equation (31) by King. In most cases, a metal–metal bond is not formed. Bergman and coworkers[55] have prepared and done elegant studies on a series of cobalt complexes of the general form shown in equation (32) that do contain metal–metal bonds. A range of transformations and reaction pathways are available to these complexes.[56]

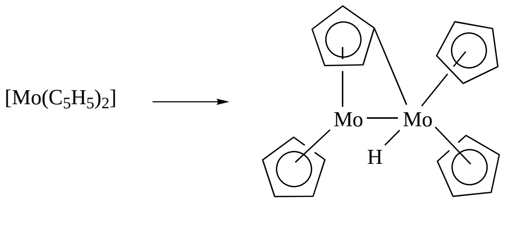
$$2NaFe(CO)_2Cp + I\text{–}(CH_2)_n\text{–}I \longrightarrow Cp(CO)_2Fe\text{–}(CH_2)_n\text{–}Fe(CO)_2Cp \quad (31)$$



(32)

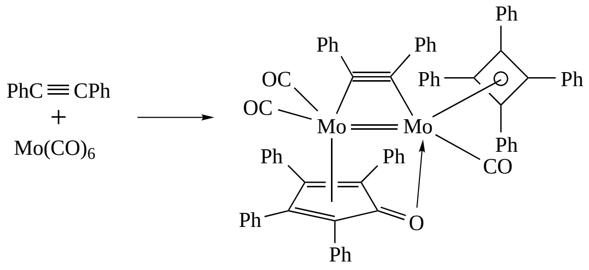
4.12 Molybdenocene, π-bound Organic Ligand-bridged Dimers

In addition to monocyclopentadienyl dimers, various molybdenocene derivatives can form dimers, as shown in equation (33). This is one example of a vast range of organic ligands that bridge metal–metal bonded complexes.[57] Another example[58] is one of the several products obtained by reaction of diphenylacetylene and molybdenum carbonyl (equation 34).



(33)

d(Mo–Mo) = 3.19 Å



(34)

To some extent, these complexes fall into the category of tethered ligand systems. One difference is the 'template' effect: they are often assembled from simpler units as opposed to the use of preformed, designed, tethered ligands. Complexes prepared in this fashion contain oligomerized organic ligands whose color and spectra indicate the presence of metal–metal bonding. A novel azulene Ru–Ru system has been prepared by metal-mediated ligand assembly.[59] The detailed mechanisms for many of these reactions remain unknown.

4.13 Carboxylate-bridged Dimers $Mo_2(OAc)_4$ and Related Complexes

Oxidation of molybdenum hexacarbonyl with acetic acid produces the carboxylate-bridged quadruple-bonded dimers, as shown in equation (35). This complex can undergo a number of substitution reactions that leave the metal–metal bond intact.[60,61]

$$Mo(CO)_6 + HOAc \longrightarrow Mo_2(OAc)_4 \quad (35)$$

The carboxylate dimers resemble, in some ways, the dimeric alkoxides with multiple metal–metal bonds. This chemistry has been extensively developed by Chisholm and coworkers.[62,63] These complexes react with CO to cleave the metal–metal bond, as shown in equation (36).

$$2Mo_2(OR)_6 + 6CO \longrightarrow Mo(CO)_6 + 3Mo(OR)_4 \quad (36)$$

While the alkoxide derivatives are viewed primarily as inorganic dimers, they undergo reactions with a number of organic compounds. In addition, a number of mixed alkyl/alkoxide complexes have been prepared. For example, compare the Mo–Mo distances in two complexes: (1) alkoxy complex $Mo_2(OCH_2\text{-}t\text{-}Bu)_6$, d(Mo–Mo) = 2.222 Å; (2) alkoxy/alkyl complex $Mo_2(O\text{-}t\text{-}Bu)_2(CH_2SiMe_3)_4$, d(Mo–Mo) = 2.209 Å. There is a clear relation between these complexes. As mentioned in the introduction and as highlighted in Scheme 1, there is a full range of characteristic reactivities being developed for metal–metal bonded dimers.

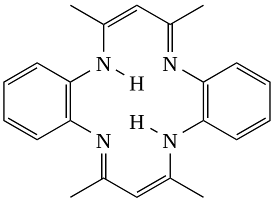
Reactions of $Mo_2(NMe_2)_6$ with *p-tert*-butylcalix[4]arenes have generated Mo≡Mo complexes incorporating that functionality.[64]

4.14 Porphyrin and Related Model Systems

Owing to their relevance to biological chemistry, metalloporphyrin (*see Metalloprotein*) complexes and their analogs have been widely studied.[65] While most of these are mononuclear, a range of metal–metal bonded porphyrins and porphyrin-like complexes also exist. For example, the acetate groups of $Mo_2(OAc)_4$ (discussed in Section 4.13) can be replaced by the porphyrin-like ring with retention of the metal–metal bond (equation 37).[66]

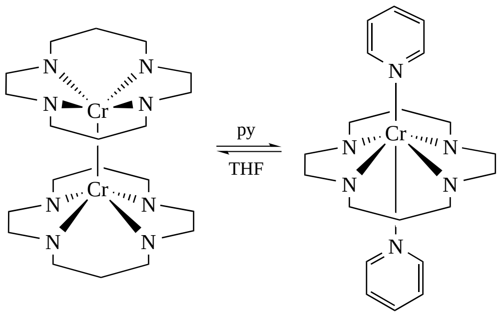
$$Mo_2(OAc)_4 + 2Li_2TMTAA \longrightarrow (TMTAA)MoMo(TMTAA)$$

H_2TMAA =



(37)

In keeping with the generally weaker bonds of first-row metals, the chromium complex in equation (38) has been shown[67] to reversibly bind pyridine with cleavage of the metal–metal bond.



(38)

True porphyrin complexes also exist for molybdenum, and their chemistry has been explored by Collman and coworkers (equation 39). Oxidation of these complexes has been shown to increase the bond order from 2.0 to 3.0 for these redox-active systems.[68]

$$\underset{2.0}{[(OEP)M]_2} \longrightarrow \underset{2.5}{[(OEP)M]_2^{+}} \longrightarrow \underset{3.0}{[(OEP)M]_2^{2+}} \quad (39)$$

A range of heteronuclear metal–metal bonded dimeric porphyrin complexes have also been prepared.[69]

4.15 Heteronuclear Complexes

The complexes discussed above have been primarily homonuclear; however, the range of complexes and their properties have been greatly expanded by work on heteronuclear dinuclear metal–metal bonded complexes (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***). These complexes can involve all combinations of main group, transition metal (both early and late), and lanthanide (*see* ***Scandium, Yttrium & the Lanthanides: Organometallic Chemistry***) and actinide (*see* ***Actinides: Organometallic Chemistry***) complexes (equations 40–42).

$$[Mo(CO)_3Cp]_2 + Co_2(CO)_8 \longrightarrow 2Cp(CO)_3Mo\text{–}Co(CO)_4 \quad (40)$$

$$3HMo(CO)_3Cp + Sn(Cp)_2 \longrightarrow HSn\text{–}[Mo(CO)_3Cp]_3 + 2CpH \quad (41)$$

$$Cp_3U\text{–}NMe_2 + HFe(CO)_2Cp \longrightarrow Cp_3U\text{–}Fe(CO)_2Cp + HNMe_2 \quad (42)$$

Particular areas of interest are the chemistry of early–late metal–metal bonded complexes,[70] main group metal–transition metal dimers,[71] transition metal carborane derivatives,[72] and lanthanide and actinide transition metal complexes.[73]

5 LITERATURE SOURCES FOR METAL–METAL BONDED COMPLEXES

The section above illustrated the range of metal–metal bonding complexes, highlighting organomolybdenum chemistry but with references to the general literature. In addition to computer-based literature searches, *Chemical Abstracts*, and Gmelin, another excellent source to bring the reader up to date is the Organometallic Chemistry volumes of Specialist Periodical Reports published by the Royal Society of Chemistry. Each year has sections on metal–metal bonds. An introduction and broad overview can be obtained from Cotton and Wilkinson's textbook on inorganic chemistry, which contains a chapter on metal–metal bonds.[30] Several texts on organometallic chemistry[74–76] also contain sections on metal–metal bonding. Listed in Table 1 are some additional references to introduce the reader to this area.

6 SYNTHETIC METHODS

A number of different routes are available for preparing metal–metal bonded dimers. The conditions used and the stability of the dimers produced vary widely. Some complexes such as $[CpW(CO)_3]_2$ are as air stable as solids and are only slowly oxidized in solution. Some, such as $[CpCr(CO)_3]_2$, are so air sensitive that they are pyrophoric when finely divided. Most of the complexes are intensely colored. The literature in this area is so vast that it is difficult to do more than just illustrate some of the proven techniques.

6.1 Nucleophilic Substitution

One of the most general methods of preparing metal–metal bonded organometallics is the reaction of metal carbonyl anions[54] with metal halides in a 'salt-elimination' reaction. The $Fe(CO)_2Cp^-$ anion has been widely used in reactions of this type (equation 43).

$$NaFe(CO)_2Cp + Cl\text{–}W(CO)_3Cp \longrightarrow Cp(CO)_2Fe\text{–}W(CO)_3Cp + NaCl \qquad (43)$$

The success of these reactions depends on the nucleophilicity of the anions used. Numerous accounts have discussed the basicity and the nucleophilicity of metal carbonyl anions and their influence on reactivity. Electrochemical studies (see Section 9.3) are particularly helpful in predicting the feasibility of reactions. The driving force for these reactions is often attributed to the precipitation of the insoluble salt. In spite of this, the free energies of reaction can be close to zero. In some cases, the metal–metal bond is cleaved by salts or an

equilibrium is established (equation 44).[122]

$$Cp(CO)_3Mo\text{–}Mo(CO)_3Cp + KBr \longrightarrow KMo(CO)_3Cp + BrMo(CO)_3Cp \quad (44)$$

In addition to displacement of halides, ligands can also be displaced by metal carbonyl anions, as shown in equation (45). These reactions need not be restricted to formation of dimers. Incorporation of the anions into existing polymetallic complexes has proven to be a general means of expanding the cluster size.

$$Na^+Co(CO)_4{}^- + Fe(CO)_5 \longrightarrow Na^+[(CO)_4Co\text{–}Fe(CO)_4]^- + CO \quad (45)$$

Controlled reduction of carbonyls often leads to dinuclear compounds. This may involve attack by the reduced species on the unreacted starting material. The complex chemistry of iron carbonyls, going back to the pioneering work of Hieber and Hein, is a good example (equation 46).

$$Fe(CO)_5 \xrightarrow{\text{base, reducing agent}} Fe_x(CO)_y{}^{n-} \quad (46)$$

6.2 Elimination of Neutral Molecules

A second major route to metal–metal complexes, related to the ‘salt-elimination’ method described above, is elimination of neutral molecules with concurrent formation of metal–metal bonded complexes. Transition metal hydrides readily undergo these dinuclear reductive elimination reactions. The oxidative addition/reductive elimination (*see Oxidative Addition* and *Reductive Elimination*) reaction of molecular hydrogen is a key reaction in this area (equation 47).

$$2H\text{–}ML_n \rightleftharpoons L_nM\text{–}ML_n + H_2 \quad (47)$$

Thermodynamically, the free energy of this reaction can be strongly negative (evolution of hydrogen to form metal–metal bond), near zero (equilibrium situation, good for a catalyst), or strongly positive (no formation of dimetallic complex, retention of metal hydride). Kinetically, the mechanism of loss of hydrogen is complex and radical intermediates are often implicated. This is reminiscent of main group metal hydride chemistry where, for example, formation of ditin complexes is catalyzed by free radical initiators, light, or trace metal catalysts (equation 48).

$$2R_3Sn\text{–}H \longrightarrow H_2 + R_3Sn\text{–}SnR_3 \quad (48)$$

In practice, it is often observed that *pure* metal hydrides reluctantly eliminate hydrogen to form dimetals. Trace impurities can generate autocatalytic reactions that rapidly evolve hydrogen. Elimination can occur between homonuclear metal compounds (equation 49) or in heteronuclear reactions (equation 50). It can also occur between main group metals and transition metals (equation 51). Under appropriate conditions, these reactions are often clean and can be used to readily generate the dinuclear complexes.

$$2H\text{–}Co(CO)_4 \longrightarrow H_2 + Co_2(CO)_8 \quad (49)$$

$$H\text{–}Co(CO)_4 + H\text{–}Mn(CO)_5 \longrightarrow H_2 + (CO)_4Co\text{–}Mn(CO)_5 \quad (50)$$

$$HSnR_3 + H\text{–}Mo(CO)_3Cp \longrightarrow R_3Sn\text{–}Mo(CO)_3Cp \quad (51)$$

A related reaction is stoichiometric hydrogenation of dienes. For example, the complexes $[(C_5R_5)M(CO)_3]_2$ (M = Cr, Mo, W) can be generated quantitatively[123] by the reaction of $H\text{–}M(CO)_3C_5R_5$ with excess cyclohexadiene (equation 52).

$$2H\text{–}M(CO)_3C_5R_5 + 1,3\text{-}C_6H_8 \longrightarrow [M(CO)_3C_5H_5]_2 + C_6H_{10} \quad (52)$$

Unlike reactions involving nucleophilic substitution that rely on polar solvents to achieve sufficient solubility of the reactants, eliminations and reactions based on hydrides have the advantage that the hydrides are often soluble in alkane or arene solvents and the dimetallic complexes are not. Thus, under favorable conditions the pure product crystallizes out of solution.

Reductive elimination of hydrocarbons or their derivatives is another viable route to metal–metal bonded systems. A good example is dinuclear reductive elimination, as studied by Bergman and coworkers (equation 53).[124] In this case, both the single and triple-bonded complexes are formed. Exposure to CO instantly converts the triple-bonded complex to the single-bonded one.

$$HMo(CO)_3Cp + EtMo(CO)_3Cp \longrightarrow EtC(O)H + Cp(CO)_3Mo\text{–}Mo(CO)_3Cp + Cp(CO_2)Mo{\equiv}Mo(CO)_2Cp \quad (53)$$

Elimination of hydrogen halides, particularly in the presence of base, is also a common reaction (equation 54). The actual mechanism of these reactions could involve nucleophilic displacement of halide by the metal carbonyl halide that is formed *in situ* from the hydride (equations 55 and 56).

$$H\text{–}ML_n + X\text{–}ML_n \xrightarrow{\text{base}} L_nM\text{–}ML_n + HX{\bullet}\text{base} \quad (54)$$

$$H\text{–}ML_n + \text{base} \rightleftharpoons ML_n{}^- + B\text{–}H^+ \quad (55)$$

$$ML_n{}^- + X\text{–}ML_n \longrightarrow L_nM\text{–}ML_n + X^- \quad (56)$$

Reaction of metal hydrides with metal–metal bonded complexes can result in transfer of hydrogen from one metal to another with concomitant formation of new metal–metal

bonds (equation 57). For example, Markó and coworkers[125] have shown that the reactions in equation (58) occur.

$$2\text{H–ML}_n + \text{J}_n\text{M}'\text{–MJ}_n \longrightarrow \text{L}_n\text{M–ML}_n + 2\text{H–M}'\text{J}_n \quad (57)$$

$$\text{H–Co(CO)}_4 + \text{Mn}_2(\text{CO})_{10} \longrightarrow \text{H–Mn(CO)}_5 + (\text{CO})_4\text{Co–Mn(CO)}_5 \quad (58)$$

Similar reactions can occur between radicals and hydrides and involve H-atom transfer, followed ultimately by formation of the most stable metal–metal bonded systems (equation 59). The mixed-metal complex formed slowly disproportionates (equation 60).

$$\bullet\text{Cr(CO)}_3\text{C}_5\text{Me}_5 + \text{H–W(CO)}_3\text{C}_5\text{H}_5 \longrightarrow \text{H–Cr(CO)}_3\text{C}_5\text{Me}_5 + \tfrac{1}{2}\text{C}_5\text{Me}_5(\text{CO})_3\text{Cr–W(CO)}_3\text{C}_5\text{H}_5 \quad (59)$$

$$\text{C}_5\text{H}_5(\text{CO})_3\text{Cr–W(CO)}_3\text{C}_5\text{H}_5 \longrightarrow \bullet\text{Cr(CO)}_3\text{C}_5\text{Me}_5 + \tfrac{1}{2}[\text{W(CO)}_3\text{C}_5\text{H}_5]_2 \quad (60)$$

It is common to observe both homonuclear and heteronuclear products since metathesis (*see Metathesis*) of metal–metal bonded complexes is a common reaction, as discussed in Section 6.6.

6.3 Condensation Reactions

Loss of a ligand from saturated metal complexes often generates highly reactive fragments. In the absence of other reaction pathways, these fragments can condense to metal–metal bonded dimers or higher-order clusters. The best example of this reaction is loss of carbon monoxide from metal carbonyls to yield dimers and clusters. For example, photogenerated $Fe(CO)_4$ species readily react with $Fe(CO)_5$ to yield $Fe_2(CO)_9$ (equation 61).

$$\text{Fe(CO)}_5 \longrightarrow \text{CO} + \text{Fe(CO)}_4 + \text{Fe(CO)}_5 \longrightarrow \text{Fe}_2(\text{CO})_9 \quad (61)$$
$$\text{Fe(CO)}_4 + \text{Fe(CO)}_5 \downarrow \tfrac{1}{3}\,\text{Fe}_3(\text{CO})_{12}$$

A competing reaction is trimerization to $Fe_3(CO)_{12}$. This process can be reversible and the dimers or clusters are suitable 'staging grounds' for breakup of the clusters. These often lead to complex equilibria, which have been investigated by Bor and coworkers for a number of systems.[126]

6.4 Ligand Substitution on Existing Metal–Metal Frameworks

A general method of extending and changing the character of metal–metal bonds is by substitution of ligands. While this type of reaction does not generate new metal–metal bonds, it can be of use in modifying the properties and reactivities of existing metal–metal bonded complexes. In particular, where more sterically demanding ligands are incorporated, the metal–metal bond strength can be expected to change (equation 62).

$$\text{Mn}_2(\text{CO})_{10} + 2\text{PR}_3 \longrightarrow (\text{CO})_4(\text{PR}_3)\text{Mn–Mn}(\text{PR}_3)(\text{CO})_4 \quad (62)$$

Replacement of the carbonyl ligand by the bulky phosphine ligands shown generally destabilizes the metal–metal bond. Kinetics of ligand substitution in dimers and clusters have been reviewed by Poe.[127]

6.5 Insertion Reactions

A number of species, such as Hg and $SnCl_2$, insert into metal–metal bonded complexes to form metal–metal bonds (equations 63 and 64).

$$[\text{Cp(CO)}_2\text{Fe}]_2 + \text{SnCl}_2 \longrightarrow \text{Cp(CO)}_2\text{Fe–SnCl}_2\text{–Fe(CO)}_2\text{Cp} \quad (63)$$

$$\text{Co}_2(\text{CO})_8 + \text{Hg} \longrightarrow (\text{CO})_4\text{Co–Hg–Co(CO)}_4 \quad (64)$$

The mechanisms of these reactions are probably complex but radical processes seem likely. The final products of insertion into the metal–metal bond are actually trinuclear species. Insertion into terminal metal–hydride or metal–alkyl bonds could, in principle, generate mixed-metal dimers. In practice, aside from insertion into the metal–halogen bond, such as that shown in equation (65), few such reactions have been reported.

$$\text{X–Co(CO)}_4 + \text{Hg} \longrightarrow \text{X–Hg–Co(CO)}_4 \quad (65)$$

6.6 Metathesis Reactions

A common reaction of metal–metal bonded complexes is σ-bond metathesis (*see σ-Bond Metathesis*), such as that shown in equation (66).

$$\text{Co}_2(\text{CO})_8 + \text{Mn}_2(\text{CO})_{10} \longrightarrow 2(\text{CO})_4\text{Co–Mn(CO)}_5 \quad (66)$$

This type of reaction has been studied by Vahrenkamp in a classic paper in this field.[128] In the majority of cases, a nearly statistical distribution of products is formed. This result implies that in most cases, the heteronuclear complexes have bond strengths that are the average of the parent homonuclear complexes. This observation also carries implications about the 'group electronegativity' of the complexes studied. The original Pauling scale of electronegativity is based on experimental enthalpies of metathesis (equation 67). If the enthalpy of this reaction is zero, then the difference in electronegativity is also zero. Thus, the results of Vahrenkamp imply a similar electronegativity for the groups studied. This is not surprising since the study focused on relatively 'soft' metal carbonyl complexes. Exceptions to this could occur for

crowded complexes where steric strain is reduced in the mixed dimer or where there are significant electronic differences between the two metals groups.

$$\text{A–A} + \text{B–B} \longrightarrow 2\text{A–B} \quad (67)$$

A second type of metathesis reaction involves metals multiply bonded to nonmetals (equation 68). In one sense, this corresponds to a special case of dinuclear reductive elimination of neutral molecules in which multiply bonded species are involved. This reaction can occur in both directions. Multiply bonded metal–metal complexes can be cleaved by multiply bonded main group species.

$$\text{M}{\equiv}\text{C} + \text{M}{\equiv}\text{C} \longrightarrow \text{M}{\equiv}\text{M} + \text{C}{\equiv}\text{C} \quad (68)$$

7 REACTIONS OF METAL–METAL BONDED COMPLEXES

Reactions of metal–metal bonded complexes can be divided into three categories: (1) cleavage of the metal–metal bond; (2) reduction in the metal–metal bond order (e.g. for multiply bonded metal species); and (3) retention of the metal–metal bond order. Dimers undergo a wide range of reactions, and it is only possible to illustrate some of them in the following sections.

7.1 Reactions that Cleave the Metal–metal Bond

7.1.1 Radical Formation

One characteristic reaction of metal–metal bonded complexes is cleavage to form radicals. In some cases, such as those shown in equations (69) and (70), an equilibrium has been shown to exist,[129–132] and the radical species in solution are readily detected spectroscopically.

$$[\text{C}_3\text{H}_5(\text{CO})_3\text{Fe}]_2 \rightleftharpoons 2\text{C}_3\text{H}_5(\text{CO})_3\text{Fe}\bullet \quad (69)$$

$$[\text{C}_5\text{H}_5(\text{CO})_3\text{Cr}]_2 \rightleftharpoons 2\bullet\text{Cr}(\text{CO})_3\text{C}_5\text{H}_5 \quad (70)$$

In other cases, the radical species cannot be detected spectroscopically but kinetic evidences for their existence and their involvement in reaction pathways is convincing (equation 71). In the case of the Rh(OEP) complex, use of bulkier groups (such as mesityl) on the porphyrin ring decreases the metal–metal bond strength and radicals can be detected and characterized.[133]

$$[(\text{OEP})\text{Rh}]_2 \rightleftharpoons 2\text{Rh}(\text{OEP})\bullet \quad (71)$$

$$\text{OEP} = \text{octaethylporphyrin}$$

Wayland and coworkers[134] have recently prepared a novel diporphyrin linked dirhodium(II) bimetallo radical complex whose ligand parameters preclude a strong metal–metal interaction but allow binuclear activation of methane and methanol.

These reactions are important in that the 17-electron radicals produced may undergo ligand substitution or additional reactions and then recombine. The rates of radical recombination are generally fast, and approach diffusion-controlled limits. This is one of the mechanisms of ligand substitution of metal–metal bonded complexes that is discussed in Section 7.3.1.

7.1.2 Photochemical Disproportionation

The photochemistry of metal–metal bonded complexes has been the subject of several reviews[135,136] (*see* ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds*** and ***Photochemistry of Transition Metal Complexes: Theory***). Strong σ bonding to σ^* antibonding transitions are often observed in metal–metal bonded systems. These lead to photogenerated fragments that undergo reactions and may ultimately recombine (equation 72).

$$\text{Mn}_2(\text{CO})_{10} \xrightarrow{h\nu} 2\bullet\text{Mn}(\text{CO})_5 \longrightarrow \bullet\text{Mn}(\text{CO})_4(\text{L}) \longrightarrow \text{Mn}_2(\text{CO})_9(\text{L}) \quad (72)$$

In many cases, parallel pathways exist for photochemical loss of ligands, particularly for CO. In addition, many of the radicals have appreciable lifetimes and can also undergo photochemical reactions. This type of reactivity can be used in designed synthesis and, possibly, photocatalysis. It also has to be guarded against since many metal–metal bonded complexes that are relatively stable, even in solutions in the presence of oxygen in the dark, are rapidly oxidized in the presence of stray light.

7.1.3 Disproportionation

In the presence of excess base, a number of metal carbonyl complexes disproportionate (equations 73 and 74).

$$\text{Co}_2(\text{CO})_8 + \text{B} \rightleftharpoons \text{CoB}_6^{2+}[\text{Co}(\text{CO})_4]_2^- \quad (73)$$

$$[\text{CpMo}(\text{CO})_3]_2 + \text{diphos} \longrightarrow \text{CpMo}(\text{CO})_2(\text{diphos})^+ + \text{CpMo}(\text{CO})_3^- \quad (74)$$

These reactions are often reversible and depend on temperature, concentration, and nature of the base. In addition, since this reaction involves changing from a metal–metal bonded system that is soluble in organic solvents to an ionic complex that is water soluble, the solubility patterns change greatly. Phase transfer catalysis (*see Phase Transfer*

Catalyst)[137] of cobalt-carbonyl reactions can utilize the water solubility of the salt and the hydrocarbon solubility of the metal–metal dimer. Ion pairing is important in the disproportionated metal complexes, and traces of water in organic solvents can not only serve as catalysts for this reaction but can also influence the equilibrium position by stabilizing the ionic products.

7.1.4 H_2 Addition

Perhaps the most important metal–metal bonded reaction from the point of view of catalysis is addition of hydrogen. In spite of years of study, the exact mechanism of hydrogenation of even dicobalt octacarbonyl is not fully understood. Oxidative addition (*see Oxidative Addition*) of hydrogen to metal–metal bonds is generally slower than oxidative addition to mononuclear complexes that have vacant sites. Two principal mechanisms have been proposed in this chemistry. The first relies on cleavage of the metal–metal bond to generate radicals (equation 75). The second mechanism involves dissociation of CO to generate a coordinatively unsaturated complex that retains the metal–metal bond (equation 76). In spite of the apparent simplicity of these two possibilities, the reaction mechanism is unknown and it is likely that parallel reaction mechanisms occur.

$$Co_2(CO)_8 \rightleftharpoons 2Co(CO)_4\bullet + H_2 \longrightarrow \text{Products} \quad (75)$$

$$Co_2(CO)_8 \rightleftharpoons Co_2(CO)_7 + CO + H_2 \longrightarrow \text{Products} \quad (76)$$

The conflict between the two general modes of reactivity of metal–metal bonded complexes (metal–metal or metal–ligand bond homolysis) is finely balanced and varies from complex to complex. The classic example in this field is illustrated by the chemistry of $M_2(CO)_{10}$ (M = Mn, Re). Using isotope labeling techniques, Muetterties and coworkers[138] were able to show definitively that in this system, it is the metal–ligand rather than the metal–metal bond that is cleaved in substitution and scrambling reactions. Phosphine substitution, however, can weaken the metal–metal bond and then, metal–metal bond cleavage becomes the favored reaction channel. Detailed kinetic study has shown that $C_5Me_5(CO)_3Cr–Cr(CO)_3C_5Me_5$ reacts with H_2 by dissociation to radicals, which then form a termolecular $Cr\bullet\cdots H_2\cdots\bullet Cr$ transition state.[139] More complex modes of splitting of hydrogen have evolved. Heterolytic cleavage of H_2 by a W–Ru-bonded sulfido-bridged dimer occurs with net H^+ addition to a terminal W=O and H^- addition to Ru. During this process, the metal–metal bond is retained.[140]

7.1.5 Reduction

In most cases, the metal–metal bond is cleaved by reducing agents. Dilute sodium amalgam is often used to generate anion radicals from organometallic dimers (equation 77). In addition to Na/Hg, other reducing agents such as Na/benzophenone, or even other metal carbonyl anions, have been used to reduce a metal–metal bond.

$$Mn_2(CO)_{10} + \text{Na/Hg} \longrightarrow 2NaMn(CO)_5 \quad (77)$$

7.1.6 Oxidation

Organometallic complexes of any type are thermodynamically unstable with respect to oxidation and this is true of metal–metal bonded complexes as well. Reaction with oxygen or chlorine will ultimately lead to the metal oxide or chloride. Milder oxidizing agents cleave the metal–metal bond selectively, leaving the other bonds intact. For example, reaction with iodine is often a fast, clean reaction (equation 78).

$$[Cp(CO)_3M]_2 + I_2 \longrightarrow 2I–M(CO)_3Cp \quad (78)$$
$$M = Cr, Mo, W$$

Related reactions using similar 'soft' oxidants, such as disulfides, are also common (equation 79).

$$[Cp(CO)_2Fe]_2 + RSSR \longrightarrow RS–Fe(CO)_2Cp \quad (79)$$

7.2 Reactions That Reduce the Metal–metal Bond Order

For metal–metal bonded complexes that contain multiple bonds, addition of ligands can reduce the bond order but does not have to destroy the metal–metal interaction entirely. The reactions shown below are written in the forward direction, which highlights addition reactions leading to a loss in multiple-bond character. It should be kept in mind that these are often in equilibria, and ligand elimination in the reverse direction can be a source of the multiply bonded species.

Addition of the ligand can occur at both metals, as shown in equations (80) and (81). Interestingly, addition of triphenylphosphine sulfide does not proceed to yield products on both metals but an unsymmetrical product is formed (equation 82).

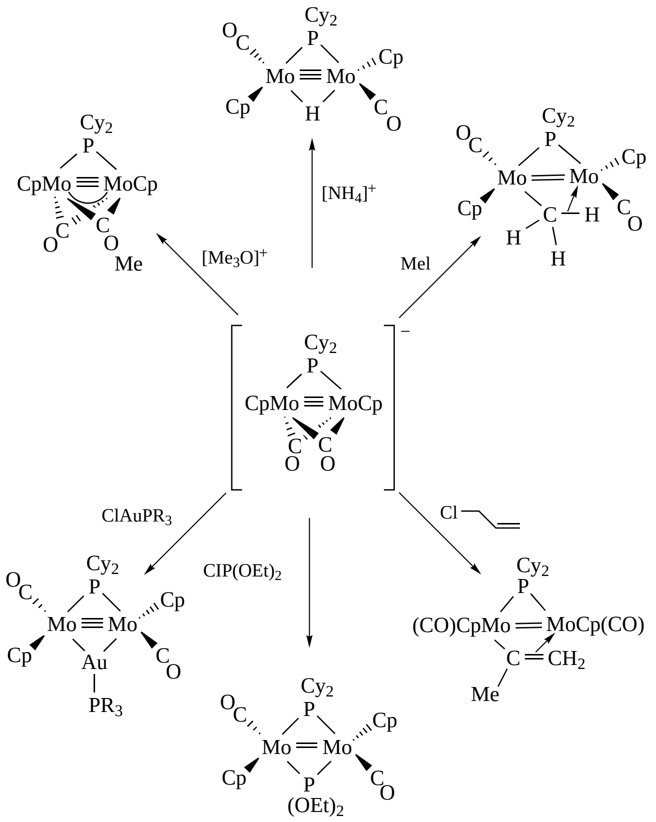
$$M_2(OR)_6 + 2L \rightleftharpoons M_2(OR)_6(L)_2 \quad (80)$$
$$L = \text{P or N donor}$$
$$M = Mo, W$$

$$Cp(CO)_2M{=}M(CO)_2Cp + 2L \rightleftharpoons CpM(CO)_2(L)M–M(CO)_2(L)Cp \quad (81)$$
$$L = PR_3, CO$$
$$M = Cr, Mo, W$$

$$Cp(CO)_2Mo{\equiv}Mo(CO)_2Cp + 2L \rightleftharpoons CpM(CO)(L)_2Mo–Mo(CO)_3Cp \quad (82)$$
$$L = PPh_3S$$

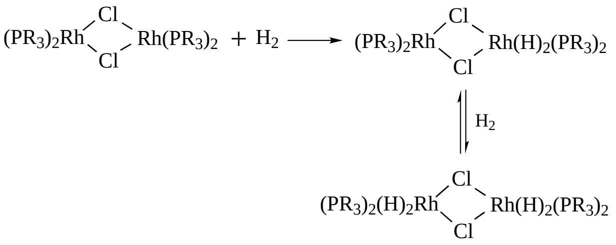
A range of complicated reactions can occur between metal–metal multiply bonded complexes and ligands that

also have multiple bonds. The reader is referred to the review by Curtis[44] for numerous examples. The triply bonded dimolybdenum carbonyl anion has been shown to undergo a range of reactions, as displayed in equation (83).[141]



(83)

It is well known that the chlorine-bridged dimeric complex (which does not contain a metal bond) obtained from Wilkinson's catalyst can react via stepwise addition of H_2 to rhodium (equation 84) (*see* ***Rhodium: Organometallic Chemistry***).



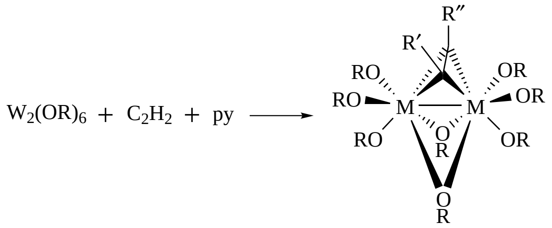
(84)

It is likely that metathesis reactions, such as those shown in equations (85) and (86), proceed through intermediates with reduced metal–metal bond order.

$$W_2(OR)_6 + RC{\equiv}CR \longrightarrow 2(RO)_3W{\equiv}CR \quad (85)$$

$$W_2(OR)_6 + RC{\equiv}N \longrightarrow (RO)_3W{\equiv}N + (RO)_3W{\equiv}CR \quad (86)$$

Addition of pyridine and acetylene results in generation and trapping of the complex shown in equation (87), which has a reduced bond order. In this complex, the acetylene bridges the two metals.[142] This type of chemistry was initially developed by Schrock and coworkers for alkyne metathesis (*see Alkyne Metathesis*) reactions[143] but has been subsequently developed by a number of other researchers.



(87)

7.3 Reactions That Retain the Metal–metal Bond Order

7.3.1 Ligand Substitution Mechanisms for Dimers

The topic of ligand substitution was discussed above in the context of ways of generating different metal–metal bonded complexes from existing ones. Ligand substitution is one of the most fundamental reactions of mononuclear organometallic compounds. Ligand binding, transformation, and exchange are all key elements of catalytic cycles. For dinuclear complexes, ligand exchanges that take place while retaining the metal–metal bond occur by a range of mechanisms. This section will outline some of them. It is well to keep in mind that reaction mechanisms cannot be proven: evidence supporting them or ruling out other pathways is all that can be provided. There are a number of mechanisms for ligand substitution, and sometimes, it is difficult to tell the operational differences between them. Furthermore, where several mechanisms are possible, complexes can follow more than one reaction channel. Several groups (nitrosyl, indenyl) are known to accelerate reactivity by a change in the donor ability of the ligand at the transition state. Metal groups could play a similar role, but the influence of a second metal on ligand substitutions is still not well understood. In the discussion below, the complex $Mn_2(CO)_{10}$ is used to illustrate possible mechanisms.

Dissociative Loss of a Ligand Followed by Uptake of the New Ligand. In this type of mechanism, the metal–ligand bond is broken and the metal–metal bond remains intact (equation 88). It is expected to show an activation energy reflective of the metal–ligand bond strength. The proposed intermediate, $Mn_2(CO)_9$ in this example, could be partially stabilized by an increase in the Mn–Mn bond strength upon loss of CO. This might not be reflected in the transition state, however, since loss of ligand might precede any increase in metal–metal bonding. The major differences between substitution of the dimer and a comparable monomer would be (1) possible stabilization of the transition state via a partial

multiple bond and (2) steric crowding in the ground state.

$$(CO)_5Mn\text{–}Mn(CO)_5 \longrightarrow CO + Mn_2(CO)_9 + L \longrightarrow Mn_2(CO)_9(L) \quad (88)$$

Associative Ligand Displacement. In the same way that mononuclear complexes can undergo both associative and dissociative ligand displacement, dinuclear complexes can be expected to show the same type of behavior. These reactions would be expected to show more favorable enthalpies of activation than pure dissociative reactions but less favorable entropies of activation (equation 89).

$$Mn_2(CO)_{10}L \longrightarrow Mn_2(CO)_{10}(L) \longrightarrow Mn_2(CO)_9(L) + CO \quad (89)$$

Owing to concentration effects, the solvent can also participate in this second order displacement, as shown in equation (90). The presence of a metal–metal bond may or may not stabilize such an associative transition state. Steric factors would probably argue against such stabilization, especially for first-row complexes.

$$Mn_2(CO)_{10} + S \longrightarrow Mn_2(CO)_{10}(S) \longrightarrow Mn_2(CO)_9(S) + CO \downarrow Mn_2(CO)_9(L) \quad (90)$$

Cleavage of the Metal–metal Bond into Radical Fragments. In cases where the metal–metal bond is weaker than the metal–ligand bond, fragmentation of the complex into two radicals is preferred over ligand dissociation (equations 91–93).

$$(CO)_5Mn\text{–}Mn(CO)_5 \longrightarrow 2{\bullet}Mn(CO)_5 \quad (91)$$

$${\bullet}Mn(CO)_5 + L \longrightarrow {\bullet}Mn(CO)_4L + CO \quad (92)$$

$${\bullet}Mn(CO)_5 + {\bullet}Mn(CO)_4L \longrightarrow Mn_2(CO)_9L \quad (93)$$

The 17-electron species (*see Seventeen Electron Configuration*) formed can undergo rapid substitution since associative pathways of low activation energy exist for them. Recombination of the substituted fragments can yield the monosubstituted, disubstituted, or more fully substituted complexes. The rate-determining step would be cleavage of the metal–metal bond since all other steps are relatively fast. This pathway may be preferred for photochemical substitution. Clearly, this pathway is not open to mononuclear analogs. The reactivity of low valent metal radical complexes has been reviewed.[144]

Cleavage of Metal–metal Bond to Ion Pairs. In polar solvents, heterolytic cleavage to anion/cation complexes is an equilibrium process. This can also be involved in substitution reactions in polar solvents (equations 94 and 95). Substitution at the cation is shown here since, for carbonyl ligands, due to a decrease in back bonding (*see Back Bonding*), the cationic carbonyl complexes often undergo more rapid substitution. Recombination by anion/cation pair annihilation will regenerate the metal–metal bonded complex. This process can yield polar metal–metal bonded complexes, referred to as 'xenophilic', between hard open-shell Werner-type complexes and softer metal carbonyl anions.[145]

$$(CO)_5Mn\text{–}Mn(CO)_5 + S \longrightarrow Mn(CO)_5(S)^+ + Mn(CO)_5^- \quad (94)$$

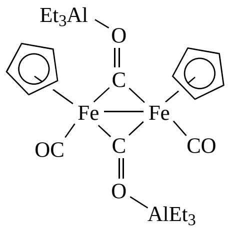
$$Mn(CO)_5(S)^+ + L \longrightarrow Mn(CO)_5(L)^+ + Mn(CO)_5^- \longrightarrow Mn_2(CO)_9(L) \quad (95)$$

Cleavage of the Metal–metal Bond to 17- and 19-electron Fragments. A final mechanistic possibility involves cleavage, either photochemically or thermally, of the metal–metal bond to 17- and 19-electron fragments (*see Nineteen Electron Configuration*). This is ligand induced and differs somewhat from the normal dissociative mechanism that generates 17-electron species. Initially, mechanisms involving 19-electron intermediates were met with skepticism. Evidence supporting them has grown to the point that they are now well accepted, particularly due to the work of Tyler and coworkers.[146]

7.3.2 Reactions at Coordinated Ligands of Dimers

For mononuclear complexes, reactions at coordinated ligands is a topic of major study, and numerous reviews and even books have been written on this topic.[147] At the time of writing this review, the authors could find no major review articles in this area for dinuclear compounds. The best examples are probably those on the reactions of coordinated molybdenum sulfides discussed earlier. A related observation is the reaction of metal carbonyls with Lewis acids. It has been observed by Shriver and coworkers[38] that carbonyl ligands bridging metal–metal bond atoms show increased tendency to coordinate Lewis acids (equation 96).

$[Co(CO)_2Fe]_2 + Et_3Al \longrightarrow$



(96)

8 METAL DIMERS AS CATALYSTS AND CATALYST PRECURSORS

A principal motivation in the study of dinuclear organometallic complexes is the hope that they can accomplish catalytic reactions that are not achievable by mononuclear complexes. There are a number of cases where metal–metal complexes are catalysts precursors. The most famous is

Table 2 Processes that could be catalyzed by metal dimers and clusters[148]

Alkene isomerization	Reduction of CO and ketones
Alkene hydrogenation	Hydroformylation
Ketone hydrogenation	Fischer–Tropsch synthesis
Hydrogenation of cyanides	Synthesis of methanol from CO
Hydrogenation of nitro group	Hydrogenation of amides
Alkyne hydrogenation	Alkyne cyclization
Aminomethylation	Hydroxymethylation
Water gas shift reaction	

dicobalt octacarbonyl, which can be used in the Oxo Process (*see Oxo Process*) but which is probably not itself involved in the catalytic cycle, except as a dead-end by-product of certain loops.

It should be kept in mind that it is often difficult to ascertain what the active catalyst is. There are, in fact, very few proven catalytic mechanisms where the structure of the actual catalyst is known with certainty. There are, to the author's knowledge, few, and possibly no, *proven* useful homogeneous catalytic processes that involve metal dimers *in the catalytic cycle*. In an excellent review on cluster catalysis, Muetterties[148] lists the following processes as metal-cluster-catalyzed reactions (see Table 2). This review also lists the important classes of metalloenzyme clusters; however, these compounds do not normally involve metal–metal bonds per se but are usually bridged by chalcogens, such as sulfur or oxygen donors.

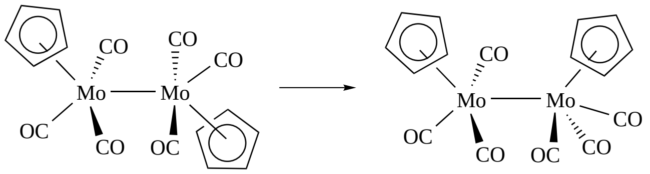
For a dimer or cluster to be the active catalyst, it must survive the catalytic reaction conditions of the system. These are often high pressure and high temperature. At high temperatures, entropic factors will favor cleavage of the metal–metal bond into radical fragments. In view of the increase in metal–metal bond strength in going from first to second to third row metals (see below), the heavier congeners show the greatest promise for the development of robust dinuclear catalysts. In addition, high pressures of CO and H_2 or other reactants provide an additional pathway for decomposition. Bridging ligands (*see Bridging Ligand*) will increase the thermodynamic stability of the dimer or cluster in the face of these conditions. Thus, in general, the best prospects for genuine catalysis by homogeneous dimers and clusters is, under mild conditions and using either second or third row metals, preferably with bridging ligands. Photochemical activation, provided the metal–metal bond is not cleaved in the process, would also meet these conditions.

9 PHYSICAL PROPERTIES OF METAL–METAL BONDED DIMERS

9.1 Structural Studies

Definitive proof of metal–metal bonding usually relies on X-ray crystallography (*see* ***Diffraction Methods in Inorganic Chemistry***). Development of this field has accelerated greatly since the advent of modern structural techniques. This is such a widely used physical measurement that it is now considered routine.

While solid-state structures are readily generated by crystallography, evidence for structures in solution is usually generated by spectroscopic techniques. Rotation about the metal–metal bond of single-bonded dimers has been studied extensively by NMR and IR (*see* ***Structure & Property Maps for Inorganic Solids***). For example, the complex $[Mo(CO)_3Cp]_2$ exists as anti and gauche isomers that interconvert (equation 97).



(97)

As the physical database increases, it can be expected that computer calculation of molecular conformations will play an increasing role in this chemistry. From the beginning, molecular orbital calculations have played a strong role in assessing the nature of the metal–metal bond. While molecular mechanics calculations have played a large role in organic chemistry and biochemistry, they have yet to play a prominent role in metal–metal bonded chemistry. It can be anticipated that this area will experience rapid development in the near future.

9.2 Spectroscopic Studies

The metal–metal bond is normally a strong chromophore, and nearly all metal–metal bonded dimers are strongly colored. Electronic transitions from bonding to antibonding orbitals are normally of low energy and have high extinction coefficients. The photochemistry of these complexes is discussed in several reviews.[135] The electronic transition in complexes such as that shown in equation (98) has been used to estimate that the strength of the δ-bond is on the order of $10\,\text{kcal mol}^{-1}$.[149]

$$Re_2Cl_8^{2-} \xrightarrow{h\nu} \text{excited state} \qquad (98)$$

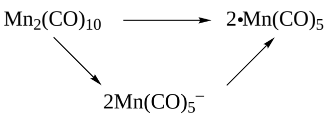
Photoelectron spectroscopy (*see* ***Photoelectron Spectroscopy of Transition Metal Systems***) has also been applied to gain information about metal–metal bonding. For example, the metal–metal bonded complexes $M_2(OR)_6$ (M = Mo, W) show clearly defined ionizations attributed to the σ-orbital as well as to the π-orbital manifold.[150]

Finally, vibrational spectroscopy has been used to measure metal–metal force constants using both IR and Raman spectroscopy. In general, the metal–metal bond stretching frequencies are in the 100 to $500\,\text{cm}^{-1}$ region and vibrational

studies in this area are difficult to conduct. For that reason, this area of research is largely restricted to specialists. The reader is referred to literature treatment of this topic by Maslowsky[151] as well as the book on IR spectroscopy by Nakomoto.[152]

9.3 Electrochemical Studies

As discussed above, reduction of metal–metal bonded complexes is common, particularly for carbon monoxide–substituted complexes. The electrochemical potential of these reactions has been widely studied (*see* ***Electrochemistry: Applications in Inorganic Chemistry***). In addition, Meyer[153] has shown that the metal–metal bond strength can be estimated via electrochemical techniques. The results applied to $Mn_2(CO)_{10}$ are in agreement with values obtained by other methods and could provide a means of generating a wide range of metal–metal bond strengths. The legs of the electrochemical cycle are shown in equation (99).



(99)

Concerted two-electron transfer and reversible metal–metal bond cleavage in phosphine-bridged dimers have been investigated, and extended Hückel molecular orbital calculations have shown that the redox-active orbital is a metal–metal antibonding orbital.[154] A Ru–Ru-bonded dimeric cation $[Ru(Cp)2]_2^{++}$ has been prepared and characterized electrochemically.[155] The electrochemistry of these dimers may give insight into more complex clusters and polymeric metals.

9.4 Thermochemical and Kinetic Studies

A key question in determining the thermodynamic stability of dimers and clusters is the strength of the metal–metal bond.

Table 3 Selected estimates of metal–metal bond dissociation enthalpies

Complex	D (kcal mol^{-1})
$[Cr(CO)_3C_5H_5]_2$[131]	15
$[Cr(CO)_3C_5Me_5]_2$[131]	14
$[Cr(CO)_2\{P(Ome)_3\}C_5H_5]_2$[131]	12
$[Mo(CO)_3C_5H_5]_2$[156]	33
$[W(CO)_3C_5H_5]_2$[157]	56
$Mn_2(CO)_{10}$[158]	38
$[Fe(CO)_2C_5H_5]_2$[159]	27
$[Fe(CO)_3(\eta\text{-}C_3H_5)]_2$[160]	14
$Hg[Cr(CO)_3C_5H_5]_2$[131]	20
$[Ru(OEP)]_2$[161]	17
$[Mo(CO)_2C_5H_5]_2$[162]	69
$Mo_2(O_2Cme)_4$[163]	77
$Mo_2(NMe_2)_6$[164]	95

This corresponds to the enthalpy of dissociation (step (i) in equation 100).

$$L_nM\text{–}ML_n \underset{}{\overset{(i)}{\rightleftharpoons}} 2{\bullet}ML_n + 2S \overset{(ii)}{\rightleftharpoons} 2{\bullet}ML_n(S) \qquad (100)$$

In view of the apparent propensity of 17-electron radicals to be in equilibrium with 19-electron adducts, it must always be considered, particularly in solvents such as THF or EtCN, that solvation of the radicals occurs. In view of the general increase in metal–ligand bond strength in going from first to second to third row transition metals, such solvent coordination would seem, most likely, to occur for the heavier analogs. It is difficult to determine whether the process involved in an apparent homolysis is only due to step (i) in equation (100) or due to additional solvolysis. The metal–metal bond strengths listed in Table 3 have been derived in various ways. These include kinetic values for enthalpies of activation, direct spectroscopic measurement of the monomer/dimer equilibrium, as well as more indirect thermochemical analysis. These are meant to provide only a rough guide, and the reader is referred to the original literature for more detailed treatment. One important point is that, in addition to enthalpic (bond strength) factors, the entropy of formation of metal–metal bonded complexes can vary significantly from that predicted on the basis of the Sakur–Tetrode equation alone. Thus, particularly for first-row metals, hindered rotation about the metal–metal and metal–ligand bonds can result in entropic forces that favor dissociation. This influence appears to be most severe for first-row metals due to the shorter metal–metal bond length.

1 INTRODUCTION

Dioxygen (O_2) constitutes 21% by volume (23% by weight) of the earth's atmosphere, plus a significant quantity of dioxygen is dissolved in surface waters. This ready availability, along with the properties of dioxygen (*see* ***Oxygen: Inorganic Chemistry***), especially its ability to accept electrons, is exploited by organisms that are dependent on O_2 for life. Thus, aerobic organisms have developed mechanisms to transport, store, and activate dioxygen (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases*** and ***Copper Proteins: Oxidases***).[1] Nearly all of these mechanisms utilize proteins that incorporate one or more transition metals at their functional active sites, that is where O_2 binds and/or reacts. These metalloproteins contain one of several known metal–dioxygen interacting sites.[2,3] Examples include a single iron-heme center in hemoglobin and myoglobin (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***), a dinuclear iron nonheme active site in hemerythrin, the dicopper-containing hemocyanin (*see* ***Copper Proteins with Dinuclear Active Sites***), and a heterodinuclear site in cytochrome *c* oxidase (*see* ***Copper Proteins: Oxidases***), which features both a heme-iron center as well as a nonheme copper center in its active site. Model complexes that mimic biological processes like dioxygen binding and activation (*see* ***Copper: Hemocyanin/Tyrosinase Models***, ***Iron: Models of Proteins with Dinuclear Active Sites***) can help us understand what might be occurring at the metal centers in those complicated biological systems, and can also be developed for practical applications, such as the separation of dioxygen from the air.[4] Transition-metal catalysts that use dioxygen or related species as an oxidant[5,6] are also involved in many industrial processes (*see* ***Oxidation Catalysis by Transition Metal Complexes***). The interaction of dioxygen with metals is important to these systems as well as to the development of O_2 sensors[7] plus fuel cells, batteries, and electrocatalysts (*see* ***Electrochemistry: Applications in Inorganic Chemistry***).[8] Therefore, it is not surprising that studies of the interaction and activation of dioxygen at metal sites have occupied and fascinated researchers for quite some time.

Metal–dioxygen adducts have been known for more than a hundred years, for example, in 1898, Werner and Mylius reported[9] the Co^{III} complex $[\{(NH_3)_5Co\}_2O_2]^{4+}$. Thirty-eight years later, a Pauling and Coryell paper[10] sparked considerable interest in metal–dioxygen binding; this paper concluded that 'the oxygen molecule undergoes a profound change in electronic structure on combination with hemoglobin.' Another milestone in metal–dioxygen chemistry was the discovery by Vaska of the 1:1 reversible oxygen carrier $IrCl(CO)(PPh_3)_2$ (Vaska's complex), because the resulting dioxygen complex was extremely stable compared to previously known dioxygen adducts and, thus, provided the first crystal structure of a dioxygen complex.[11] Most d-block metals have been found to bind dioxygen, resulting in complexes with a range of oxidation states (from I to VI) and d electron counts (from 0 to 9) and a variety of coordination modes of the dioxygen-derived ligand (discussed below).[12]

2 PROPERTIES OF DIOXYGEN AND RELATED SPECIES (*See also Oxygen: Inorganic Chemistry*)

Dioxygen is a paramagnetic molecule whose electronic ground state is a triplet ($^3\Sigma_g{}^-$) in which two unpaired electrons occupy degenerate antibonding orbitals ($2p\pi^*$). Dioxygen is considered to contain a formal oxygen–oxygen double bond (Table 1). Even though dioxygen is thermodynamically a powerful oxidant, it is kinetically fairly inert because, in order to conserve spin, its diradical character requires that it reacts with another radical (which often involves one or more highly endothermic steps) or forms a product that possesses a triplet ground state.[13] Owing to the rarity of the latter process, the major reactivity pathways of dioxygen usually involve radicals (for instance, by using transition metals with unpaired electrons) or require excitation to singlet oxygen (described below). In addition, dioxygen has a fairly low solubility in water (with a 1 atm or ~45 mmol dioxygen vapor phase, the solution concentration is about 1 mmol).

The first electronic excited state ($^1\Delta_g$) for O_2 is 23 kcal mol^{-1} above the ground state and is a singlet state (no unpaired electrons); the electronic configuration is the same as the ground state except that one of the two previously unpaired $2p\pi^*$ spins has been flipped and paired with the other one. This species, simply referred to as singlet oxygen,

Table 1 Information about dioxygen and related species

Species	Bond order	O–O distance (Å)	υ(O–O) (cm^{-1})	Bond energy (kcal mol^{-1})
Oxygenyl in $[O_2^+][AsF_6^-]$	2.5	1.12	1858	149.4
Triplet O_2 ($^3\Sigma_g^-$)	2	1.21	1555	117.2
Singlet O_2 ($^1\Delta_g$)	2	1.22	1484	94.7
Superoxide in $[K^+][O_2^-]$	1.5	1.34	1145	
Peroxide in $[Na^+]_2[O_2^{2-}]$	1	1.49	794	48.8
Peroxide in H_2O_2	1	1.46	880	34.3

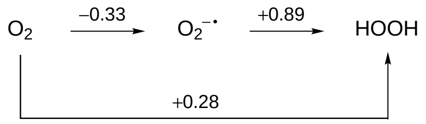

Figure 1 Standard reduction potentials for dioxygen species in water [1 atm O_2, pH 7, V vs. NHE]

has a half-life in water of about 2 µs and is very reactive. The enhanced reactivity of singlet oxygen versus ground-state oxygen is due to the fact that two of the barriers associated with the ground state have been overcome: the problem of matching electron spin is discussed above and the problem of adding an electron to an already occupied orbital is mentioned below. In fact, singlet oxygen has been estimated to be one volt more oxidizing than ground-state oxygen, which makes it more electrophilic and potentially useful, for instance, in chemical synthesis and wastewater treatment.[14] Most reactions of O_2 with transition metals use ground-state oxygen, although there have been some studies with singlet oxygen, which, in many cases, is quenched by the complex.

Simple reduction of dioxygen by one electron to produce the superoxide ion (O_2^-) is thermodynamically unfavorable (Figure 1); it requires adding an electron to a half-filled antibonding orbital. Reduction to peroxide (i.e. O_2^{2-}), however, is downhill, both from superoxide and dioxygen. Owing to the increased population of antibonding orbitals in reduced O_2 species, the O–O bond order decreases, the O–O distance increases, and the O–O stretch decreases compared to dioxygen (Table 1).

3 TRANSITION METAL–DIOXYGEN COMPLEXES OVERVIEW

The synthesis of transition metal–dioxygen complexes is often carried out by the addition of dioxygen to a precursor complex. Binding involves some shift of electron density from the metal to the O_2 ligand, generally regarded as resulting in either a superoxo (one-electron reduced or superoxide-like) or peroxo (two-electron reduced or peroxide-like) ligand when the O–O bond remains intact. Consistent with this, metal–O_2 complexes have also been synthesized from superoxide or peroxide sources.

Spectroscopic methods are used to decide whether the complex is best described as containing a superoxo or peroxo ligand. This is typically done by comparing the oxygen–oxygen vibration [υ(O–O)] obtained by infrared and/or Raman spectroscopies and/or the O–O distance, usually acquired from an X-ray crystallographic structure determination, to data for the ionic oxygen species (Table 1). There has been some discussion of this system and of assignment of oxidation states in metal–dioxygen complexes.[15]

A classification scheme devised by Vaska was used to describe the earliest dioxygen complexes: type I for superoxo and type II for peroxo, with the additional descriptors a and b to represent mononuclear and dinuclear binding, respectively. Because other binding modes are now known that cannot easily be distinguished using Vaska's system, an alternative more descriptive nomenclature has since been adapted (Figure 2). In this system, μ (mu) signifies a bridging dinuclear M_2O_2 (M = metal center) species with a numerical subscript added if the ligand bridges more than two metal centers, for example, μ_4 signifies bridging of the indicated ligand between four metal ions. In addition, the binding mode is delineated: η_1 (eta-one or monohaptic) indicates a monodentate O_2 (one oxygen atom is bound to one metal ion, sometimes referred to as *end-on coordination*) and η^2 (eta-two or dihaptic, sometimes called *side-on binding*) designates bidentate O_2 (both oxygen atoms are bound to the same metal center). The binding mode does not indicate the reduction state of the dioxygen ligand, for instance, both superoxo and peroxo η^2-O_2 and *trans*-μ-η^1:η^1-O_2 complexes have been reported (*trans* indicates that the two metal centers are diagonally located on opposite sides of the O_2 ligand and *cis* signifies that the metal centers are on the same side of the O_2 ligand). Therefore, superoxo or peroxo is also stated to fully describe the metal–dioxygen interaction in a complex.

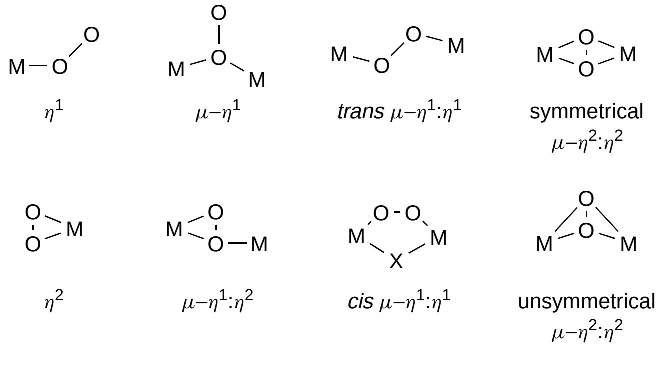

Figure 2 Mononuclear and dinuclear metal–dioxygen binding modes

In general, superoxide complexes exhibit υ(O–O) between about 960 and 1200 cm^{-1} and usually contain planar metal–O_2 units with O–O distances usually falling between about 1.20 and 1.35 Å, whereas peroxide complexes result in υ(O–O) between 650 and 950 cm^{-1} and typically have nonplanar metal–O_2 units with longer O–O distances, typically between ~1.38 and 1.55 Å, although there are a few exceptions to these generalities. Mononuclear superoxide and peroxide complexes usually give higher υ(O–O) values within those ranges and dinuclear dioxygen-containing complexes typically result in lower υ(O–O) values, with the μ-η^1:η^1 systems giving greater magnitude of υ(O–O) than the μ-η^2:η^2 systems.[16] For some time, all metal–dioxygen complexes were thought to exhibit υ(O–O) greater than 800 cm^{-1} and, in fact, most M–O_2 complexes do give υ(O–O) values above 800 cm^{-1}, with the notable exception of some μ-η^2:η^2-peroxo complexes (discussed in more detail below). In addition, an equilibrium between the μ-η^2:η^2-peroxo and bis(μ-oxo) species (equation 1) has been demonstrated in Cu_2O_2 complexes (discussed below).[17]

(1)

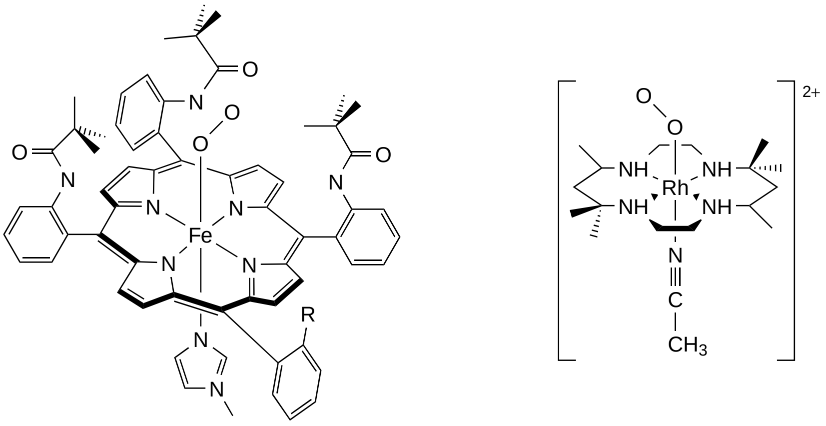
4 EXAMPLES OF SUPEROXO COMPLEXES

4.1 η^1-superoxo Complexes

Many of the structurally characterized η^1-superoxo complexes are cobalt containing, or are iron complexes with sterically hindering porphyrins. Co^{II} compounds often react with dioxygen to form mononuclear superoxo complexes, although frequently further reaction occurs to form binuclear peroxo-bridged species.[18] Therefore, 1:1 adducts are often isolated by working quickly at low temperatures and/or at high dilution to prevent reaction with a second metal center. The typical O–O distances are from 1.21 to 1.35 Å, M–O–O angles from 115 to 135°, and υ(O–O) are of 1100 to 1220 cm^{-1}. Representative examples of this 'end-on' coordination mode include Fe(picket fence porphyrin)(MeIm)(O_2)[19] [picket fence porphyrin = *meso*-tetrakis(α, α, α, α-*ortho*-pivalamidophenyl); MeIm = 1-methyl-imidazole] and the superoxorhodium^{III} complex containing an N_4-macrocyclic ligand shown in Figure 3,[20] plus a Cu^{II} complex with a hydrogen-bonded superoxo ligand.[21] In addition, oxy-myoglobin and oxy-hemoglobin appear to have η^1–superoxo dioxygen ligands with O–O vibrations occurring at 1103 and 1132 cm^{-1}, respectively. Disorder of the dioxygen ligand is a common occurrence in crystal-structure determinations, especially with this type of dioxygen complex, and must be treated carefully or unrealistic O–O bond lengths may result (e.g. ≤1.10 Å). This binding mode is also found for some hydroperoxide or alkyl peroxide complexes.

4.2 η^2-superoxo Complexes

This binding mode for dioxygen complexes is almost invariably seen in complexes that also incorporate multidentate supporting ligands. Thus, this binding mode is found in the substituted tris(pyrazolyl)hydroborate (Tp) ligated Sm^{III} and Co^{II} complexes[22,23] shown in Figure 4 as well as in the Tp–Cr^{III} and V^V complexes that have been recently reported.[24,25] The Co^{II} superoxo complex (Figure 4(b)) is generated by addition of dioxygen to a Co^I dinitrogen precursor complex. Interestingly, this complex displays a υ(O–O) that is more consistent with a peroxo ligand, although the O–O



R = NC(O)C(CH_3)$_3$
O–O 1.24(8) Å
<Fe–O–O 136(4)°

O–O 1.306(5) Å
<Rh–O–O 115.3(3)°

Figure 3 Examples of η^1-superoxo complexes

Ni–O 1.956(5) Å	υ(O–O) 832 cm^{-1}
υ(O–O) 1096 cm^{-1}	

Figure 5 Examples of μ-η^1:η^1-O_2 complexes with similar ancillary ligands: Ni^{II}_2-bis(superoxo) complex (a) and Cu^{II}_2-peroxo complex (b)

distance is reasonable for a superoxo ligand. If the substituents on the Tp ligand directed at the cobalt ion are changed from *tert*-butyl to *iso*-propyl groups, a similar monomeric complex is formed that dimerizes to form a complex with two *trans*-μ-η^1:η^1 superoxo ligands.[23]

4.3 μ-η^1-superoxo Complexes

The μ-η^1-superoxo binding mode is uncommon, occurring in the aluminum compound $[(Me_3Al)_2O_2]^-$ shown in Figure 4(c).[26] The spectrochemical data for this compound fit a peroxo ligand instead of the superoxo ligand that it must be to make chemical sense, reminding us that oxidation states and levels of reduction are just bookkeeping and may be an oversimplification (or that this ligand is actually μ-OOH^-). This mode of bonding is more commonly seen for a different class of compounds where the dioxygen is protonated or alkylated (i.e. a bridging hydroperoxide or alkylperoxide ligand).

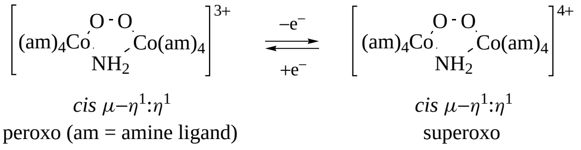
4.4 *Trans*-μ-η^1:η^1-superoxo Complexes

These are often referred to as *trans*-μ-1,2 complexes. The superoxo *trans*-μ-η^1:η^1-O_2 complexes typically give υ(O–O) in the range 1000 to 1100 cm^{-1} and O–O bond distances between 1.24 and 1.36 Å and the dioxygen moiety is generally planar (dihedral angle, $\Phi = 180°$). Examples are the tetrameric superoxo complex $[O_2\{Co(F{-}salen)(H_2O)\}_2]_2$ [F−salen = *N*,*N*′-ethylenebis(3-fluorosalicylideneiminato)] that has a dihedral angle of 122° and an O–O distance of 1.31 (3) Å and the Ni^{II}_2-bis(superoxo)

complex shown in Figure 5 that was generated in an unusual reaction from a $Ni^{III}{}_2$-bis(μ-oxo)$_2$ complex.[27]

4.5 *Cis*-μ-η^1:η^1-superoxo Complexes

These complexes are doubly bridged, with an $O_2{}^-$ group as well as one or more other bridging ligands, often an amide ($NH_2{}^-$), hydroxo (OH^-), or alkoxo (OR^-, R = alkyl or aryl group) ligand. The O–O distances in these complexes are similar to those found in the corresponding *trans*-μ-η^1:η^1-superoxo complexes, with planar metal$_2$–superoxo groups ($\Phi = 0°$). Most of the reported *cis*-μ-η^1:η^1-superoxo complexes contain cobalt and interconversions between the superoxo and peroxo complexes have been reported (e.g. equation 2).[28]



(2)

5 EXAMPLES OF PEROXO COMPLEXES

5.1 η^2-peroxo Complexes

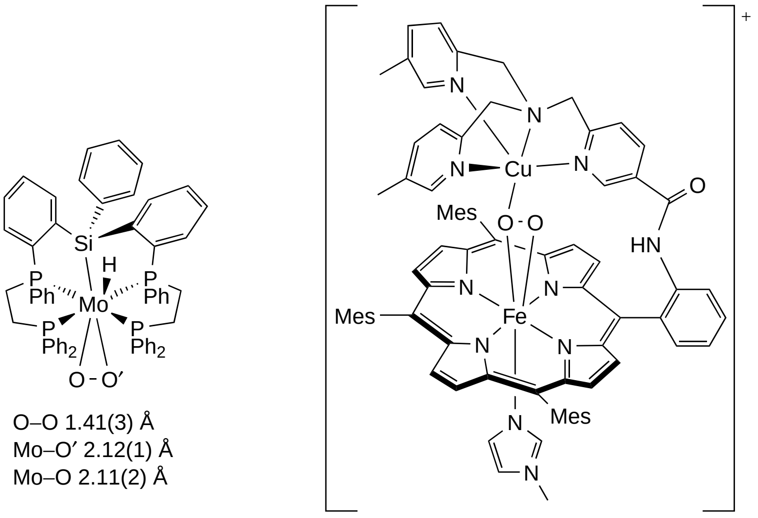
This is a very common binding mode for transition metal complexes, found for a variety of metals including members of all three periods of d-block elements as well as early metals such as Ti, V, Nb, and Ta and late metals like Ir, Ni, Pd, and Pt. Usually, the coordination is not quite symmetrical, the M–O and M–O′ distances vary slightly, and the O–O′ bond length is in the range 1.40 to 1.50 Å. Typical examples include the peroxide complex *trans*-$Ir(O_2)Cl(CO(PPh_3))_2$,[11] which is derived from the simple addition of dioxygen to Vaska's compound, and the Mo^{IV} complex shown in Figure 6. A redetermination of an iridium structure lead to the conclusion that data yielding unusual or extreme O–O bond lengths have to be examined carefully.[29]

5.2 μ-η^1:η^2-peroxo Complexes

This is one of the rarer bonding modes for metal–dioxygen complexes, found in only a handful of cases, including the heterodinuclear complex[30] shown in Figure 6 that was synthesized to model the active site of cytochrome *c* oxidase (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***). In addition, *ab initio* calculations have suggested this binding mode for the peroxo species formed by the diiron containing enzyme, methane monooxygenase (*see* ***Iron Proteins with Dinuclear Active Sites***).[31]

5.3 *Trans*-μ-η^1:η^1-peroxo Complexes

Peroxo *trans*-μ-η^1:η^1-O_2 complexes typically have υ(O–O) between 790 and 885 cm^{-1} and O–O distances between 1.38 and 1.53 Å and have nonplanar, twisted metal$_2$-peroxo groups ($\Phi < 180°$). An example of a peroxo *trans*-μ-η^1:η^1 complex has been reported by Karlin and



O–O 1.41(3) Å
Mo–O′ 2.12(1) Å
Mo–O 2.11(2) Å

Mes = 2,4,6-trimethylphenyl
O–O 1.460(6) Å
<Fe–O–Cu 166.0(3)°

(a) (b)

Figure 6 Examples of a η^2-peroxo complex (a) and a μ-η^2:η^1-peroxo complex (b)

coworkers.[2] This complex has a dihedral angle of 180° and is shown in Figure 5(b), next to a Ni^{II} *trans*-μ-η^1:η^1-superoxo complex (Figure 5(a)) with a similar ancillary ligand for easy comparison.

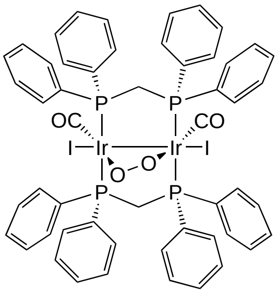
5.4 *Cis*-μ-η^1:η^1-peroxo Complexes

These complexes are usually doubly bridged, with an O_2^{2-} ligand as well as another bridging group, which is frequently an amide, hydroxide, or alkoxide group. The O–O distances are similar to those found in the corresponding *trans*-μ-η^1:η^1-peroxo complexes, and the $metal_2$–peroxo group is nonplanar ($\Phi > 0°$). Most of the reported *cis*-μ-η^1:η^1-peroxo complexes contain cobalt, iron, or copper,[32] although an account has appeared of an interesting Ir^{II} complex (Figure 7(a)) with a peroxo ligand straddling an Ir–Ir bond.[33]

5.5 Symmetrical μ-η^2:η^2-peroxo Complexes

This is a fairly unusual binding mode for dioxygen, occurring in a few cases, including the Kitajima complex shown in Figure 7(b).[34] The O–O vibration for this complex is essentially identical to that found for the dioxygen-carrier protein oxy-hemocyanin [υ(O–O) 740 cm^{-1}] (*see* ***Copper Proteins with Dinuclear Active Sites***), which has also been found to contain a symmetrical μ-η^2:η^2-peroxo ligand.

Interestingly, an equilibrium between the μ-η^2:η^2-peroxo (**A**) and bis(μ-oxo) (**B**) species has been found to exist in Cu_2O_2 systems (Figure 8).[17] Structurally, the Cu–Cu distance is longer in **A** (~3.6 Å) compared to **B** (~2.8 Å), and there are notable spectroscopic differences for the two species. For example, **A** typically has a low υ(O–O) in the resonance Raman spectrum (~750 cm^{-1}). In contrast, **B** gives a resonance Raman feature at ~600 cm^{-1} that is assigned to be a symmetric vibration of the $Cu_2(\mu\text{-}O)_2$ core as the band shifts when ^{18}O is incorporated into the complex.[17] Whether **A** or **B** is favored appears to be strongly dependent on the size and orientation of the ligand substituents because **B** has a much more compact dicopper core that requires a closer approach of ligand groups.[35] There is also postulated to be an electronic effect that is not as important in determining the equilibrium position as the steric influence.[17] The oxo-containing compounds **B** are reactive, often displaying different reactivity than the peroxo-containing compounds **A**; however, the reactivity can also be similar to **B** and appears to depend on the choice and possible



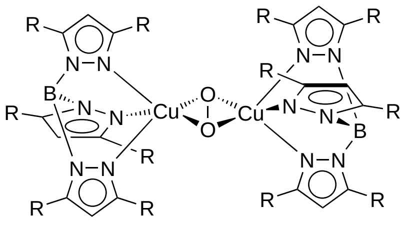


Figure 7 (a) A *cis*-μ-η^1:η^1-peroxo complex that also contains a metal–metal bond and (b) a symmetrical μ-η^2:η^2-peroxo model complex for the dioxygen-carrier hemocyanin

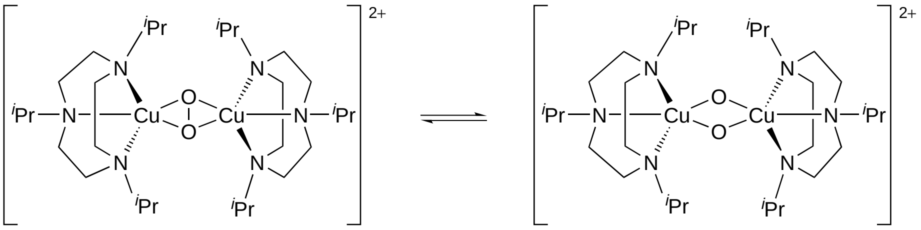

Figure 8 An example of the equilibrium found between some μ-η^2:η^2-peroxo and bis(μ-oxo) species (^{i}Pr = –CH(CH$_3$)$_2$)

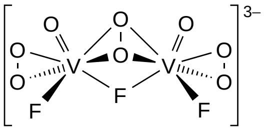
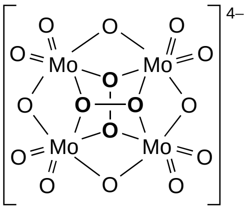


μ-η^2:η^2 O-O 1.467(5) Å
η^2 O-O 1.447, 1.441(5) Å

(a)



O–O 1.48 Å

(b)

Figure 9 An unsymmetrical μ-η^2:η^2-peroxo complex (a) and a μ_4-peroxo complex (b)

relative orientations of potential substrates.[17] The fact that the reactivity of species **B** can resemble that of **A** means that some metalloenzymes, like tyrosinase (*see* ***Copper Proteins with Dinuclear Active Sites***), may form reactive species similar to **B** instead of **A**. The conversion of a dinuclear species complex to one containing two bridging oxo ligands has been suggested for other systems, including cobalt complexes,[16] as well as for diiron enzymes (*see* ***Iron Proteins with Dinuclear Active Sites***) that activate dioxygen, which appear to convert a peroxo-diiron species to a bis(μ-oxo) species, although the structure of the peroxo-diiron species is unknown.[36]

5.6 Unsymmetrical μ-η^2:η^2-peroxo Complexes

This is also an unusual type of dioxygen binding, occurring in the divanadium complex shown in Figure 9(a) (also contains η^2-peroxo ligands);[37] presumably, the μ-peroxo is found in an unsymmetrical configuration because of the presence of another bridging ligand.

5.7 Miscellaneous Peroxo Complexes

There are a few additional interesting complexes that contain peroxide ligands that do not fall into the categories given above. For instance, there are complexes where the peroxo ligand bridges four metal centers such as $[Mo_4O_8(\mu\text{-}O)_4(O_2)_2]^{4-}$ (Figure 9(b)), which was prepared by the reaction of K_2MoO_4 and H_2O_2 at neutral pH aqueous solution,[38] and two Cu_4O_2 complexes that have been crystallographically characterized.[39]

1 INTRODUCTION

Electrochemical methods are useful for the study of transition metal complexes because many electrochemical techniques, particularly voltammetric methods, provide information on both the energetics of redox reactions and the kinetics of electron transfers and coupled homogeneous reactions.[1–3] Electrochemical methods have therefore seen considerable application in determining redox potentials of new complexes and in evaluating chemical mechanisms of reactions initiated by an electron transfer.[4] Such systems are conveniently studied using simple, affordable potentiostats, and solid electrodes in single or multi-compartment cells. As such, electrochemical methods are generally part of the experimental repertoire of inorganic researchers (*see* ***Analytical Chemistry of the Transition Elements***).

The practice of electrochemistry by most inorganic chemists involves the use of techniques where current is measured as a function of applied potential. Generally referred to as 'voltammetric' methods, these approaches offer rich kinetic and thermodynamic information.[5] The most common technique, cyclic voltammetry, involves the linear variation of the applied potential at a given scan rate (generally in mV s^{-1}). After reaching a predetermined switching potential, the potential is returned to the starting point at the same rate. A plot of the current versus the applied potential produces a cyclic voltammogram. Note that most modern, digital potentiostats vary the potential in discrete increments, so the proper name for cyclic voltammetry is therefore cyclic staircase voltammetry, a subtlety often ignored in the literature. There are other types of waveforms that can be used to vary the potential and that provide advantages in data interpretation.[6] The discussion here will be limited to cyclic voltammetry, since it remains the primary method by which inorganic complexes are studied.[4] The reader is encouraged to explore other pulsed voltammetric methods to complement cyclic voltammetry.[6]

2 FUNDAMENTALS OF CYCLIC VOLTAMMETRY

Numerous excellent texts exist on the fundamentals of cyclic voltammetry.[1–3] The reader is referred especially to the recent text by Bond,[2] which provides an excellent treatment of fundamentals as well as applications. The important aspects of cyclic voltammetry are illustrated by the diagram shown in Figure 1 of a typical voltammogram of a soluble, reversible couple subjected to a linear potential sweep (and return scan) between applied voltages E_1 and E_2. The characteristic curve shown in Figure 1 provides peak potentials (E_p^{red} and E_p^{ox}) as well as peak currents (I_p^{ox} and I_p^{red}). Note that the diagram in Figure 1 utilizes a convention for plotting currents and potentials that shows positive potentials on the right and oxidative current up; other conventions are often used.

The four values obtained from the voltammogram provide three important insights that are readily visible in the idealized voltammogram:

1. The splitting between the E_p^{ox} and E_p^{red} values is 56/n mV where n is the number of electrons transferred.
2. The midpoint potential, $E_{1/2}$, is the average of the E_p^{ox} and E_p^{red} values and is generally very similar to the formal potential (E°) for the redox couple (the formal potential is different from $E_{1/2}$ only when the oxidized and reduced forms of the complex have different diffusion coefficients).

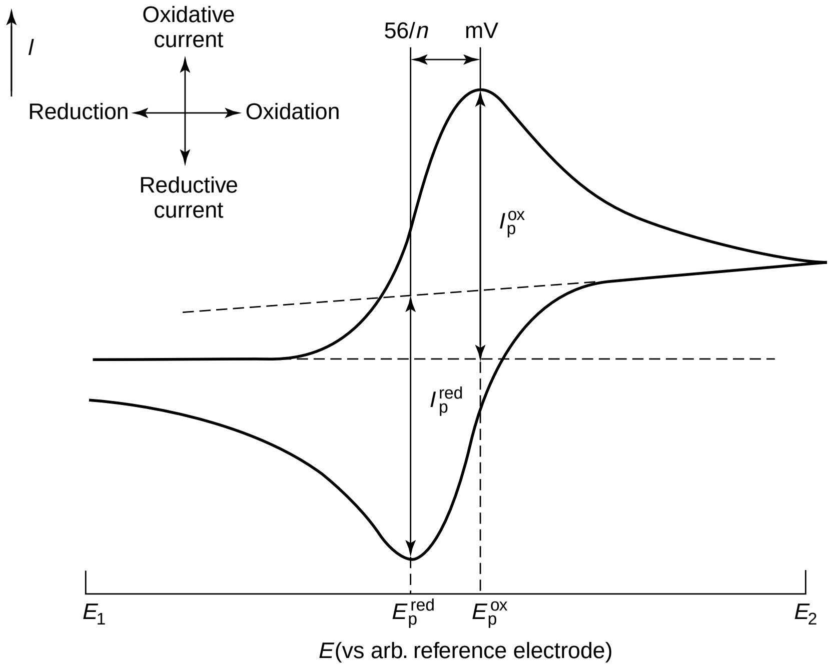

Figure 1 Typical cyclic voltammetric response. Indicated variables are described in the abbreviations section. (Reprinted from Ref. 2. © 1999, with permission from Elsevier)

3. The peak currents (I_p^{ox} and I_p^{red}) are equal for a reversible process, and at 25 °C are described by the Randles–Sevcik expression:

$$I_p^{ox} = -I_p^{red} = (2.69 \times 10^5) n^{3/2} A D^{1/2} \nu^{1/2} C \quad (1)$$

where n is the number of electrons transferred, A is the electrode area (in cm^2), D is the diffusion coefficient of the oxidized form, ν is the scan rate (in $V\,s^{-1}$), and C is the bulk concentration of the oxidized form (in $mol\,cm^{-3}$).

Note that the conclusions derived above are for the idealized, reversible reaction and are subject to assumptions regarding kinetics, diffusion, and the presence of coupled chemical reactions.[1–3]

3 COMPUTATION OF REDOX POTENTIALS IN SOLUTION

Under appropriate conditions, analysis of cyclic voltammograms such as that shown in Figure 1 provide simple measures of the solution redox potentials of transition metal complexes, derived as $E_{1/2}$. Extensive tabulations of redox potentials are available,[1,7] and provide a key resource for inorganic chemistry. The correlation redox potentials with parameters such as ligand field strength, ligand hardness, and ionization energy of the transition metal forms an important theoretical framework for transition metal chemistry.

Recently, a number of efforts have sought to use new theoretical methods, particularly density functional theory (DFT), to predict redox potentials in solution. While considerable progress has been made toward predicting gas-phase ionization potentials,[8] the role of solvation and coupled chemical reactions are of high importance to solution chemists. Baik and Friesner have recently discussed the ability of new methods for incorporating solvation effects[9] into DFT calculations. Using these solvation methods, DFT calculations can be used to determine solution redox potentials to within 150 mV.[10]

3.1 Applications of Calculating Redox Potential

The ability to calculate redox potentials has powerful implications. For example, electrocatalytic reactions of metal complexes, such as $Ru(bpy)_3^{2+}$, with DNA nucleobases, such as guanine, provide a sensitive method for detection of nucleic acids on surfaces in electrochemical DNA chips (*see* ***Nucleic Acid–Metal Ion Interactions***).[11,12] In these reactions, voltammetric oxidation of $Ru(bpy)_3^{2+}$ to $Ru(bpy)_3^{3+}$ in the presence of guanine produces an enhancement in the oxidative current due to the reaction of Ru(III) with guanine (Figure 2).[13] On surfaces, the extent of electrocatalytic enhancement is indicative of the quantity of bound nucleic acid;[14] levels of DNA as low as 40 attomoles have been detected using related methods.[15–17]

One limitation of electrocatalytic detection for nucleic acid detection was its limitation to native guanine as an

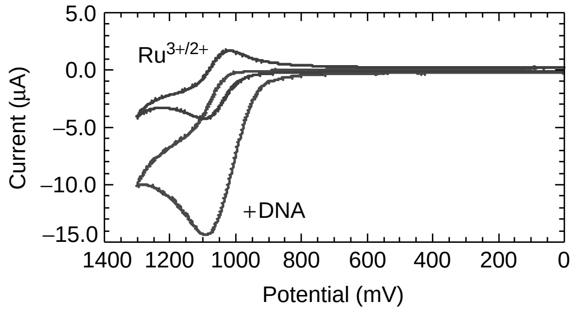

Figure 2 Cyclic voltammograms showing the response of $Ru(bpy)_3^{2+}$ both without and with DNA. The current enhancement in the presence of DNA arises from the catalytic oxidation of guanine by Ru(III) according to equations (2) and (3)

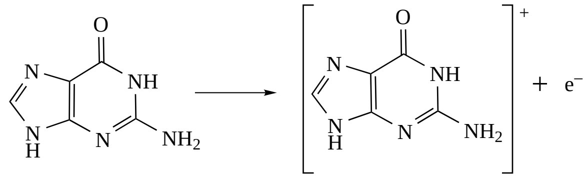
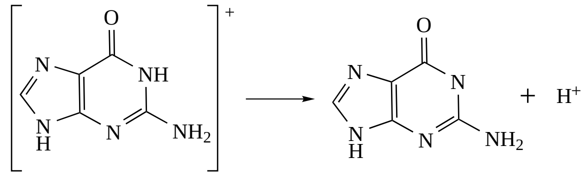
oxidizable nucleobase. The use of DFT calculations with modern solvation corrections was applied to the determination of solution redox potentials for a variety of native and synthetic nucleobases.[18] In addition to treating the solvation, reliable calculation of the redox potentials also required inclusion of deprotonation of the nucleobase radical (equation 3)[19,20] following oxidation:



(2)



(3)

The inclusion of the solvation correction therefore led to two important insights. The first is on the role of the deprotonation in the electrocatalytic process.[19,20] The second was to modified nucleobases useful in sophisticated and sensitive schemes for nucleic acid detection.[15]

4 DIGITAL SIMULATION

Another key computational advance in electrochemistry has been the development of convenient programs for simulating voltammetric responses.[5,6] Such programs, which can be run on conventional personal computers, allow for determination of fundamental electrochemical parameters and reaction rates for coupled chemical reactions. Because of the prevalence of cyclic voltammetry, the majority of such applications are performed using DigiSim,[5] which calculates cyclic voltammetric responses. However, simulation packages are also available for pulsed voltammetry, which provide a useful complement.[6]

One of the earliest applications of digital simulation to inorganic chemistry was for analysis of isomerization of $CpCo(1,3\text{-}C_8H_8)$ to $CpCo(1,5\text{-}C_8H_8)$, which proceeds via a simple square scheme (Figure 3).[21] Because the 1,3 and 1,5 isomers have different $E_{1/2}$ values (−2.27 V and −2.51 V, respectively), resolution of the two species in voltammetric curves is possible. Variation of the scan rate produces different currents for the electrogenerated species based on

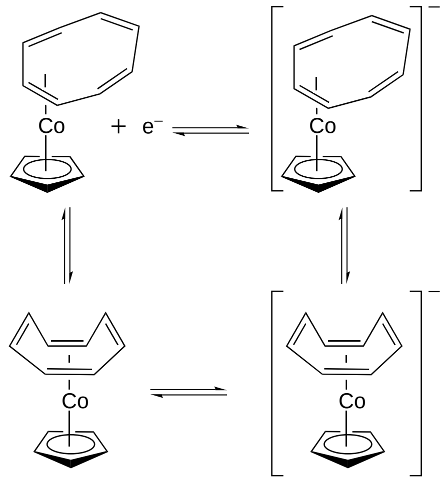


Figure 3 Isomerization of $CpCo(1,3\text{-}C_8H_8)$[21]

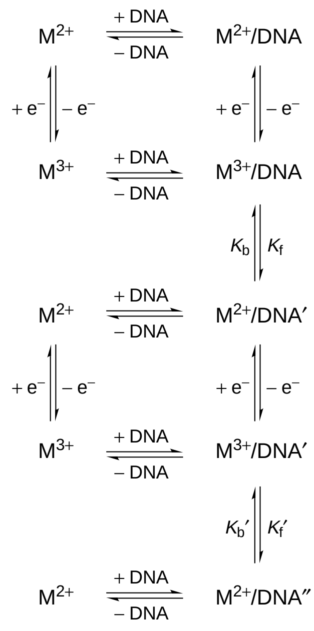

Figure 4 Multiple square schemes for electrocatalytic oxidation of DNA by $M(bpy)_3^{3+/2+}$ couples[24]

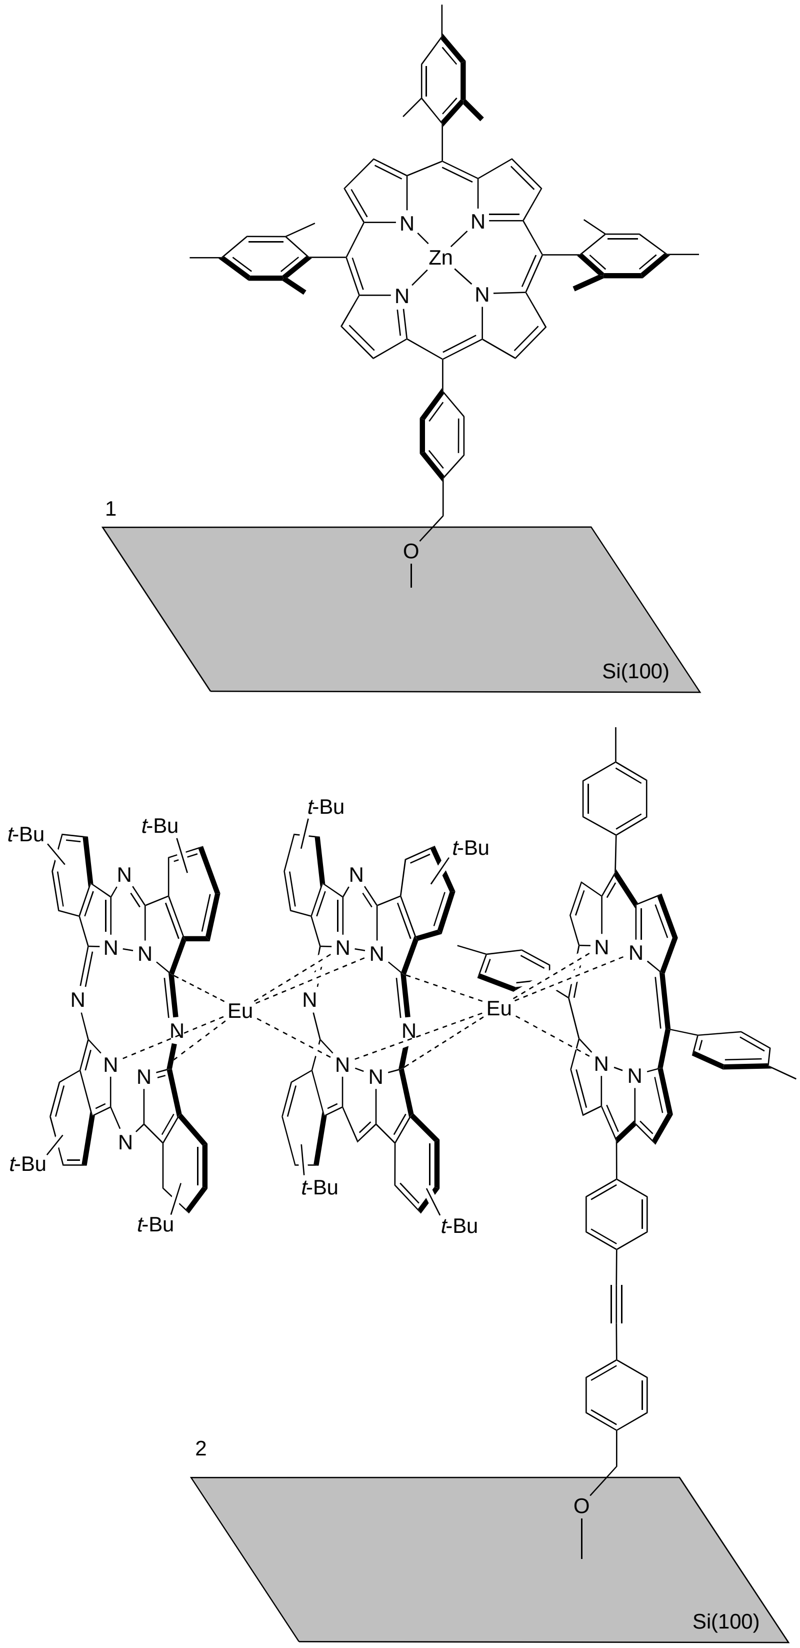

Figure 5 Remarkably stable porphyrin complexes for use in molecular electronics[34]

the time available for isomerization during the sweep. By simulating the generated curves using the input square scheme (Figure 3), characteristic voltammograms can be obtained. Simulation requires input of the fundamental electrochemical parameters as well as the equilibrium and rate constants for the isomerizations.[21] Similar applications to metal complex reactions are now routine using the DigiSim package have been performed, for example, on coupled proton-electron transfers in polyoxometallates (*see* ***Polyoxometalates***)[22] and on organometallic isomerizations (*see* ***Electronic Structure of Organometallic Compounds***).[22]

Digital simulations have been applied to numerous aspects of the oxidation of nucleic acids by polypyridyl complexes. The mechanistic scheme needed for such analysis is shown in Figure 4. In addition to the fundamental electrochemical parameters for the metal complex ($M^{3+/2+}$), numerous other parameters are required. The first is the diffusion coefficient of the DNA. These were determined by simulation of the normal pulse voltammetry of strongly binding metal complexes, such as $Os(bpy)_2(dppz)^{2+}$.[23] For more weakly binding complexes, which effect more efficient electrocatalysis, binding constants for each complex to DNA (the horizontal reactions in Figure 4) were also required (*see* ***Nucleic Acid–Metal Ion Interactions***).[24] With these parameters in hand, it was possible to determine the electron transfer rate constants (k_f, k_b) for oxidation of guanine by the bound metal, which were determined independently by stopped-flow analysis and compared favorably with values determined by simulation of cyclic voltammograms or square-wave voltammetry.[13] This methodology has since been applied to DNA oxidation using a number of complex systems, including high-viscosity solutions,[25] guanine tetrads,[26] and heterobinuclear complexes.[27]

5 MOLECULAR ELECTRONICS

The notion of using molecules as storage centers for electronic memory is seductive.[28–30] Use of molecules in memory clearly allows for extraordinary miniaturization, thereby permitting a high density of information storage.[31] Because of their capacity to store multiple electrons (bits) and to exhibit diverse stereochemistries, metal complexes are of particular interest.[32,33] One feature needed for a practical molecular memory is the ability of the redox functionality to sustain multiple read–write cycles, that is, to withstand multiple oxidations and reductions without decomposition. Such a consideration is a concern for metal complexes that are typically more stable in one redox form compared to the others.

Certain porphyrin complexes have been shown to be remarkably stable to redox cycling. The Zn and Eu complexes shown in Figure 5, can be attached to device-grade silicon surfaces and exhibit two or four reversible redox waves, respectively.[34] Remarkably, these systems are stable over as many as 10^{12} redox cycles, making them particularly suitable for stable storage devices.

1 INTRODUCTION

The transfer of a single electron between two chemical entities is the simplest of oxidation-reduction processes, but it is of central importance in vast areas of chemistry. Electron transfer processes constitute the fundamental steps in biological utilization of oxygen, in electrical conductivity, in oxidation–reduction reactions of organic and inorganic substrates, in many catalytic processes, in the transduction of the sun's energy by plants and by synthetic solar cells, and so on. The breadth and complexity of the subject is evident from the five volume handbook *Electron Transfer in Chemistry* (V. Balzani, Ed.),[1] published in 2001. The most fundamental principles that govern the efficiencies, the yields or the rates of electron-transfer processes are independent of the nature of the substrates. The properties of the substrates do dictate the conditions for applicability of those fundamental principles: that is, the boundary conditions and limiting forms of the theoretical models most suitable for the description of the electron-transfer processes vary from one area to another. Transition metal complexes have several unique features that must be considered in accounting for their patterns of electron-transfer reactivity; for example: (1) one-electron oxidation and reduction processes of nonradical species are commonplace; (2) one-electron oxidation and one-electron reduction of the complexes can occur at relatively mild potentials; (3) these complexes can have several electronic states with energies relatively near to those of the reacting species; (4) the number of electronic states and the energy differences between them can vary with changes of coordination sphere geometry and ligation; (5) the transition metal reaction centers can be shielded from the environment by the ligands, or the ligands may permit only a limited range of specific, molecular level reaction pathways. These properties contribute to the importance of transition metal electron-transfer processes in biological and catalytic systems, but they can lead to very complex models, or to models that are useful for one type of system that appear to be vastly different from those most useful for another. This article emphasizes the most basic, common features of electron-transfer reactions in coordination complexes. The modifications necessary to adapt standard approaches to electron-transfer reactivity to the specific requirements of selected, different reaction classes is noted.

The transfer of a single electron from one transition metal center to another is appropriately described as a nonradiative electronic relaxation process during which the locus of electron density is changed from a molecular orbital (MO) largely localized at a donor center in the initial state to a MO that is largely localized at an acceptor center in the final state. In an idealized limit, the donor (D) and acceptor (A) centers are each single transition metals. The MOs appropriate for describing the highest occupied molecular orbital (HOMO) or the lowest unoccupied molecular orbital (LUMO) of most complexes involve some contributions from several atoms; this is most notably an issue in the systematic discussion of bridged D/A complexes. The 'correct' MO descriptions of electron-transfer reactants and products are important concerns in the discussion of many contemporary issues, particularly those involving D/A electronic coupling, the adiabaticity of reactions, the contributions of anharmonicities of the potential energy (PE) surfaces, and so on.[2,3] This article takes a largely phenomenological approach and emphasizes simple limiting models of electron-transfer reactivity rather than detailed MO treatments. Details of theoretical approaches can be found in books by Kuznetsov[4,5] or by Kuznetsov and Ulstrup,[6] or in specialist monographs such as the two volumes of *Advances in Chemical Physics*, edited by Jortner,[7] or the volume edited by Kornyshev, Tosi, and Ulstrup.[8] Other specialized monographs and special issues of journals, sometimes based on symposia, may be consulted for a broad range of electron-transfer topics,[9–15] on heterogeneous photochemical

electron transfer,[16] on photochemical and radiation chemical methods for study of electron transfer,[17] and on biological and biophysical aspects of electron transfer.[18–20] A useful chapter by Meyer and Taube[21] describes the evolution of electron-transfer studies of coordination complexes and the experimental bases for distinguishing between classes of electron-transfer reactions. A more recent chapter by Endicott[22] integrates spectroscopic and kinetic studies in an overview of electron transfer issues and problems.

The material presented in this article is partly organized around some concepts whose basis is discussed in Section 3 below. Most of these concepts have evolved to describe reactions in homogeneous solutions, and this is the focus of most of this article. Extensions to gas-phase, solid-state, biological, and heterogeneous reactions are very briefly considered.

2 ELECTRON-TRANSFER REACTION CLASSES AND SOME DEFINITIONS

It is useful to separate the information about electron-transfer reactions into classes in order to make their discussion tractable and to highlight the important distinctions. Bimolecular electron-transfer reactions in solution have been traditionally separated into two classes: (1) outer-sphere reactions, in which there is no significant chemical bonding between the reactants in the transition state (as in equation 1; in aqueous solution); and (2) inner-sphere reactions, in which some ligand is bonded to both the oxidant and reductant in the transition state (as is inferred from equation 2; in aqueous solution).[21,23–25] The second order rate constant for reaction 2 is several orders of magnitude larger than that for reaction 1, but the interpretation of this rate advantage is somewhat complicated by differences in the free energy change during the electron-transfer step. Studies of the analogous reactions of cobalt(III) and low-spin cobalt(II) complexes in which the amine (or imine) ligands are linked together in a tetraaza-macrocyclic ring (N_4) have demonstrated that, in the limit that there is no free energy change (ΔG°_{DA}) accompanying electron transfer, the halide-bridged inner-sphere pathway for this class of complexes has about a million-fold rate advantage ($k_{is}/k_{os} \sim 10^6$), equations (3) and (4).[26] The size of k_{is}/k_{os} appears to vary with the electronic structure of the reactants. This dramatic contrast in reactivity could originate from: (1) enhanced coupling of the donor and acceptor electronic wavefunctions mediated by the bridging ligand in the transition state; (2) smaller displacements of nuclei for the inner-sphere than for the outer-sphere pathway (for example, there is no net change of charge of the complexes for the inner-sphere reactions and one would expect a smaller solvent contribution to the activation energy); or (3) some combination of these. The role (or roles) of bridging ligands in mediating electron-transfer processes has been a major concern of the studies of electron-transfer processes.

$$Co(NH_3)_6{}^{3+} + Cr(OH_2)_6{}^{2+} + 6H^+ \longrightarrow Co(OH_2)_6{}^{2+} + Cr(OH_2)_6{}^{3+} + 6NH_4{}^+ \quad (1)$$

$$Co(NH_3)_5Cl^{2+} + Cr(OH_2)_6{}^{2+} + 5H^+ \longrightarrow Co(OH_2)_6{}^{2+} + Cr(OH_2)_5Cl^{2+} + 5NH_4{}^+ \quad (2)$$

$$Co(N_4)(OH_2)_2{}^{3+} + Co(^*N_4)(OH_2)_2{}^{2+} \longrightarrow Co(N_4)(OH_2)_2{}^{2+} + Co(^*N_4)(OH_2)_2{}^{3+} \quad (3)$$

$$Co(N_4)(OH_2)Cl^{2+} + Co(^*N_4)(OH_2)_2{}^{2+} \longrightarrow Co(N_4)(OH_2)_2{}^{2+} + Co(^*N_4)(OH_2)Cl^{2+} \quad (4)$$

The outer-sphere/inner-sphere classification is operationally useful in the context of bimolecular reactions, but it does not help much with the full range of electron-transfer behavior that has evolved over the past several decades. The definition of useful, general reaction classes for complexes in which the donor and acceptor are covalently linked is particularly difficult. Several classification schemes have been proposed.[21,22,27]

It is probably necessary to make a primary operational distinction of reaction classes based on the phase (or phases) of matter involved; thus: (1) homogeneous, liquid phase; (2) gas phase; (3) solid phase; (4) heterogeneous. A basic subclassification distinguishes between reactions in which the reactants are chemically different from the products, as in equations (1) and (2), and reactions in which the reactants and products involve the same chemical species, as in equations (3) and (4) when (N_4) = ($^*N_4$). Equations (1) and (2) are examples of cross electron-transfer reactions (or cross-reactions), while equations (3) and (4) are examples of self-exchange electron-transfer reactions when (N_4) = ($^*N_4$). More generally, subclassifications of the primary classes are commonly based on energy or free energy considerations such as:

a. Whether the reactions are activated by thermal or light energy.
b. Whether the standard free energy of the electron-transfer step, ΔG°_{DA}, is different from zero (as in equations (1) and (2)) or equal to zero (as in equations (3) and (4) when (N_4) = ($^*N_4$)).
c. Whether the magnitude of ΔG°_{DA} is smaller than that of the reorganizational free energy, χ_r, (the 'Marcus normal region'), or whether $|\Delta G^\circ_{DA}| > |\chi_r|$ (the 'Marcus inverted region').[28–30]

Classifications based on energy (or free energy) considerations are very fundamental and useful.

Classification can also be based on potential applications (devices, enzymatic reactions, etc.).

The principle focus of this article is on electron transfer between transition metal complexes in homogeneous liquid

phase solutions. These span a very large range of energy regimes. It is frequently useful to distinguish between those electron-transfer processes that are 'weakly coupled' and those that are 'strongly coupled' based on the extent of mixing (or overlap) of the electronic orbitals of the donor and acceptor centers. The weaklycoupled classification includes most of the classical outer-sphere electron-transfer reactions, but it also includes many electron-transfer reactions of covalently linked complexes, many electron transport reactions of biological substrates, and so on. In the limit that the mixing of the donor and acceptor wave functions goes to zero, the interactions between donor and acceptor are called 'diabatic' (the term 'nonadiabatic' is often used for this limit); when the mixing is significant, the reactions are called 'adiabatic'. The simplest, basic theoretical models of electron-transfer processes are technically correct only for the diabatic limit. The reactions in this limit are described in terms of simple harmonic oscillator (sho) models of the nuclear motions that accompany the transfer of charge, and this leads to the well-known parabolic PE surfaces to describe the reactant and product states (the dashed-line curves in Figure 1). The models employed in the weakly coupled limit may be referred to as classical (e.g. the Marcus theory),[28,29,31,32] semiclassical[32,33] or quantum-mechanical,[34,35] but they are little modified from the limiting sho models. In the strongly coupled limit, the electron-transfer reactions are strongly adiabatic, and the theoretical sho descriptions of the reaction coordinate must be corrected, usually by means of perturbation theory, or completely new theoretical models developed. These concepts are conveniently illustrated with respect to a semiclassical expression for the bimolecular rate constant (equation 5).[32]

$$k_{et}(b) = K_A \kappa_{el} \nu_{nu} \kappa_{nu} = K_A k_{et} \quad (5)$$

In equation (5), K_A is the equilibrium constant for the outer-sphere association of the donor and acceptor, κ_{el} is the electronic transmission coefficient (the probability that products form once the nuclear configuration of the transition state is achieved), ν_{nu} is the effective frequency for nuclear motion along the reaction coordinate in the neighborhood of the transition state, and the nuclear transmission coefficient κ_{nu} is the classical exponential function of the activation energy. The weak-coupling limit corresponds to the limit in which $\kappa_{el} < 1$, and for the strong-coupling limit $\kappa_{el} = 1$.

When the donor and acceptor are sufficiently close, as in an ion pair or in covalently linked complexes, electron transfer can be promoted by the absorption of light. An absorption band corresponding to the light induced electron transfer is usually called a 'charge transfer (CT) absorption band'. The molecular parameters that determine the CT absorptivity, bandwidth, and band shape are the same molecular parameters that determine the magnitude of the electron-transfer rate constant.[31,36,37] In the weak-coupling limit, the absorptivity of the CT absorption band is small (much less than 10^3 M^{-1} cm^{-1}); in the strong-coupling limit, the absorptivity of the CT absorption band is large (greater than, or equal to 10^3 M^{-1} cm^{-1}).

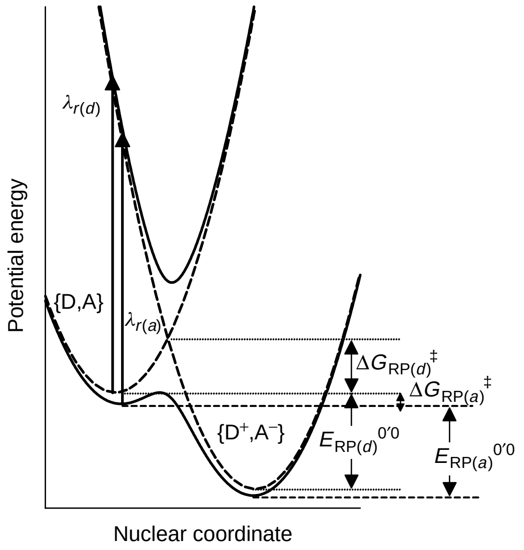

Figure 1 Illustrating diabatic (dashed lines) and adiabatic (solid lines) PE surfaces. The diabatic parameters are indicated with a subscript (d), the adiabatic parameters with a subscript (a)

3 EXPERIMENTAL TECHNIQUES

A large variety of experimental techniques is employed in the study of electron transfer phenomena. The technique employed depends on the type of substrate, the class of reaction and the aspect of electron-transfer behavior to be investigated. Only a brief summary is possible here. More detailed discussions may be found elsewhere.[1,17,38–41] The experimental techniques are organized in terms of the parameter to be measured in order to simplify discussion.

3.1 Rate Constant Determinations

The determination of reaction rate constants for cross-reactions is based on the time rate of change of concentration of a reactant and/or product (equation 6).

$$\text{Rate} = -\frac{d[\text{D}]}{dt} = K_A k_{et}[\text{D}][\text{A}] \quad (6)$$

Any technique that is sensitive to one or another of the reactant or product species may be employed. For relatively slow reactions (reaction lifetimes longer than a few ms), simple spectrophotometric, electrochemical, magnetic resonance, and so on techniques may be employed. In order to make useful determinations, the time for mixing the reactants and the instrumental response time must both be short compared to the reaction half-life (for a bimolecular reaction, $t_{1/2} \cong 0.69/\{K_A k_{et}[\textit{excess reactant}]\}$). Reactions with shorter lifetimes (10^{-3} s $> t_{1/2} > 10^{-15}$ s) can often be determined by spectral line broadening techniques at equilibrium, or by the

photochemical or pulse-radiolytic generation of reactants for reactions with large equilibrium constants.

3.2 The Experimental Determination of Values of the Reactant Properties that Contribute to the Efficiency of Electron-transfer

Some of the key properties were introduced above; all will be discussed in more detail below. Quantities related to reaction energetics may all be expressed in terms of energies, as in potential energy diagrams, or in terms of free energies, as in equilibrium constants and differences in electrode potentials. Energy and free energy quantities should not be casually mixed. The differences in these expressions of reaction energetics are discussed in a later section.

a. The free energy of the electron-transfer step, ΔG°_{DA} (or electron-transfer energy, $E^{0'0}_{DA}$). The problems in determining this parameter are nicely illustrated by reactions 1 and 2. Equations (1) and (2) represent overall reactions, each comprised of several elementary reaction steps: Association of reactants; electron transfer; dissociation of products; ligand substitution (hydrolysis). For reaction 1, the primary steps are illustrated in equations (7) and (8) (the curly brackets designate a contact ion pair).

$$Co(NH_3)_6{}^{3+} + Cr(OH_2)_6{}^{2+} \underset{}{\overset{K_A}{\rightleftharpoons}} \{Co(NH_3)_6{}^{3+}, Cr(OH_2)_6{}^{2+}\} \tag{7}$$

$$\{Co(NH_3)_6{}^{3+}, Cr(OH_2)_6{}^{2+}\} \xrightarrow{k_{et}} \{Co(NH_3)_6{}^{2+}, Cr(OH_2)_6{}^{3+}\} \tag{8}$$

The parameter ΔG°_{DA} pertains to the reaction described in equation (8). Owing to the substitutional lability of $Co(NH_3)_6{}^{2+}$, this is not directly measureable. When the electron transfer is not followed by rapid bond breaking or ligand substitution, ΔG°_{DA} may be determined from measured differences in electrode potentials for the two couples involved; this would be the case for the reaction in equation (3).

For some reactions, it is possible to infer the energy change for the electron-transfer step, $E^{0'0}_{DA}$, from the energy and bandwidth of the fundamental vibronic component of the CT absorption or emission band; see the discussion below.

b. The solvent reorganizational free energy, χ_s (or the solvent reorganizational energy, λ_r). The electron-transfer process described by equation (8) involves a substantial change in the spatial distribution of charge. The solvation of the reactant and product species must be very different (at the minima of the respective PE surfaces). However, energy conservation requires that electron transfer in the transition state be modeled as the movement of an electron between two electronic configurations whose potential energies are equal. Thus, the reactants, {D, A}, and products, $\{D^+, A^-\}$, are generally assumed to have the same solvation free energy (or energy) at the transition state (this assumption depends on the independence of nuclear motions with different vibrational frequencies). The difference between the equilibrium solvation free energy of the reactants and the solvation free energy in the transition state is generally a significant contribution to the free energy of activation (or the energy barrier to the reaction). The corresponding reorganizational energy (or free energy) parameters are defined with respect to vertical energy differences between the reactant and product states as illustrated in Figure 1. For an electron transfer self-exchange reaction in the weakly coupled limit and for no differences in the molecular structures of reactants and products, the solvent reorganizational free energy is given by $\chi_s = 4\Delta G^{\ddagger}_{DA} = -4RT\ \ln[k_{et}/A]$ (A is the product of several preexponential factors, see discussion below). The solvent reorganizational energy, λ_s, can, in principle, be inferred from the full width at half height, $\Delta\nu_{1/2}$, of the fundamental vibronic component of the CT absorption or emission; for a Gaussian band shape and if there are no other contributions to bandwidth.[31]

$$\Delta\nu_{1/2} \cong 4[RT\lambda_s \ln 2]^{1/2} \tag{9}$$

The solvent contribution to the reorganizational free energy should be distinguished from the solvent reorganizational energy; the relationship between them is

$$\chi_s = \lambda_s + RT - T\Delta S_r \tag{10}$$

There can be other significant contributions to the optical bandwidths; important among these are those that arise when the absorption (or emission) is solvent dependent and there is a distribution of solvation environments in solution or when there is a contribution from the thermal population of vibrational excited states ('hot bands'). Such contributions necessitate an additional term (or terms) in equation (9), so that, in practice, this equation provides an upper limit for λ_s.

c. The reorganizational energy associated with differences in molecular geometry, λ_M. Any differences in molecular geometry (changes in bond lengths, angles, etc.) between the reactants and the products will also contribute to the electron-transfer reorganizational energy, λ_r. The vibrational quanta that are associated with these changes span a very wide range of frequencies for transition metal complexes, and their reorganizational energy contributions are usually separated into low-frequency ($h\nu_{l,M} < 4RT$) and high-frequency ($h\nu_{h,M} \geq 4RT$) vibrations. The contributions of low-frequency, molecular vibrational modes to λ_r are not usually distinguishable from the solvent contributions and they are

combined into $\lambda_l = \lambda_{l,M} + \lambda_s$. Thus, the CT bandwidths, as in equation (9), reflect contributions of λ_l, not just those of λ_s.

The contributions of the high frequency vibrational modes to λ_r, hereafter written λ_h, appear as nuclear tunneling contributions to k_{et}, and as vibronic side bands in CT spectroscopy. The intensity of a vibronic side band relative to the intensity of the fundamental component is equal to $\lambda_h/h\nu_h$.[42] If the high frequency components can be resolved in the emission spectra, then λ_h can be determined and the nuclear tunneling contributions to k_{et} can be evaluated for each such component.[34,35]

d. The preexponential nuclear frequency term. This parameter is not readily measurable. It is usually calculated, based on sho arguments, from[43]

$$\nu_{nu}^2 = \frac{\nu_l{}^2\lambda_l + \nu_h{}^2\lambda_h}{\lambda_l + \lambda_h} \tag{11}$$

e. Electronic contributions.[2,3] These are usually formulated in terms of an electronic matrix element, $H_{RP} = \langle\psi_R^\circ|H'|\psi_P^\circ\rangle$, where ψ_R° and ψ_P° are the electronic wave functions for the diabatic states of the reactants and products, respectively, and H' is a Hamiltonian operator.[44] Obviously, electronic wavefunctions are not measurable. The matrix element is probably most often inferred from the properties of the CT absorption; it is sometimes inferred by fitting the value determined experimentally for a rate constant to some theoretical model.

The matrix element can be inferred from the deviations of observed properties from those expected of the reacting system in the diabatic limit. The size of those deviations tends to increase as a function of the fraction of an electron that is delocalized between donor and acceptor, $(H_{RP}/E_{RP}^\circ)^2$, where E_{RP}° is the vertical energy difference between the diabatic reactants and products states; $H_{RP}/E_{RP}^\circ = \alpha_{RP}$ is the coefficient for mixing ψ_R° and ψ_P°.

$$\psi_R = \frac{(\psi_R^\circ + \alpha_{RP}\psi_P^\circ)}{(1 + \alpha_{RP}{}^2)^{1/2}} \tag{12}$$

There are problems with all of these approaches, and the evaluation of H_{RP} by means of some combination of measurements is usually a good idea. The integrated intensity of an electronic absorption band is a function of the matrix element. Equation (13) expresses this relationship for a Gaussian-shaped absorption band.[31,44]

$$H_{RP} = \frac{0.0206}{r_{RP}}\left[\frac{(\varepsilon_{max}\Delta\nu_{1/2})h\nu_{max}}{g_o}\right]^{1/2} \tag{13}$$

The parameters in equation (13) are the molar absorptivity at the absorption maximum (ε_{max}), the full width at half height ($\Delta\nu_{1/2}$), the energy of the absorption maximum ($h\nu_{max}$), an orbital degeneracy factor (g_o; this is important only in comparisons involving different open shell systems) and a distance parameter (r_{RP}). The distance parameter can be interpreted as the distance between the center of charge in the ground and in the excited state.[44] In the diabatic limit (zero absorptivity!), r_{RP} can be taken to be the distance between the centers of the donor and acceptor moieties; otherwise, it is smaller than this distance and not readily measurable. A less ambiguous approach to inferring the matrix element from electronic absorption spectroscopy is based on the electric field dependence of the spectrum (electroabsorption spectroscopy).[45] This approach allows the experimental determination of both the difference of the ground and excited state molecular dipole moments ($\Delta\mu_{RP}$) and the electronic transition moment (M_{RP}), and[3,45,46]

$$H_{RP} = \frac{\left|\vec{M}_{RP}\right|}{[4M_{RP}{}^2 + \Delta\mu_{RP}{}^2]^{1/2}}E_{RP} \tag{14}$$

The electroabsorption technique involves the measurement of the changes in absorption spectra that result when very large electric fields (typically tens of thousands of volts) are applied to glassy solutions at very low temperatures. It has been used primarily for covalently linked donor–acceptor complexes that are in the strongly coupled regime.[45]

4 BASIC CONCEPTS AND SOME PERTURBATION THEORY-BASED RELATIONSHIPS OF ELECTRON-TRANSFER PARAMETERS

Some basic aspects of electron-transfer theory are necessary for discussing the important issues and for organizing general information. Some of the important concepts have been introduced in the preceding sections, and more extensive discussions may be found elsewhere.[2,3,6–8,31,32,37,47–49]

4.1 The InterRelationship of the Fundamental Electron-transfer Parameters of Spectroscopy and Kinetics

Treatments of radiative and nonradiative electron-transfer processes are conveniently formulated in terms of the probability of changing the electronic configuration from that of the initial state to that of the final state, P_{RP}.[33,36,50]

$$P_{RP}(\nu_{obs}) \propto \frac{H_{iRP}{}^2 f(\nu_{eff})}{(4\pi\chi_s k_B T)^{1/2}}(FC)_r \tag{15}$$

$$(FC)_r = \sum_j F_{j,h}[e^{-(G_j)^2/4RT\chi_s}] \tag{16}$$

$$F_{j,h} = S_h{}^j\frac{[\exp(-S_h)]}{j!}$$

$$S_h = \frac{\lambda_h}{h\nu_h} \tag{17}$$

Equations (15–17) are based on sho models; $f(\nu_{eff})$ is an algebraic function that is different for light absorption, light emission, and nonradiative relaxation; the solvent reorganizational free energy, χ_s (rather than the reorganizational energy, λ_s), is used for consistency with ΔG°_{RP}, the high frequency contribution is usually evaluated in terms of an energy contribution; FC is a 'Franck–Condon factor'. This equation differs only in detail from the expression for k_{et}, equation (5). For simplicity, this equation is written in terms of a single high frequency vibrational mode (ν_h) and it treats only the limit that $\kappa_{el} \ll 1$. The transition probability is exponential in G_j^2, where

$$G_j(r) = \Delta G^\circ_{RP} + \chi_s + jh\nu_h + rh\nu_{obsd} \tag{18}$$

Light absorption, light emission, and nonradiative electron-transfer rate constants differ in the last term of equation (18) (as well as in $f(\nu_{eff})$; note that ΔG°_{RP} is positive for light absorption and negative for emission).

$$\left.\begin{array}{l} \text{r} = -1 \text{ (light absorption)} \\ \text{r} = 0 \text{ (nonradiative)} \\ \text{r} = +1 \text{ (light emission)} \end{array}\right\} \tag{19}$$

The exponential factor of FC dominates equation (15). This feature simplifies much of the discussion. This exponential function is in Gaussian form, and it is the basis for a Gaussian analysis of absorption or emission spectra.[36,50] Equations (15–18) provide the basis for analyzing the absorption or emission spectral envelope by considering some range of values of light frequencies (ν_{obsd}), but the nonradiative rate constant corresponds to the zero-photon limit.[34,36]

Equation (15) is the basis for equation (9) and several other important relationships for electron-transfer systems. For very weak electronic coupling and when high frequency modes do not contribute, the energy of the absorption maximum corresponds to the maximum value of this term (note that the nuclei do not move during the optical transition).

$$h\nu_{max}(\text{abs}) = E_{RP}{}^{0'0} + \lambda_s + \cdots = |\Delta G^\circ_{DA}| + \chi_s + \cdots \tag{20}$$

The emission maximum is given by

$$h\nu_{max}(\text{emis}) = |\Delta G^\circ_{DA}| - \chi_s + \cdots \tag{21}$$

The pressure-volume work (equal to RT) for an optical transition is zero, so $|\Delta G^\circ_{RP}| = (E^{00}_{RP} - T\Delta S^\circ_{RP})$ and $\chi_s = (\lambda_s - T\Delta S_r)$. A necessary condition for the equality in equation (20) is that

$$\Delta S^\circ_{RP} \cong -\Delta S_r \tag{22}$$

Equation (22) indicates that the entropy contribution to the reorganizational free energy cannot be neglected. For the electron-transfer rate constant, the free energy of activation is $\Delta G^\ddagger_{RP} = [G_j(r=0)]^2/4\chi_s$, and the entropy of activation is usually expressed as

$$-\Delta S^\ddagger_{RP} = \frac{\partial(\Delta G^\ddagger_{RP})}{\partial T} \cong \frac{1}{4}\gamma^2 \Delta S_r \tag{23}$$

where $\gamma = (\Delta G^\circ_{RP} + \chi_s)/\chi_s$. Equation (23) is useful for cross-reactions, but it neglects other terms. This is most evident for a self-exchange reaction ($\Delta S^\circ_{RP} = 0$) since the equal PE of reactants and products implies that the donor and acceptor are equally solvated; this implies an entropy increase ($\Delta\sigma$) for the difference in solvation of the transition state and ground-state (for a self-exchange reaction of +3 and +2 ions in water this amounts to approximately 4–8 J K^{-1} M^{-1}). An additional contribution to equation (23), $Rln(g_s^\ddagger/g_s)$, arises from any difference in the spatial degeneracy of the ground and transition state; for a self-exchange reaction this contributes about 0.6 J K^{-1} M^{-1}. Differences in the densities of vibrational states will also contribute in cross electron-transfer reactions. The activation enthalpy is

$$\Delta H^\dagger_{RP} = \left(\frac{\partial\left(\frac{\Delta G_{RP}}{T}\right)}{\partial\left(\frac{1}{T}\right)}\right) = \frac{E_{RP}{}^{00}}{2}\gamma + \frac{\lambda_s}{4}[2-\gamma](\gamma) \tag{24}$$

When high frequency vibrational modes contribute to the difference in excited state and ground-state geometry, then the CT absorption (or emission) envelope will include a series of peaks (a vibronic progression), differing in intensity (an effect of F_j, an expression based on the vibrational overlap integral), but each with a bandwidth given by equation (9). For a single contributing high frequency vibrational mode, the energies of the maxima in the absorption and emission spectra (at $j = 0, 1, 2, \ldots$) are given by

$$h\nu_{max}(\text{abs})_j = |\Delta G^\circ_{RP}| + \chi_s + jh\nu_h \ldots \tag{25}$$

$$h\nu_{max}(\text{emis})_j = |\Delta G^\circ_{RP}| - \chi_s - jh\nu_h \ldots \tag{26}$$

The peaks of a vibronic progression will only be resolved when $2\Delta\nu_{1/2} < h\nu_h$; when $2\Delta\nu_{1/2} > h\nu_h$, the vibronic components will be unresolved, but the spectral band may not have a Gaussian shape.

The contribution of high frequency vibrational modes to k_{et} is determined by their Boltzman populations when $|\Delta G^\circ_{RP}/\chi_s| < 1$. In the Marcus inverted region, where $|\Delta G^\circ_{RP}/\chi_s| > 1$, any high frequency vibrational modes that correlate with differences in reactant and product geometries can act (qualitatively) as if they are transient reaction products (technically, as acceptor modes; this is an implication of equation (18)). If there are significant differences in reactant and product molecular geometries that correlate with modes for which $h\nu_h > 4k_BT$, then the rate constant in the normal region is small relative to expectation based on the classical limit of a continuum of vibrational energies (or to

very efficient energy exchange between all molecular and solvent vibrational modes), and nuclear tunneling factors become important.[3,32] Most electron transfer process are characterized by contributions from several high frequency vibrational modes. When this is the case, equation (15) should include a sum over the single ($j = 1$) and multiquantum ($j > 1$) contributions of these modes (h). The multiquantum contributions are analogous to the higher harmonics of a single mode and combination bands (simultaneous excitation of different modes) in infrared spectra; each vibronic component has the same bandwidth as the fundamental, so this is not a product of individual vibronic progressions. Equation (15) has far more parameters than can be determined in ordinary kinetic studies, and other types of measurement generally must supplement the kinetic data in order to establish the details of the reaction pathway.

For light absorption, equation (15) can be put into the form of equation (27).[36,50,51]

$$\varepsilon_{\nu_m} = \frac{8N\pi^3}{3000h^2c\nu_m \ln 10}\frac{\eta H_{\text{RP}}^2(\Delta\mu_{\text{RP}})^2}{(4\pi\chi_s k_B T)^{1/2}}(\text{FC})_{r=-1} \quad (27)$$

Equation (27) (N = Avagadro's number; η = refractive index; c = velocity of light) implies that $\Delta\mu_{\text{RP}}$ and H_{RP} are constant over the absorption band (Condon approximation). A closely related expression, equation (28), can be used for the emission intensity.

$$I_{\nu_m} = \frac{64\pi^4}{3h^3c^3 \ln 10}\frac{\nu_m\eta^3 H_{\text{RP}}^2(\Delta\mu_{\text{RP}})^2}{(4\pi\chi_s k_B T)^{1/2}}(\text{FC})_{r=+1} \quad (28)$$

The related expression for the electron-transfer rate constant is[33–36,52–55]

$$k_{\text{et}} = \frac{2\pi^2}{h}\frac{H_{\text{RP}}^2}{(\pi\chi_s k_B T)^{1/2}}(\text{FC})_{r=0} \quad (29)$$

Equation (29) is for the weakly coupled, $\kappa_{\text{el}} < 1$, or 'nonadiabatic' limit of equation (5). The connection to equation (5) is made clear by setting $\kappa_{\text{nu}} = (\text{FC})$ and

$$\kappa_{\text{el}} \cong \left[\frac{(1 + h\nu_{\text{nu}}\{\pi\chi_s k_B T\}^{1/2})}{2\pi^2 H_{\text{DA}}^2}\right]^{-1} = [1 + \nu_{\text{nu}}/\nu_{\text{el}}]^{-1} \quad (30)$$

In equation (30), ν_{el} is the frequency of electronic motion across the reaction coordinate near the transition state. Other expressions for κ_{el} have been proposed, for example, based on Landau–Zener approaches.[3,32,49]

4.2 Contributions to (FC) in the Weak-Coupling Limit

The important Franck–Condon contributions to k_{et} are $\Delta G^\circ_{\text{RP}}$, χ_l and χ_h (and ν_h). The high frequency vibrational contributions can be described in terms of nuclear tunneling pathways, and they are very important for reactions in the Marcus inverted region (i.e. when $-\Delta G^\circ_{\text{RP}} > \chi_l$).

The general patterns of the energy contributions to (FC) are more easily discussed than the entropy contributions, and the energy contributions will be emphasized here. Equations (15–18) and (29) predict a complex dependence of k_{et} on the reaction driving force. In the diabatic limit this corresponds to variations in the intersections of the reactants and products PE surfaces with the differences in their PE minima; this is illustrated in Figure 2 for the diabatic (a) and weak-coupling (b) limits.

Marcus described the solvent reorganizational energy (λ_s) that accompanies the transfer of a charge of magnitude e in terms of the repolarization of a dielectric continuum (with index of refraction η and static dielectric constant D_s) around two spherical reactants with radii a and b, separated a distance d_{DA}.[28,29,32]

$$\lambda_s = e^2\left(\frac{1}{2a} + \frac{1}{2b} - \frac{1}{d_{\text{DA}}}\right)\left(\frac{1}{\eta^2} + \frac{1}{D_s}\right) \quad (31)$$

The slope of a plot of λ_s versus. a^{-1} is expected to be $31.9 \times 10^5\ \text{cm}^{-1}\,\text{pm}^{-1}$ for self-exchange reactions (for which $a = b$ and $d_{\text{DA}} = 2a$). Equation (31) is expected to give the general pattern for solvational contributions to the reorganizational free energy, but it does not take account of entropy, specific solvational effects, the effect

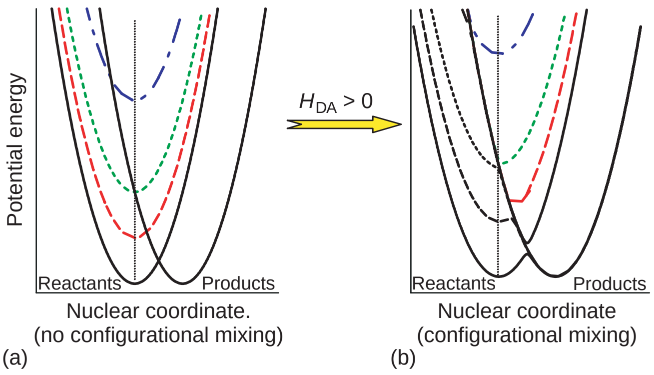

Figure 2 (a) Qualitative representation of the effects of differences in driving force on electron-transfer reactivity in the limit of no configurational mixing (diabatic limit): the black and red curves fall into the 'normal' region ($|\Delta G_{\text{RP}}| < \chi_r$); barrierless region ($|\Delta G_{\text{RP}}| = \chi_r$), green curve; and the 'inverted' region ($|\Delta G_{\text{RP}}| > \chi_r$), blue curve. The products curves are the same for each reaction represented. (b) Qualitative representation of the effects of configurational mixing on each of the cases considered in (a). The ground state (adiabatic reaction coordinate) is represented with a black curve for each different driving force; these curves all superimpose on the right-hand side for large displacements along the reaction coordinate. The electron-transfer excited states are color coded as in (a); these curves all superimpose on the left-hand side of the diabatic products parabola for small displacements along the reaction coordinate. The vertical dashed lines are drawn through the reactants PE minima

of a nonspherical transition state or ambiguities about the donor–acceptor distance (see the discussion of equation 13).[56]

In the weak-coupling (sho) limit, the inner-sphere reorganizational contributions for a self-exchange reaction can be approximated by[28,29,32,43]

$$\lambda_M = 2 \sum_{j}^{bonds} \frac{f_{D(j)} f_{A(j)}}{f_{D(j)} + f_{A(j)}} (\Delta d_{ML(j)})^2 \quad (32)$$

The summation is over all bonds, the $f_{N(j)}$ ($N = D$ or A) are local bond force constants (not normal mode force constants) for the j^{th} bond and $\Delta d_{ML(j)}$ is the bond length difference of the j^{th} bond for the oxidant and reductant. When the molecular vibrational quanta are significantly smaller than 4RT, their contributions to λ_M will appear as contributions to λ_l, as noted above.

4.3 Contributions to (FC) in the Strong-Coupling Limit

Since the PE surfaces are anharmonic in this limit, the Franck–Condon contributions can be difficult to treat. The approaches to this limit can be separated into two classes: (a) perturbation theory corrections of the weak-coupling limit; and (b) quantum-mechanical calculations of the reaction coordinate. The latter tend to be done on a reaction-by-reaction basis; this makes it difficult to generalize. The perturbation theory approaches have the advantage that they make use of the parameters used in the weak-coupling limit, and this can provide useful insights into general trends and patterns.

In this limit, $\kappa_{el} = 1$; however, configurational mixing of reactant and product PE surfaces results in a decrease of the activation free energy barrier to reaction and larger rate constants. When the distortions of the PE surfaces are not very large, the electron-transfer rate constant may be represented,

$$k_{et} = \nu_{nu}\kappa_{nu} f_{ad} \quad (33)$$

where $f_{ad} > 1$ is an adiabatic correction factor and κ_{nu} is based the Franck–Condon factor for the weak-coupling limit. For a simple electron-transfer process $f_{ad} \approx \exp[(H_{RP} + \cdots)/RT]$, the higher order correction terms arise from the shifts of the adiabatic relative to the diabatic PE minima.

In the simplest model of the strong-coupling limit, one considers only the reactant and product electronic states; this is illustrated in Figures 1 and 2, and presumed in equation (33). This is a two state model, and two state models have been used extensively to describe electron-transfer systems.[57] In many strongly coupled electron-transfer systems, the donor and acceptor are linked by a bridging ligand, and the properties of the bridging ligand are very important in determining the extent of electronic mixing between D and A. In order to describe the systematic variations in the properties of such complexes, it is often necessary to consider the mixing of the donor with the bridging ligand, the acceptor with the bridging ligand and the effects of these configurational mixings on the overall D/A coupling.[22,58] When the relevant electronic features of the bridging ligand can be described in terms of a single electronic state (e.g. in terms of a single electron in the HOMO or in the LUMO of the ligand), then the appropriate model is a three-state model. If the bridging ligand electronic structure is best described in terms of several electronic states, then a correspondingly more complicated model may be used.

For the two state limit, assume that the minima of the diabatic PE surfaces differ in energy by $E_{RP}(d)^{0'0}$ and that these minima are separated by an amount $x_{(d)}$ in some correlated nuclear coordinate. If the electronic matrix element that mixes the two states is H_{RP}, then the adiabatic energies of the electron-transfer states are the solutions of equation (34).

$$\begin{vmatrix} E^{0'0}_{RP(d)} + \frac{1}{2} f(x - x_{(d)})^2 - \varepsilon & H_{RP} \\ H_{RP} & \frac{1}{2} f x^2 - \varepsilon \end{vmatrix} = 0 \quad (34)$$

If we set $\lambda_{r(d)} = 1/2 f(x_{(d)})^2$ and $y = (x/x_{(d)})$, then the solutions are given by equation (35),[59]

$$V^{\pm}(y) = \frac{1}{2} E^{0'0}_{RP(d)} + \lambda^{\circ}_{r}(\frac{1}{2} - y + y^2) \pm \frac{1}{2}[(E^{0'0}_{RP(d)} + \lambda_{r(d)} - 2\lambda_{r(d)} y)^2 + 4H^2_{RP}]^{1/2} \quad (35)$$

For $y = 0$ and $(E^{0'0}_{RP(d)} + \lambda_{r(d)}) = E_{RP}(d) \gg H_{RP}$, one obtains for the upper surface[44]

$$V^{+}(x = 0) \cong E_{RP(d)} + \frac{H^2_{RP}}{E_{RP(d)}} \quad (36)$$

and for the lower surface[44]

$$V^{-}(x = 0) = -\frac{H^2_{RP}}{E_{RP(d)}} = -\varepsilon_{RP} \quad (37)$$

In addition to stabilization of the ground state and destabilization of the excited state (both by ε_{RP}), the two state configurational mixing results in a shift of the reactants and products PE minima nearer to one another by approximately $2\alpha^2_{RP} x_{(d)}$. The correction for this shift results in small, higher order contributions to equations (36) and (37); when $E^{0'0}_{RP}(d) = 0$, the vertical energy at the reactant PE minimum (the CT absorption maximum) is $h\nu_{max}(CT, obsd) = \lambda_{r(d)}$. These energy relationships are illustrated in Figure 3.

Figure 1 illustrates the distortions of the PE surfaces that are characteristic of the strong-coupling limit; Figure 2(b) illustrates intermediate coupling. These distortions result in smaller reorganizational energies for this than for the diabatic ($H_{RP} = 0$) limit. This effect can be estimated using the perturbation theory approach; thus, for $\alpha_{PR} = H_{RP}/E_{PR}(d)$ ($E_{PR}(d)$ is the vertical energy difference at the product PE minimum),[22,59–62]

$$\lambda_r \cong \lambda_{r(d)}[1 - 2(\alpha^2_{RP} + \alpha^2_{PR}) + \cdots] \quad (38)$$

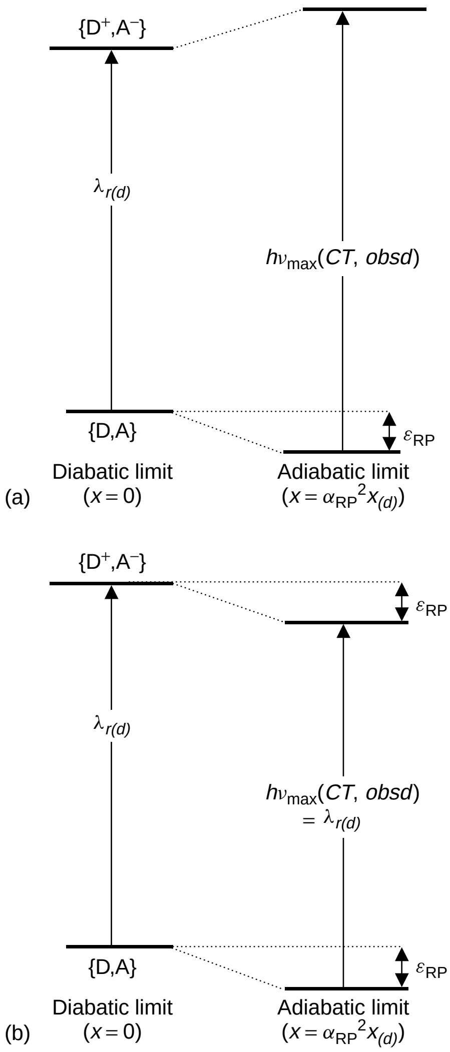

Figure 3 Qualitative two-state energy diagrams for a simple electron-transfer system (a) the limit in which there is no net free energy change for the reaction; (b) qualitatively illustrates the energy relations when the reaction is thermodynamically favorable

At the same level of approximation,

$$\Delta G^{\circ}_{\mathrm{RP}} = \Delta G^{\circ}_{\mathrm{RP}}(1 + \alpha^2_{\mathrm{RP}} + \alpha^2_{\mathrm{PR}}) \tag{39}$$

4.4 Three-state Models and Superexchange Coupling[22]

The covalent linker of a donor and acceptor, in a {D-(B)-A}, complex can function simply as a spacer, separating the donor and acceptor, or it may contribute significantly to the electron-transfer process. The contributions of the ligand to the electron-transfer process can arise even when the actual transfer of charge to the bridging ligand is thermodynamically unfavorable. This effect can be approached as an extension of the configurational mixing issues discussed above.

Most of the studies of linked transition metal D/A complexes have employed bridging ligands that have relatively low-energy π-type LUMOs and metals in which the electron-transfer process involves $d\pi$-orbitals.[63,64] There are fewer studies of purely σ analogs, partly for reasons of complex instability. Some general features are characteristic of any type of bridging ligand.

The superexchange mechanism is commonly employed to describe bridging ligand mediated D/A electronic coupling.[2] The basic concepts involved in this approach can be traced back to the theory of magnetic interactions,[65] and the first application to electron-transfer processes is attributed to McConnell.[66] The approach is simply addressed in terms of a three-state system (see Figure 3): (a) ground (or reactant) state, {(D)-(B)-(A)}; (b) bridge or metal to ligand charge transfer (MLCT) state, {(D^+)-(B^-)-(A)}; and (c) the electron-transfer excited state (or product state), {(D^+)-(B)-(A^-)}. If H_{DA} is small or zero (no direct D/A overlap; the D and A subscripts are based on a localized configurational notation for the reactant and product states), then the bridge mediated coupling will be dominant. Electron transfer mediated by a bridging ligand MLCT state is typical of the majority of linked transition metal systems. The bridging ligand state could also be a ligand to metal charge transfer (LMCT) state, {(D)-(B^+)-(A^-)}; the formalisms differ only by a factor of two that arises when the bridging ligand orbital that mixes the electronic configurations is unoccupied and the acceptor orbital is half occupied.[58] These are commonly referred to as the 'electron' and 'hole' transfer formalisms, respectively. If the mixing coefficients for the donor and acceptor mixing with the bridging ligand are $H_{\mathrm{DB}}/E_{\mathrm{DB}}$ and $H_{\mathrm{BA}}/E_{\mathrm{BA}}$, respectively, then for MLCT mediation by the LUMO of single bridging moiety and for a filled donor orbital and half-filled acceptor orbital (as in a complex with a low-spin d^6-donor and d^5-acceptor),[2,58]

$$H^{\mathrm{spx}}_{\mathrm{DA}} = \frac{H_{\mathrm{DB}}H_{\mathrm{BA}}}{2E_{\mathrm{av}}} \tag{40}$$

For a single interacting bridging unit and LMCT mediation of the electron transfer (vacant acceptor orbital),

$$H_{\mathrm{DA}}{}^{\mathrm{spx}'} = \frac{H_{\mathrm{AB}}H_{\mathrm{BD}}}{E_{\mathrm{av}}} \tag{41}$$

The value of the energy parameter in the denominators of equations (40) and (41) is based on vertical energies, usually obtained from the charge transfer spectra of the metal complexes (equation 42).[2]

$$E_{\mathrm{av}} = \frac{2E_{\mathrm{DB}}E_{\mathrm{A\text{-}B}}}{(E_{\mathrm{DB}} + E_{\mathrm{A\text{-}B}})} \tag{42}$$

For a chain of linkers ($B^{(1)}$, $B^{(2)}$, . . ., $B^{(n)}$), when only the interactions between nearest neighbor moieties of the bridging ligand are considered, and for γ_{ij} the mixing coefficient

between the ith and jth bridging ligand moieties, the D/A coupling matrix element is given by equation (43).[2,3,66]

$$H_{DA} = \frac{H_{DB^{(1)}}}{E_{DB^{(1)}}}\left[\prod_{(i)=1}^{(i)=n-1}\gamma_{(i)(i+1)}\right]H_{B^{(n)}A} \tag{43}$$

In the limit of an infinite chain of identical bridging ligand moieties, equation (43) takes the form of an exponential dependence on the geometrical distance between the donor and acceptor, d_{DA}.[2,3,66]

$$H_{DA} = H_{DA}(i=0)e^{-\beta d_{DA}} \tag{44}$$

An algebraically similar expression can be based on the overlap of spherical wavefunctions far from their nucleus of origin;[67] in this case β is an inverse orbital radius. The interpretation of β in a superexchange-based expression is more complicated.[3]

Equation (31) suggests that the solvent reorganizational energy should increase as the linker increases in length (i.e. for the linker length defined as $d_L = [d_{DA} - a - b]$). This can be a substantial effect, even if the linker does not otherwise affect the electron-transfer rate constant. One expects H_{RP} to decrease with distance (equation 44), so α_{DA}^2 decreases rapidly with d_L and any attenuation of χ_s due to the delocalization of electron density as in equation (38) will also decrease. The different distance dependencies of χ_s and H_{DA} make them difficult to resolve. A further complication is that the linker itself usually has dielectric properties (e.g. η and D_s in equation 31) that differ from those of the solvent. The increase of χ_s with d_L implied in equation (31) suggests that the bandwidth for absorption or emission should also increase with d_L; the maximum increase in $\Delta\nu_{1/2}$ is about 40%. There should be a correlated, systematic shift to higher energies of the electron-transfer absorption maxima of the linked complexes as d_L increases.

The differences between the observed electron-transfer parameters (χ_r, ΔG_{DA}, $h\nu_{max}$, etc.) and their values for an appropriate reference, when the D/A electronic coupling is mediated by a bridging ligand, can provide useful information about the extent of configurational mixing between the donor and acceptor moieties with the bridging ligand.[68,69] When the direct coupling between the donor and acceptor can be neglected, as when they are far apart, the effect of the bridging ligand in mediating their coupling can be expressed as in equations (45–47).[2,44]

$$\psi_R = \frac{[\psi_{R(d)} + \alpha_{RB}\psi_{B(d)}]}{[1+\alpha_{RB}^2]^{1/2}} \tag{45}$$

$$\psi_P = \frac{[\psi_{P(d)} + \alpha_{BP}\psi_{B(d)}]}{[1+\alpha_{BP}^2]^{1/2}} \tag{46}$$

$$\psi_B = \frac{[\psi_{B(d)} - \alpha_{PB}\psi_{B(d)} - \alpha_{BR}\psi_{B(d)}]}{[1+\alpha_{PB}^2+\alpha_{BR}^2]^{1/2}} \tag{47}$$

The configurational mixing with the ligand reduces the energy of the ground state by $\varepsilon_s(R) = H_{RB}^2/E_{RB}$, and that of the electron-transfer excited state by $\varepsilon_s(P) = H_{BP}^2/E_{PB}$. Since $E_{RB} > E_{PB}$ (see Figure 4), the absorption maximum of the $D \rightarrow A$ electronic transition is shifted to lower energy,

$$h\nu_{max}(\mathrm{D/A}) = h\nu_{max}(\mathrm{ref}) + \varepsilon_s(\mathrm{R}) - \varepsilon_s(\mathrm{P}) \tag{48}$$

The reference chosen for evaluating this shift should be a D/A complex in which there is no configurational mixing ($H_{DB} = H_{AB} = 0$), and evaluated for general conditions as in the system investigated. The shifts in the absorption maxima are a measure of the configurational mixing with the bridging ligand in strongly coupled systems. For a chemically symmetric system, $H_{RB} = H_{PB}$, and when no other factors contribute to the shifts in absorption maximum,

$$\Delta h\nu_{max} = [h\nu_{max}(\mathrm{D/A}) - h\nu_{max}(\mathrm{ref})] = H_{RB}{}^2\left(\frac{E_{RB}-E_{PB}}{E_{RB}E_{PB}}\right) \tag{49}$$

Comparison of equation (41) with equation (49) indicates that in a simple, chemically symmetrical system (assuming one partly filled acceptor orbital, as in Ru^{II}/Ru^{III} couples), the shift of the absorption maximum should be closely related to

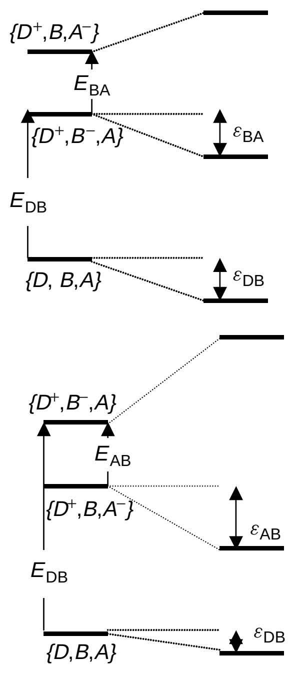

Figure 4 Qualitative three-state energy level diagrams. All energies are with respect to ground-state nuclear coordinates (vertical energies). The lower diagram illustrates the usual case in which a higher energy bridging ligand electronic state mediates the donor–acceptor coupling by means of configurational mixing. The upper diagram illustrates the limit in which the vertical energy of the bridging ligand electronic state is less than that of the electron-transfer excited state. Diabatic states on the left and adiabatic states on the right of each diagram

the single, linker MLCT excited state mediated superexchange coupling.[68,69]

$$\Delta h\nu_{max} \cong 4H_{DA}{}^{spx}\left[\frac{E_{DA}}{E_{DB}+E_{AB}}\right] \tag{50}$$

Appropriate parameters can often be inferred from the properties of related but separate donor and acceptor complexes, or from the extrapolation of the properties of a closely related series of linked complexes to the limit that $\alpha_{DA}^2 = 0$.

4.5 Vibronic Coupling and the Mixing of Nuclear and Electronic Coordinates[48,70–72]

It is usually assumed that the electronic coupling matrix element is a constant across the reaction coordinate. Since the electronic wavefunction is a function of both the electronic and nuclear coordinates, even in the Born-Oppenheimer approximation, it is not surprising that in some systems the assumption that the nuclear and electronic coordinates are independent (the Condon approximation) is not appropriate. The most obvious example of the failure of this approximation is for a system in which the matrix element is dominated by superexchange contributions, since the vertical energies, E_{DB} and E_{BA}, vary with the nuclear coordinates. There are other, probably less obvious kinds of such vibronic coupling:

a. H_{DA} may be different in different vibrational states.
b. A change in the nuclear coordinates of the ligands of one of the reactants may be directly coupled with a change in the nuclear coordinates of the other reactant (e.g. for a mono-atomic bridge).
c. Electron delocalization between the donor, the acceptor, and/or the bridging ligand may lead to significant anharmonicities along the reaction coordinate that alter the reactant-bridging ligand interaction.
d. The timescale for electron transfer (i.e. $(\nu_{el})^{-1}$) may be comparable to that for coupled nuclear vibrations (ν_{nu}^{-1}).
e. The timescale for electron transfer (i.e. $(\nu_{el})^{-1}$) may be shorter than or equal to that for the relaxation of vibrational excited states (k_{vib}^{-1}) of the products.

Each of these effects may be referred to as 'vibronic coupling' even though the underlying physics and/or the experimental manifestations of the coupling are often different. Although, the issues related to vibronic coupling are very complicated, it is possible to get some insight into them from the consideration of some idealized, limiting cases:[22]

Case 1. A one-dimensional system in which the donor and acceptor differ only in the distances between metal and some nonbridging ligand(s),

$$[L\text{—}M^{II}]\text{-}B\text{-}[^*M^{III}\text{-}L] \rightleftharpoons \{[L\rightsquigarrow M]\text{-}B\text{-}[^*M\rightsquigarrow L]\}^{\ddagger} \rightleftharpoons [L\text{-}M^{III}]\text{-}B\text{-}[^*M^{II}\text{—}L] \tag{51}$$

A lengthening of a bond at one center and compression at the other accompanies the transfer of charge between metal centers. Simple vibronic models assume that the electron is equally distributed over the metals in the transition state, designated $\{\ldots\}^{\ddagger}$, or, alternatively, that the 'hopping frequency' (see equation 30) $\nu_{el} > \nu_{ML}$, ν_{*ML} (note that in the transition state, $\nu_{ML}^{\ddagger} = \nu_{*ML}^{\ddagger}$ for the M–L stretches of the respective moieties for a symmetrical system). The classical, transition-state-based Marcus–Hush-type of models assume that the vibrations ν_{ML} and ν_{*ML} are completely independent. In a simple vibronic model it is assumed that the compression of *[L–M]* and the extension of *[*M–L]* occur simultaneously along the electron-transfer coordinate. The transfer of electron density couples these vibrations of the donor and acceptor moieties. The nuclear coordinate implicated in this simple model is the antisymmetric combination of component stretching coordinates,[72] $r_{ML}^{-} = (r_{ML} - r_{*ML})/2^{1/2}$. The corresponding vibration is $\nu_{ML}^{-} = \nu_{ML}^{\ddagger} - \delta_{ML}$; where δ_{ML} is the coupling between the local bond stretches.

Case 2. For a reaction in which the donor and acceptor differ significantly in their distances to the bridging ligand,

$$[L\text{-}M^{II}]\text{—}B\text{-}[^*M^{III}\text{-}L] \rightleftharpoons \{[L\text{-}M]\rightsquigarrow B\rightsquigarrow[^*M\text{-}L]\}^{\ddagger} \rightleftharpoons [L\text{-}M^{III}]\text{-}B\text{—}[^*M^{II}\text{-}L] \tag{52}$$

The coupled nuclear motion is $r_{MB}^{-} = (r_{MB} - r_{*MB})/2^{1/2}$, and $\nu_{MB}^{-} = \nu_{MB}^{\ddagger} - \delta_{MB}$. This could be used as a model for reactions 2 and 4.

Case 3. The nuclear coordinates within the bridging ligand of the D/A complex may be different from those in the complexes with the metals in identical oxidation states.

$$[L\text{–}M^{II}]\text{–}(B\text{-}^*B)\text{–}[^*M^{II}\text{–}L] \xrightarrow{-e} [L\text{–}M^{II}]\text{–}(B\text{–}^*B)\text{–}[^*M^{III}\text{–}L] \xrightarrow{-e} [L\text{–}M^{III}]\text{–}(B\text{–}^*B)\text{–}[^*M^{III}\text{–}L] \tag{53}$$

This process and the symmetry of the system are both different from those of *Cases 1* and *2*. This corresponds to a system in which there is appreciable delocalization of electron density between the donor (acceptor) and the bridging ligand, the bridging ligand mediates donor–acceptor coupling and the bridging ligand distortion enhances the D/A coupling.

The coupling of the nuclear and electronic coordinates is probably not a major issue in the discussion of most outer-sphere electron-transfer reactions because: (1) the nuclear motions, or molecular vibrations, at the donor and acceptor centers are independent of one another; and (2) the D/A electronic coupling and the fraction of delocalized electron density are both small. One perspective on the classical, Marcus–Hush description of the electron-transfer reaction

coordinate is that $\kappa_{el} = 0$ for all nuclear coordinates except for those of the transition state, and that $\kappa_{el} = 1$ at the transition state (a resonance condition). This description is conceptually useful since the nuclear motions are treated as random and independent at the donor and acceptor. A consequence of this independence of the nuclear motions is that when the reactant system is near to the transition state, a fluctuation in the positions of the nuclei that moves the system away from the product configuration is more probable than one that moves it towards that configuration. On the other hand, any coupled nuclear motions of the reactant system near to the transition state that correspond to nuclear motion across the reaction coordinate will tend to couple to the electronic distribution. This is especially possible for some bridging moieties that link the donor to the acceptor; for example, some vibrations of the bridge may be directly coupled to the electronic distribution between the donor and the acceptor.[73]

Finally, it is to be noted that configurational mixing-related anharmonicities of the PE surfaces have the effect of mixing the nuclear and electronic coordinates, even in the two state model (see equations 35–40). These anharmonicities must result in changes in the frequencies of some vibrational modes that are correlated with the reaction coordinate. The size of the anharmonic contribution increases with electron delocalization.

5 EXPERIMENTAL OBSERVATIONS AT THE WEAKLY-COUPLED LIMIT

Much of the pertinent information has been summarized previously, and the details can be found in the references cited in those summaries.[21,22,74]

5.1 A Summary of Outer-Sphere Electron-transfer Reactions

Overall, the outer-sphere electron-transfer reactions of transition metal complexes reactions are consistent with the expectations of the semiclassical Marcus–Hush theory.[3,21,22,25,32,43,57,71,75–78] For the most part, this agreement of theory with experimental observations is based on the correlations between different experimentally measured parameters (such as the variations of experimental rate constants with driving force, with different solvents, with the size or separation of donor and acceptor, with bond length changes, etc.). There are some notable exceptions. Many of these are for reactions involving a high-spin cobalt(II) complex among the reactants or the products,[79,80] and these deviations from expected behavior have usually been attributed to contributions from $\kappa_{el} \ll 1$. Another class of notable exceptions is for reactions in the Marcus inverted region. Thus, the physical properties of the coordination complexes that influence the Franck–Condon parameters χ_s and ΔG°_{RP} alter the observed rate constants in a manner that is nearly quantitatively predictable from the semiclassical approaches when $|\Delta G^\circ_{RP}| < \chi_s$. Observations on the various contributing parameters are briefly summarized.

5.1.1 *Solvent reorganizational contributions*

In principle, the importance of the solvent contribution to the electron-transfer reorganizational energy should be most evident in a comparison of reaction rates in the presence to those in the absence of a solvent. Gas-phase electron-transfer reactions provide this contrast. There are important differences between solution and gas-phase reactions: (a) electrostatic interactions between reactants are far more important in the gas phase since solvent polarization tends to moderate these interactions in solution; (b) the translational energy difference that the reactants bring into the collision complex must be distributed over the internal degrees of freedom during the lifetime of the reactive collision; (c) in the absence of solvent, only the molecular geometry changes contribute to χ_r. Several useful studies have employed ion cyclotron resonance (ICR) spectroscopic techniques to study the gas-phase electron-transfer reactions of bis-cyclopentadienyl (Cp; Cp* designates the pentamethyl-cyclopentadienyl ligand) complexes,[81,82]

$$[M(Cp)_2] + [M(^*Cp)_2]^+ \rightleftharpoons [M(Cp)_2]^+ + [M(^*Cp)_2] \quad (54)$$

Isotopic labeling of the Cp^- rings enables the study of self-exchange reactions using the ICR technique. The rate constants for the gas-phase reactions are close to the diffusion limit and about 10^4 times larger than their solution phase equivalents. The slower solution reactions correspond to $\chi_s \sim$ (12 to 13) $\times 10^3\ cm^{-1}$.

The bimolecular self-exchange reactions of Ru^{II}/Ru^{III} complexes in aqueous solution involve the exchange of an electron between largely nonbonding orbitals so the accompanying changes in molecular geometry tend to be very small. Even when there are geometry differences between the two electron-transfer states, the metal–ligand vibrational quanta are small enough ($300–600\ cm^{-1} < 4k_BT$)[83] that the contributions of high frequency modes, χ_M, to χ_r are small. This makes these couples a convenient choice for examining the contributions of χ_s to k_{et}. The self-exchange rate constants for these complexes are relatively large,[21,22] and values of χ_s can be estimated from the experimental rate constants ($\chi_r = 4\Delta G^\ddagger_{DA}$) with only small corrections for χ_M. These estimates of χ_s for several ruthenium couples are summarized elsewhere,[22] and tend to increase with the inverse mean external radius of the complex (r^{-1}_{mean} in pm^{-1})[84] as expected from equation (31). They correlate well ($r^2 = 0.99$ for the ammine-polypyridine complexes) with the reciprocal of the estimates of the mean external radius[84] of the complexes. The least squares fit (χ_s in units of $10^3\ cm^{-1}$) of the observations for the ammine-polypyridine Ru(III)-(II) couples in aqueous

solutions is[22]

$$\chi_s = \frac{(4570 \pm 2)}{r_{mean}} + (0.1 \pm 0.4) \quad (55)$$

The slope of this correlation is about 50% larger than predicted by equation (31). This contrast may arise from an underestimate of the external radii of the complexes, or (more likely) some specific solvation effects and the inadequacies of the dielectric continuum model on which equation (31) is based. Equation (55) seems to be a good basis for estimating the contributions of χ_s, provided the same procedure is used to estimate r_{mean}.[84] Relatively elaborate solvation models, in which the solvent structure near to the reactants plays an important role, are being explored.[85]

5.1.2 *The intramolecular contributions, χ_M*

Among six-coordination complexes, the changes of metal–ligand bond length that accompany the transfer of an electron tend to be the largest for cobalt(III)-(II) couples. The self-exchange electron-transfer rate constants of a wide range of Co^{III}/Co^{II} complexes for which X-ray and/or solution EXAFS data are available is in agreement with equation (33) within the limits of the experimental uncertainties.[22]

5.1.3 *The purely electronic contributions, H_{RP}*

The contributions of (FC) to k_{et} tend to be very large, as noted above, and the exponential dependence of k_{et} on the experimental uncertainties in the determination of Franck–Condon parameters is often large enough to overwhelm the determination of H_{RP} from rate constant measurements. This has made systematic studies of this parameter difficult and controversial. That κ_{el} is less than unity for many reactions, particularly of Co^{III}/Co^{II} couples, has been demonstrated by the contrasting effects (compared to Ru^{III}/Ru^{II} couples) of purely electronic, ion-pair charge transfer perturbations of the rate constant (this is a superexchange contribution),[79] and by the complex dependencies of the electron-transfer rates of simple coordination complexes on the intensities of external magnetic fields.[86]

The simple self-exchange reaction in equation (56) has been extensively investigated.

$$[Fe(CN)_6]^{4-} + [^*Fe(CN)_6]^{3-} \rightleftharpoons [Fe(CN)_6]^{3-} + [^*Fe(CN)_6]^{4-} \quad (56)$$

This reaction is strongly 'catalyzed' by cations; the uncatalyzed rate constant in aqueous solution (25 °C, $I = 0.2$ M) is $K_A k_{et} = 2.2 \times 10^2\ M^{-1}\ s^{-1}$.[87,88] The {*[Fe(CN)*$_6$]$^{4-}$, *[Fe(CN)*$_6$]$^{3-}$} ion pair (see section 5.2, below) has been reported ($[K^+] = 2.5$ M, ionic strength ~10 M and K_A determined as $0.05\ M^{-1}$) to have an absorption maximum at $12.2 \times 10^3\ cm^{-1}$ with $\varepsilon_{max} = 28\ cm^{-1}\ M^{-1}$ and $\Delta\nu_{1/2} = 7.9 \times 10^3\ cm^{-1}$.[89] Based on the ion-pair absorption spectrum and equation (13) (neglecting g_o), $H_{DA} = 116\ cm^{-1}$ ($\kappa_{el} \cong 0.5$).

Several studies of bimetallic complexes in which the donor and acceptor are linked across aliphatic chains have demonstrated that these are generally weakly coupled systems.[90–92] Studies of complexes linked by 1,2-bis(2,2′bipyridyl-4′-yl)ethane (bb; see Figure 5), indicate that these are good models of the precursor complexes for outer-sphere electron-transfer reactions of tris-bipyridyl complexes. A careful comparison of kinetic and spectroscopic data with computational studies has led to an estimate of $H_{RP} \cong 20\ cm^{-1}$ for the $[Fe(bb)_3Fe]^{5+}$ self-exchange electron transfer.[91] In a related cross-reaction, the Ru/bpy MLCT excited state of $[(bpy)_2Ru(bb)Co(bpy)_2]^{5+}$ is efficiently quenched by electron transfer to the cobalt center in several resolved steps, equations (57) and (58).[90]

$$[(bpy)_2Ru^{II}(bb)Co^{III}(bpy)_2]^{5+} + h\nu \longrightarrow [^3MLCT(bpy)_2Ru^{III}(bb)(^2E)Co^{II}(bpy)_2]^{5+} \quad (57)$$

$$[^3MLCT(bpy)_2Ru^{III}(bb)(^2E)Co^{II}(bpy)_2]^{5+} \longrightarrow [(bpy)_2Ru^{III}(bb)(^4T)Co^{II}(bpy)_2]^{5+} \quad (58)$$

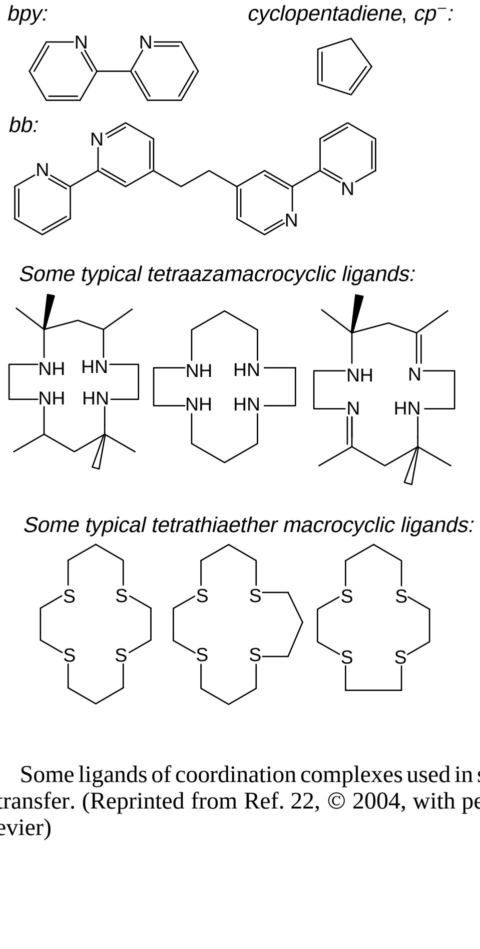

Figure 5 Some ligands of coordination complexes used in studies of electron transfer. (Reprinted from Ref. 22, © 2004, with permission from Elsevier)

This is followed by very fast back electron transfer to regenerate the ground state.

$$[(bpy)_2Ru^{III}(bb)(^4T)Co^{II}(bpy)_2]^{5+} \longrightarrow [(bpy)_2Ru^{II}(bb)\,Co^{III}(bpy)_2]^{5+} \qquad (59)$$

The process in equation (59) was estimated to have $H_{RP} \cong 8\,cm^{-1}$ ($\kappa_{el} \approx 10^{-2}$).[90]

5.2 Correlations of Kinetic, Electrochemical, and Spectroscopic Parameters of Ion Pairs

Ion pairs of the type $\{ML_n^{z+}, {}^*MX_m^{y-}\}$ generally exhibit weak CT absorption bands. When self-exchange kinetic data and reduction potentials are available (or can be estimated) for the $ML_n^{z+}/ML_n^{(z-1)+}$ and $MX_m^{(y+1)-}/{}^*MX_m^{y-}$ couples, then the thermal parameters can be compared to the spectroscopic based on equation (20). In this limit, the free energy contribution can be approximated by the difference in the half-wave potentials of the donor and acceptor as in equation (60); $\Delta G^{\circ}_{RP} - F\Delta E_{1/2}$ (F = Faraday's constant; in this limit, the correction for the difference in the species involved in light absorption and the electrochemical process, proportional to α^2_{RP}, is small).[22,93]

$$h\nu_{max}(abs) \cong F\Delta E_{1/2} + \chi_r + \cdots \qquad (60)$$

The ion-pair charge transfer absorption (IPCT) band maxima are combined with the electrochemical and kinetic data in Figure 6 to illustrate that equation (60) works very well, over nearly a 5-eV range, in the weak-coupling limit.[22] The reorganizational parameters for most of the cationic acceptors in the ion pairs in Figure 6 have been derived from rate constant data (those involving $[Co(NH_3)_6]^{3+}$ have been corrected for the estimated effects of κ_{el}),[22] the resulting parameters may contain a contribution from some additional factor such as $2RT \ln \kappa_{el}$; the deviations from the least squares correlation line average about $1600\,cm^{-1}$ for Ru complexes and about $2700\,cm^{-1}$ for Co complexes. The self-exchange and electrochemical reactions of many of these ion pairs involve high-spin Co^{II} complexes, while the spin-allowed IPCT transitions involve low-spin Co^{II}. That these cobalt ion pairs come close to the line of unit slope suggests that the reorganizational energy is smaller and the free energy change is larger for the couples involving low spin than for those involving high-spin Co^{II}, and that the differences are small on the ~5 eV scale of Figure 6. Some of the deviations may arise because this correlation combines data obtained independently in more than 40 different laboratories.[22]

The observations summarized in this subsection demonstrate that the magnitudes of solvational changes and geometrical differences dominate electron-transfer reactivity, and that these contributions to the Franck–Condon factor are readily

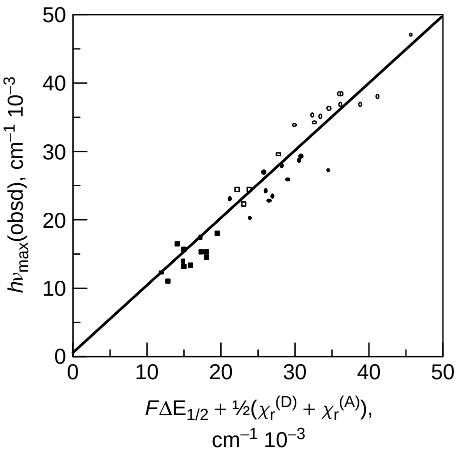

Figure 6 The correlation, based on equation (61), of the absorption maxima of ion-pair charge transfer transitions to the difference in reduction potentials and the average of the reorganizational energies of the constituent electron-transfer couples.[22] ■, Ru^{III} with $M(CN)_n{}^{k-}$; □, Ru^{III} with halides; •, Co^{III} with $M(CN)_n{}^{k-}$; ○, Co^{III} with halides

interpreted and analyzed in the weak-coupling limit. Electron-transfer behavior in this weak-coupling limit constitutes a useful reference for evaluating the behavior of more complex systems. Thus, the deviations of the Franck–Condon parameters found for systems that fall into the strongly coupled limit can be evaluated with respect to representative systems in the weakly coupled limit.[22]

5.3 Intermediates, Gated Electron-transfer and Vibrational Excited States

Electron-transfer processes that generate metastable 'intermediates' are frequently encountered in the reactions of transition metal donors and acceptors. Any initial reaction product is considered an intermediate in this context if its lifetime is long compared to the intrinsic lifetime of electron transfer (i.e. ν_{el}^{-1} in equation 30). Thus, low-energy electronic excited states are often important in the Marcus inverted region (e.g. see equations 57–59) because the electron-transfer rate in this region decreases rapidly with increasing driving force. When the reactants and products of a cross-reaction differ significantly in geometry, then the electron-transfer step may involve the formation of a product in a metastable geometry if the conformational equilibration (k_{conf}) of the products is slow.

Similarly, if the rate of vibrational relaxation (k_{vib}) is small compared to ν_{el}, then vibrational excited states of the products can act as intermediates in the electron-transfer process. Since vibrational modes with large quanta tend to relax more slowly than modes with small quanta, the role of high frequency vibrational modes in the Marcus inverted region can be interpreted as electron transfer to form a vibrationally excited

intermediate with a net driving force of $(\Delta G^\circ_{RP} + jh\nu_h)$ (see equations 18 and 29). It should be noted that the lifetimes of the high frequency vibrational modes depend in large part on the rate of transfer of the excess energy to the solvent (or ‘bath’) modes and this is not easy to predict when there are specific solvation effects.

The generation of intermediates with the product electronic structure is only important when the relaxation (or equilibration) of these intermediates to the equilibrium geometry occurs more slowly than ν_{el}, and when the metastable product state is thermodynamically accessible and kinetically advantageous compared to direct generation of ground-state products from the reactants. The intervention of conformationally dictated pathways raises the possibility that protein conformational changes might enable the regulation of electron transfer in metallo-enzyme systems. Such ‘gated’ electron-transfer pathways have been explored theoretically.[94,95]

Rorabacher and coworkers have found that rate comparisons (based on a classical Marcus model) of the oxidations of $Cu^I(S_n)_{(j)}$ and reductions of $Cu^{II}(S_n)_{(j)}$ complexes, where $(S_n)_{(j)}$ is a polythiaether ligand, often suggest that these processes occur by means of different pathways. Since $Cu^{II}L$ and Cu^IL generally have very different equilibrium coordination geometries, these pathways have been associated with the generation of metastable $Cu^{II}L(Q)$ and $Cu^IL(P)$ intermediates, respectively. In principle, the reactivity associated with the resulting pathways can be interpreted in terms of self-exchange reactions that involve these intermediates: that is, the $Cu^{II}L(O)/Cu^IL(P)$ and the $Cu^{II}L(Q)/Cu^IL(R)$ self-exchange reactions, where $Cu^{II}L(O)$ and $Cu^IL(R)$ are the equilibrium species.[96] Self-exchange reactions may also proceed through metastable intermediates, although they need not be the same intermediates as in the cross-reactions. In the simplest limit, there is no direct electron exchange between $Cu^{II}L$ and Cu^IL and the intermediates are in equilibrium with the reactants. In this limit, the rate constants for electron transfer for the different pathways, $k_{et(a)}$ and $k_{et(b)}$, will be determined only by the solvent reorganizational energy, χ_s. Yu *et al.*[96] have observed that the variations in the observed self-exchange rate constants are very nearly accounted for by the variations in the equilibrium constants for formation of the intermediates. If the complexes are all about the same size (~440 pm), then from equation (56) $\chi_s \cong 10.5 \times 10^3\ \text{cm}^{-1}$, and the observed (second order) self-exchange rate constant is given by equation (61).

$$K_A k_{et}(\text{obsd}) = K_A \left[\frac{K_a}{1+K_a} + \frac{K_b}{1+K_b}\right] k_{et}(\text{solv}) \qquad (61)$$

The value estimated for χ_s corresponds to $K_A k_{et}(\text{solv}) \cong 3 \times 10^5\ \text{M}^{-1}\ \text{s}^{-1}$. Only the values self-exchange rate constants for the $[Cu([14]aneS_4)]^{2+,+}$ and the $[Cu([15]aneS_4)]^{2+,+}$ couples are sufficiently different to infer an important contributions from intermediates. The equilibrium constants, $K_a = 4 \times 10^{-5}$ and $K_b = 0.02$, have been determined from rapid-sweep cyclic voltammetry for $[Cu([14]aneS_4)]^{2+,+}$.[96] For these values, $K_A k_{et}(\text{solv}) = 4 \times 10^5\ \text{M}^{-1}\ \text{s}^{-1}$, in excellent agreement with the estimate based on the solvent reorganizational energy for complex ions of this size.

The reactions of the $[Cu(S_n)_{(j)}]$ complexes appear to involve well-defined chemical intermediates, and reaction pathways involving these intermediates are important because they are thermodynamically accessible and because the direct conversion of the equilibrium reactant species to the equilibrium product species would involve a substantial reorganizational energy, χ_{RP}. The reorganizational energy, χ_{int}, for the reaction pathway involving the intermediate must be smaller than χ_{RP} for such an effect to be observed. In the $[Cu(S_n)_{(j)}]$ systems, this constraint can be interpreted in terms of significant molecular distortions (bond breaking, conformational changes, etc.) along the ground-state reaction coordinate, but only solvent reorganization along the reactant-intermediate reaction coordinate. This approach to the role of conformational intermediates presumes well-defined chemical species characterized by a local PE minimum.

6 STRONGLY COUPLED, BRIDGED ELECTRON-TRANSFER SYSTEMS

The literature on covalently linked transition metal donor and acceptor complexes is enormous.[1,11,12,21,58,63,64,74,97–103] Much of it is covered in the article on ***Mixed Valence Compounds***.

General matters of principle and the basic physics are the same as for the outer-sphere reactions. Figure 7 illustrates how increases in the configurational mixing can alter the reaction coordinate (or the reactants-products ground-state PE surface) for chemically degenerate, or mixed valence systems. This range of behavior is often classified as: (a) diabatic limit, Robin-Day class I; (b) delocalized limit, Robin-Day class III; (c) intermediate cases, Robin-Day class II[27] (see Figure 7). There is an intermediate situation in which the adiabatic ground-state PE surface cannot be approximated as a parabola, and this has sometimes been called class II-III[98,100] (see Figure 7).

There can be some significant deviations from the properties characteristic of the weak-coupling limit. For example, the Gaussian absorption band shapes expected based on equation (15) may not be appropriate. Those Gaussian shapes can be attributed to the projection of the ground-state vibrational wave packet onto the excited state PE surface.[50] When there is a very great deal of configurational mixing, as illustrated in Figure 7, the ground-state vibrational wave function and the resulting vibrational wave packet, may be better represented as a sum of Gaussian functions. This will lead to non-Gaussian absorption band shapes. Some of the other contrasts in properties can be attributed to the size of

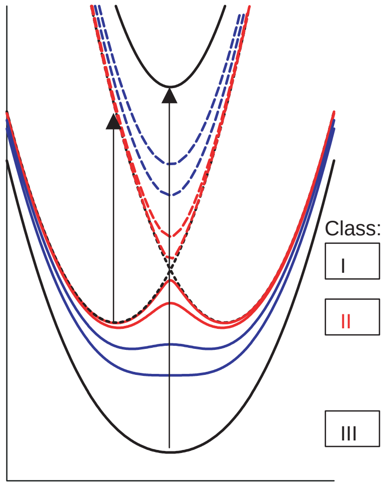

Figure 7 Qualitative effects of configurational mixing in the degenerate ($\Delta G^{\circ}_{RP} = 0$) limit. The dashed black curves are for the diabatic limit. H_{RP} increases with the vertical distance of the center of the adiabatic curves from the crossing point of the diabatic curves; the separation of the ground and excited state adiabatic curves along a vertical line through this region is $2H_{RP}$. The red curves correspond to mixed valence complexes with significant configurational mixing, but 'valence localized' reactant and product states ($H_{RP} < \lambda_r$); Robin-Day class II. The Robin-Day classifications are noted in the boxes on the right. The blue curves correspond to the intermediate situation that is not easily classified

the adiabatic correction factors and some issues are more important in bridged than in outer-sphere electron-transfer processes. A feature of bridged, strongly coupled complexes is that the electronic structure of the bridging ligand can contribute profoundly to their electron-transfer properties (see Section 4.4 and Figure 4, above). The interpolation between the diabatic limits and the adiabatic complexes is most often based on standard perturbation theory (see section 4.4 above). It is to be noted that these approaches are usually constructed, in terms of stationary state wave functions of the system, assuming vertical energies, fixed nuclei, and large differences in the vibrational and electron-transfer timescales. These assumptions are not always appropriate in the linked electron-transfer systems.[70,71,98,104–106]

The presence of a ligand bridging the donor to the acceptor can change many properties of the resulting complex relative to those of the appropriate diabatic limit. Typical changes are: (a) in the separation and orientation of donor and acceptor (from constraints imposed by the bridge); (b) stereochemically dictated differences in orbital overlap; (c) in solvation and ion-pairing; (d) configurational mixing of the bridging ligand orbitals with those of donor and/or acceptor; or (e) the bridge can directly participate in the electron-transfer process.

6.1 Complexes with Aromatic Bridging Ligands

A large number of complexes have been prepared in which the donor and acceptor are bridged by 4,4′-bipyridine and closely related ligands.[21,22,58,63,64] The values of H_{DA} estimated for these complexes are comparable to those of simple ion pairs, and the fraction of delocalized electron density, α^2_{DA}, is small.[22] Most of these complexes fit into the weakly coupled limit.

A wide range of range of electron-transfer behavior is exhibited by D/A systems that are classified as very strongly coupled. The properties of such systems have been extensively reviewed.[63,64,98,99] The Creutz–Taube ion, $[\{Ru(NH_3)_5\}_2pz]^{5+}$,[107] has an electron-transfer CT absorption band at $6.4 \times 10^3\ cm^{-1}$ (absorptivity, in water, of $5 \times 10^3\ M^{-1}\ cm^{-1}$; $\Delta\nu_{1/2} = 1400\ cm^{-1}$), and it has been regarded as the prototype of a very strongly coupled D/A system. The electron transfer CT spectroscopy of related pyrazine-bridged bimetallic complexes range from that of $[\{Os(NH_3)_5\}_2pz]^{5+}$, which does not exhibit a clearly defined Os^{II}/Os^{III} absorption band,[108] to a pyrazine-bridged $\{(Ru_3)_2pz\}$-cluster complex ($Ru_3 = [Ru_3(\mu_3\text{-}O)(\mu\text{-}CH_3CO_2)_6(CO)(py)]^-$ for the $Ru^{II}/Ru^{II}/Ru^{III}$, 'reduced' complex) in which a $12 \times 10^3\ cm^{-1}$ absorption band with an absorptivity of $12200\ M^{-1}\ cm^{-1}$ and $\Delta\nu_{1/2} = 3760\ cm^{-1}$ (in dichloromethane) has been assigned as an metal-to-metal charge transfer (MMCT) absorption.[105] All of these pyrazine-bridged complexes have values of $\Delta E_{1/2}$ of several hundred meV, consistent with very strong electronic coupling.

For the diabatic limit one expects $h\nu_{max}(abs) \cong \chi_s \cong 13 \times 10^3\ cm^{-1}$ for the pentaammines (zero absorptivity and $\Delta\nu_{1/2} \sim 5400\ cm^{-1}$);[22] since the Ru_3 cluster complexes are larger and their net charges are smaller than those of the pentaammines, one expects that in the corresponding diabatic limit for the cluster complexes, $h\nu_{max}(abs) < 6.5 \times 10^3\ cm^{-1}$ and $\Delta\nu_{1/2} < 3700\ cm^{-1}$ (based on the dielectric properties of the solvents[109] and equations (20) and (31); based on equation (13), $H_{RP} \sim 1500\ cm^{-1}$). Equations (49) and (50) indicate that when the perturbing bridging ligand electronic state is higher in energy than the electron-transfer states, the electron-transfer excited state should decrease in energy as the configurational mixing increases. In a perturbation theory-based three-state model, the reverse is characteristic of a system in which the diabatic electron-transfer excited state is higher in energy than the configurationally mixed bridging ligand electronic state.

6.2 Cyanide and Di-Nitrogen Bridged Donor–Acceptor Complexes

Many mixed valence complexes with N_2, or CN^- bridging ligands have been investigated. The cyanide bridge is the most versatile. These relatively simple ligands have cylindrical symmetry, they have a single, well-characterized intraligand vibrational mode and they have general molecular orbital properties analogous to the more complicated polypyridyl bridging ligands. These complexes illustrate many interesting issues of electron-transfer systems.

The $[(NH_3)_5M(NCM'(CN)_5)]^{n-}$ complexes are among the simplest of this class. Hupp and Barbara and their coworkers have extensively examined such complexes (with M = Ru or Os and M′ = Fe, Ru or Os).[110–112] The electronic coupling in These complexes typically exhibit an intense near-infrared M/M′ absorption and H_{DA} is of the order of 2×10^3 cm^{-1}. One of the interesting characteristics of many of these complexes is that the photogenerated electron-transfer excited state returns to the ground state with a rate constant $k_{et} \approx 10^{13}$ s^{-1}. This is faster than faster than the CN^- vibrational relaxation rate: the back electron-transfer occurs from an upper vibrational level of the electron-transfer excited state to form a ground state with vibrationally excited cyanides. This vibrational state-to-vibrational state electron-transfer process is not properly described in terms of electronic PE surfaces and the usual approaches to electron-transfer problems.

The donor–acceptor properties of complexes of the general stoichiometry $[(L)_nM(CNRu(NH_3)_5)_{(6-n)}]^{m+}$ ($n = 4$ or 5; L = a polypyridyl or am(m)ine nonbridging ligand; M = Fe, Ru, Os, Cr, Co, Rh) have also been reported.[68,113–117] One very striking feature of the CN^--bridged D/A complexes is that the CN stretch of a $(L)_nM(CNRu)$ moiety shift to lower frequency,[115–117] opposite to expectation for a bridging cyanide.[83] The size of this shift of ν_{CN} to lower frequencies in CN^--bridged D/A complexes, $\Delta\nu_{CN}$, is proportional to the oscillator strength of the Ru^{II}/M^{III} MM′CT absorption band,[115,116] and this suggests that the CN-nuclear coordinates (Q_{CN}) are a significant factor in determining the D/A electronic coupling. The shift in ν_{CN} appears to be a symmetry-dependent molecular, not a local $Ru^{II}(CN^-)$ Cr^{III}, coupling of electronic and nuclear properties. A vibronic model corresponding to vibronic coupling case 3 has been proposed to account for this behavior,[116,117] with

$$H_{DA} = H^{\circ}_{DA} + bQ_{CN} \tag{62}$$

Complexes with more than one cyanide, such as $[(L)_4M(CN)_2]^{p+}$, can function as bridging ligands. For a series of complexes of the type $[(NH_3)_5Ru^{II}\{(NC)(N_4)M^{III}(CN)\}Ru^{III}(NH_3)_5]^{6+}$, where (N_4) is a cyclic tetraamine, the Ru^{II}/Ru^{III} MMCT absorption band energies decrease in proportion to increasing absorptivity and decreasing energy of the Ru^{II}/M^{III} 'MLCT' absorption, as expected (equations 48 and 49), but the Ru^{II}/Ru^{III} MMCT absorptivities are nearly independent of the Ru^{II}/M^{III} MMCT absorption properties and weak ($\varepsilon_{max} \cong 120$ M^{-1} cm^{-1}) contrary to expectation based on equation (41). Thus, it appears that superexchange coupling is 'turned off' for this type of bridging ligand.[68] This amounts to a vibronic selection rule for the electron-transfer absorption. If H°_{DA} in equation (62) is very small, then the Ru^{II}/M^{III} electronic coupling depends mostly on bQ_{CN}, and nuclei are configured for optimal electronic coupling (bQ_{CN} maximized) in the ground state of the complex; the C–N bridging Ru^{II} and M^{III} stretched; the cyanide bridging Ru^{III} and M^{III} compressed. In the excited state the oxidation states are reversed but the nuclei are fixed (for a vertical transition), and the coupling is minimized. This amounts to a phase restriction on electron transfer. It is relaxed in $[(py)_4Ru^{II}(CNRu^{II}(NH_3)_5)_2(CNRu^{III}(NH_3)_5)]^{5+}$ because the vertical energies of the (terminal–terminal) electron-transfer and Ru^{II}(central)-to-Ru^{III}(terminal) CT excited states are very similar, leading to appreciable excited state-excited state configurational mixing so that the $Ru^{II}(NH_3)_5 \rightarrow Ru^{III}(NH_3)_5$ MMCT transition is relatively intense ($\varepsilon_{max} = 1500$ M^{-1} cm^{-1}).

The $[(NH_3)_5Ru^{II}\{(NC)(N_4)Cr^{III}(CN)\}Ru^{II}(NH_3)_5]^{6+}$ complexes are characterized by intense ($\sim$4000 M^{-1} cm^{-1}/Ru^{II}), Ru^{II}/Cr^{III} metal-to-metal CT absorption bands at approximately 500 nm.[114] The irradiation of these absorption bands of the complexes in 77 K DMSO/H_2O glassy solutions results in $Ru^{III}/Cr^{II} \rightarrow Ru^{II}/Cr^{III}$ electron-transfer emissions.[114] The emission bands have maxima at 850–775 nm (depending on N_4), are relatively broad ($\Delta\nu_{1/2} \approx 1000$ cm^{-1}) and have roughly microsecond lifetimes. The emission energies are consistent with estimated electron-transfer parameters. These emission bands have relatively strong vibronic components with $h\nu_h \cong 400$–500 cm^{-1} (metal–ligand vibrations) and approximately 2000 cm^{-1} (C≡N stretch), and much weaker N–H stretching and NH_2 deformation components (at $\sim$3100 and l600 cm^{-1}, respectively). The very large k_{NH}/k_{ND} isotope effects, in the range of 15–30, imply that the low-temperature excited state back electron transfer in these complexes is by means of a nuclear tunneling pathway mediated by the N–H stretch (the highest frequency vibrational modes). These complexes illustrate the electron-transfer behavior expected in the Marcus inverted region when thermally activated pathways are not accessible.

6.3 Complexes in Which the Donors and Acceptors are Bridged by a Single Atom

Although the reaction in equation (2) has long been a paradigm for efficient, single-atom-bridged electron-transfer reactions,[23] few simple model complexes exist that have a similarly linked donor and acceptor. A problem in such systems is that ligand-substitution rates tend to be very large when the d σ-orbitals are partly or fully occupied.[40]

Bimetallic complexes with a σ-bridging ligand between a transition metal donor and acceptor have been constructed by means of a of a pair of tetraaza-macrocyclic ligand complexes linked through carbon atoms of the macrocyclic rings to xylene, forming face-to-face bimetallic complexes. The $[L\{M^{II}(N_4)\}_2]^{4+}$ complexes have large ion-pair association constants with halides and they are potentially good models for σ-bridged donor–acceptor systems.[118]

Gamelin, *et al.*[73] characterized the oxy-bridged mixed valence $[\{(Me_3[9]aneN_3)Fe\}_2(OH)_3]^{2+}$ complex using a variety of spectroscopic and computational techniques. The 13.4×10^3 cm^{-1} MMCT absorption band has a non-Gaussian band shape and a 3.7×10^3 cm^{-1} bandwidth (300 K in a

propionitrile/butyronitrile solvent). The iron atoms lie along the molecular 3-fold rotational axis and resonance Raman probing of the near-infrared MMCT absorption led to the conclusion that the electron density is delocalized between the iron atoms in this complex. The non-Gaussian band shape was attributed to anharmonicities in the excited state PE surface. The Fe–Fe electronic coupling was inferred to be mediated by Fe($d\pi$)–O–Fe(dσ) superexchange mechanism and H_{DA} was inferred to be a function of the Fe–Fe distance.

7 EXTENSIONS AND APPLICATIONS

There are many studies of the transfer of electrons from enzymes to substrates, across biological membranes, to (or from) electrodes from (or to) substrates, between adsorbed molecular dyes and semiconductor particles, within synthetic films and nano-scale arrays, within 'molecular wires', and so on. Only a few, general comments will be offered on these topics here. The basic physics of molecular electron transfer does not change with the scale of the system, as long as identifiable molecular moieties are present with at least partly localized electronic configurations. The nature of the properties observed, the experimental probes available, and the level of theoretical treatment that is useful may be very different. Different approaches, different limiting models are used for extended arrays (or lattices) of very strongly coupled moieties.

7.1 Electron Transfer in Biological Systems

Electron transfer is an essential component of energy transduction in biological systems. Elementary electron transport steps often involve donors and acceptors separated by cell membranes or protein structure. Multielectron processes are also important. Electron-transfer mechanisms in biological systems have provided challenges to the understanding of fundamental issues and inspirations for the design of efficient, synthetic catalytic systems and a large number of studies.[6,7,19,75,119–126] A combination of studies, employing synthetic 'model systems' that attempt to isolate and mimic selected aspects of the more complicated biological systems and chemical or genetic modification of key components of the biological systems, has been used to probe important features of biological electron-transfer behavior.

Issues related to the preferred pathways and the distance dependence of electron transfer in biological systems have been addressed by covalently linking electron-transfer donors or acceptors (e.g. a ruthenium complex) to specific sites (e.g. a histidine) of a protein or an enzyme.[124,126,127] The distance dependence of the electron-transfer rate constants is generally fitted to equation (44), with most values of β for proteins falling in the range of 1.0 to 1.3 Å $^{-1}$.[124] The protein in these experiments can be regarded as a huge, largely aliphatic bridging ligand, and in most cases it is possible to identify several feasible σ-bonded pathways for the coupling of the donor to the acceptor. A variation on the superexchange coupling model (see equation 43) has been used to identify the most likely of different possible pathways.[124,128–130] The size and flexibility of the protein makes it difficult to accurately define either a precise distance between the donor and acceptor, or a unique pathway.[127,129,131]

In related model complex studies, Isied and coworkers, have examined photo-induced (or pulse-radiolytically initiated) electron-transfer processes in which a polypyridine-ruthenium(II) complex is linked by means of a 4-carboxylato,4′-methyl,2,2′-bipyridine ligand and a polyproline chain to a $[Co(NH_3)_5]^{3+}$ or $[(\text{-NH-py})Ru^{III}(NH_3)_5]$ acceptor.[126] Chains composed of from zero to six cis-prolines have been examined. The apparent distance dependence of the electron-transfer rate constant, corrected for variations in the solvent reorganizational energy, seems to exhibit two types of distance dependence, $\beta \approx 0.7-1$ Å $^{-1}$ for short chains and $\beta \approx 0.3$ Å $^{-1}$ for long chains. A very detailed theoretical analysis of electron transfer in the complexes with four proline linkers has indicated that the electronic coupling is sensitive to conformational variations within the proline chain.[3]

When the appropriate equilibrium constants are not extremely small, direct electron (or hole) transfer to bridge units may occur and the electron (or hole) may then hop from moiety-to-moiety (randomly) along the bridge. When this happens, the electron-transfer rate will decrease only slowly with bridge length. This behavior has been treated in terms of standard nonadiabatic electron-transfer theory.[119]

When metallo-enzymes effect the oxidation or reduction of organic substrates or simple molecules such as H_2O, N_2 or O_2, they often function as multielectron donors or acceptors with two or more metals at the active site.[121–125,132,133] The electronic coupling between the metals is often accompanied by unique spectroscopic features such as electron spin–spin coupling.[73,134–137] The metal–metal electronic coupling may facilitate the multi-electron-transfer reactions with the substrates. In simpler molecular systems, two electron-transfer processes most often require substrate 'binding', as in an inner-sphere, group (or 'atom') transfer process.[138,139]

7.2 Complexes Containing Multiple Donors and/or Acceptors

Trimetallic complexes can be regarded as the first steps in the construction of nano-scale materials from simple molecular species. As the complex aggregates become larger, some of the factors dominating their electron-transfer properties may differ from the factors important in their bimetallic analogs. The observation of vibronic phase effects observed in the dicyano-complex-bridged $Ru(NH_3)_5{}^{2+}$ /$Ru(NH_3)_5{}^{3+}$ complexes may be a hint of this.

The issue of the 'wire-like' properties of arrays of metal complexes has been of some interest, has been reviewed recently.[140,141] See Volume 5 of the series *Electron Transfer in Chemistry*.[1,142,143]

7.3 Heterogeneous Electron-transfer Systems

Heterogeneous electron-transfer processes are important, they have been extensively studied and they span a wide range of phenomena. These include studies of electron transfer from (or to) molecular substrates within (or across) micelles and vesicles,[144] porous solid media,[145,146] layered materials,[147–149] and to (or from) semiconductors and electrodes.[150–156]

The study of heterogeneous systems in which a donor or acceptor is linked to the surface of a conductor or semiconductor has been of special interest when the electron injection into the semiconductor or electrode can be induced by light absorption of the linked dye molecule.[16,149,152,154,157–163] Grätzel and coworkers have used a ruthenium(II) complex linked to TiO_2 by means of a *bis*-carboxylato-bipyridine ligand to construct an efficient photocell.[16,152–154,157] Many details of the functioning of this photocell are not well understood, but it is based on efficient photo-induced injection of electrons, from the MLCT excited state, into the semiconductor. Femtosecond pump and probe experiments have demonstrated that at least some of the photoelectrons are injected within 50 ps of the MLCT excitation.[161,164] This is one of the fastest electron-transfer rates yet measured; it apparently occurs in competition with vibrational relaxation of the excited state.

1 INTRODUCTION

This article is concerned with reactions in which the net effect is transfer of one or more electrons, with little permanent rearrangement of the structures surrounding the donor and acceptor sites. Typical examples are the following: an outer-sphere reaction (equation 1), an inner-sphere reaction (equation 2) that involves direct bridging Cr–Cl–Cr in the transition state, and a two-electron reaction (equation 3) that could be classed as atom transfer, but is formally analogous to equation (2).

$$MnO_4^- + {}^*MnO_4^{2-} \longrightarrow MnO_4^{2-} + {}^*MnO_4^- \quad (1)$$

$$[Cr(OH_2)_5Cl]^{2+} + [{}^*Cr(OH_2)_6]^{2+} \longrightarrow [Cr(OH_2)_6]^{2+} + [{}^*Cr(OH_2)_5Cl]^{2+} \quad (2)$$

$$C_5H_5NO + PPh_3 \longrightarrow C_5H_5N + O = PPh_3 \quad (3)$$

Symmetrical reactions such as equations (1) and (2) are called self-exchange reactions, and are often abbreviated; for example, $MnO_4^{-/2-}$ denotes equation (1). Excluded from this review are reactions such as $[Fe(OH_2)_6]^{2+} + NO \rightarrow [Fe(OH_2)_5NO]^{2+} + H_2O$, in which substantial charge transfer is believed to occur but the final oxidation states are not well defined, and reactions with drastic coordination changes such as reductive elimination and oxidative addition. Also excluded are noncomplementary reactions such as $Tl^{3+} + 2Fe^{2+} \rightarrow Tl^{+} + 2Fe^{3+}$, which involve more or less complicated reaction pathways, except insofar as the individual steps of such reactions include simple electron transfers of the type defined above.[1]

It is generally assumed that even the simplest reactions can be dissected into still smaller steps:

$$A^+ + Bs \rightleftharpoons A^+ \cdots B \qquad k_{ip}, k_{pi} \quad (4a)$$

$$A^+ \cdots Bs \rightleftharpoons A \cdots B^+ \qquad k_{ps}, k_{sp} \quad (4b)$$

$$A \cdots B^+ s \rightleftharpoons A + B^+ \qquad k_{sf}, k_{fs} \quad (4c)$$

Here A, B denote the reacting centers and the superior plus signs denote the higher of the two oxidation states, regardless of the actual ionic charge. The letters i, p, s, and f, denote the initial, precursor, successor, and final states of the reacting system. Provided the two intermediates remain at low concentration throughout, the overall rate law is:

$$\text{Rate} = -\frac{d[A^+]}{dt} = k[A^+][B] \quad (5)$$

where

$$k^{-1} = k_{ip}{}^{-1} + (K_{ip}k_{ps})^{-1} + (K_{ip}K_{ps}k_{sf})^{-1} \quad (6)$$

where K_{ip} and K_{ps} are the equilibrium constants for equations (4a and b). Actual precursor and successor complexes have been detected in a number of cases, and various combinations of rate and equilibrium constants have been measured under favorable conditions, but the commonest case for reactions between separated complexes in solution is for equation (4b) to be rate determining, so that

$$k = K_{ip}k_{ps} \quad (7)$$

and equations (4a) and (c) are diffusion controlled. A second important situation arises when the precursor complex can be synthesized and k_{ps} can be measured directly.[2] This has been done with complexes such as (**1**) in which by various means the extra electron is rapidly and selectively added to one of the two centers and then transfers intramolecularly to the other, and with quasi-symmetrical mixed-valence molecules such as (**2**) in which the two centers differ only by the number of electrons, as in a self-exchange reaction.

$[(H_3N)_5Co^{III}(pz)Ru^{II}(NH_3)_4SO_4]^{3+}$ (**1**)

$[O_2NC_6H_4OC_6H_4NO_2\bullet]^-$ (**2**)

The formulas quoted in this section have been used to estimate absolute rates of a considerable number of outer-sphere electron-transfer reactions. The reactions $Ru(OH_2)_6^{3+/2+}$ and $Ru(NH_3)_6^{3+/2+}$,[3] and $MnO_4^{-/2}$,[4] are particularly well-studied examples. The dependence of rate on solvent polarity implied by equation (6) has proved more difficult to test and it has only recently become clear that some reactions, such as $[Ru(hfac)_3]^{0/-}$, fit the equation well, while others, such as $[Mn(NC(C_6H_{11})_6)]^{2+/+}$, do not.[5] The variation in polarity is usually achieved by using mixed solvents in varying proportions, and selective solvation by one component may be one reason for discrepancies.

2 THE ELECTRON-TRANSFER PROCESS

In equation (1) the precursor complex is a loose ion-pair of formula $[(MnO_4)^- \cdots (MnO_4)^{2-}]$·aq. The questions arise, why is the electron-transfer reaction not instantaneous, or why does the complex not adopt a stable symmetrical structure owing to resonance? That it does not do so is shown by the fact that the rate of reaction is less than the rate of diffusion-controlled encounter between the ions.[1] There are several other well-recognized chemical and physical analogs to electron transfer. (1) Electron transfer can be viewed as a radiationless transition of the precursor complex and it is well established that such processes can be slow. (2) If the complex were constrained to the symmetrical configuration, it would evidently change spontaneously to the less symmetrical form, and this recalls the Jahn–Taller effect, as in an octahedral copper(II) complex that tends to distort to a tetragonal configuration. (3) The localization of one extra electron on one side of the binuclear species is analogous to the localization of a solvated electron or polaron in a liquid or solid medium. The theories of all these effects have in fact been successfully adapted to electron-transfer kinetics. We begin here with the semiclassical two-state model of a mixed-valence dimer first outlined by Mayoh and Day.[6]

In a molecule $(A\cdots B)^+$ the electronic wavefunctions can be written

$$\Psi_1 = \rho\phi_A + \sqrt{(1-\rho^2)}\,\phi_B \tag{8a}$$

$$\Psi_2 = \sqrt{(1-\rho^2)}\phi_A - \rho\,\phi_B \tag{8b}$$

so that $\rho = 0$ corresponds to a ground state with the electron localized on redox center B and an excited state with the electron localized on redox center A, and $\rho = 1$ corresponds to the reverse localization. Partial localization, with $0 < \rho < 1$, means electron densities of ρ^2 and $(1 - \rho^2)$ on the respective sites in the ground state, and vice versa in the excited state. Localization is due to differences in metal–ligand bonds and solvation, and the electron is trapped in a potential well, as shown in Figure 1. The curves drawn in Figure 1 show the potential energy of the electron as a function of position along the internuclear axis.

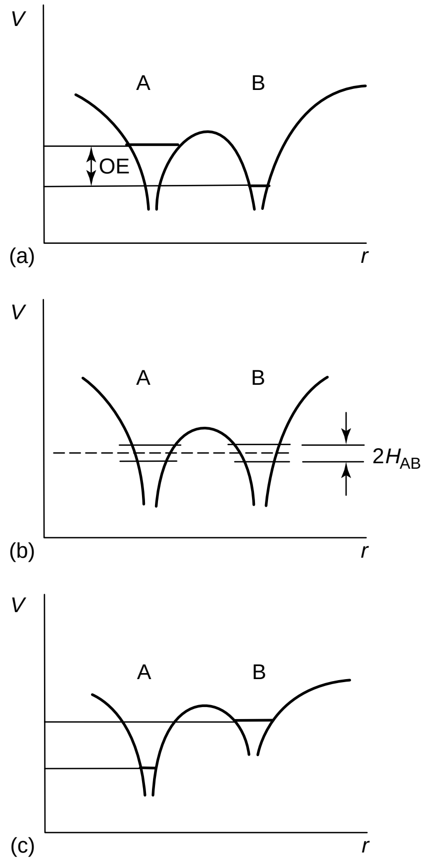

Figure 1 Potential wells for an electron trapped by polarization of solvent or ligand environment in a dinuclear complex $(A\cdots B)^+$. V = electron potential energy, r = distance along the A–B axis. (a) Ground state $p(A^+\cdots B)$ with electron localized mainly at site B, excited state s^* $(A\cdots B^-)$ with electron mainly transferred to site A. (b) The energy wells adjusted to equal 'depth' by solvent and ligand motion. The electron is delocalized with two energy levels separated by $2H_{AB}$. (c) The reverse polarization, ground state $s(A\cdots B^+)$, excited state $p^*(A^+\cdots B)$

In this model, electron transfer occurs when the potential wells change shape to the point where $\rho = 1/2$. The change comes about as a result of a suitable combination of adjustments of positions of ligand and solvent molecules. At this point the electron has, over time, an equal probability of being found on either site, and if the atomic positions continue to evolve in the same sense, the electron transfer goes to completion. Alternatively, if the electron were somehow constrained to one site and then released, it would oscillate between the two sites, or rather, its wavefunction would oscillate between the two forms ϕ_A and ϕ_B. The process whereby the electron passes from one potential well to the other is electron tunneling since in quantum mechanics it is not necessary for the electron to acquire the potential energy corresponding to the top of the barrier.

The energy gap between the donor and acceptor electronic states ΔE (Figure 1) defines the reaction coordinate $X = \Delta E$.

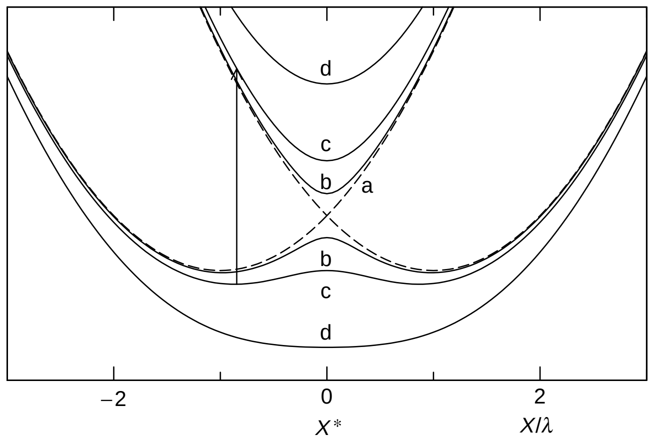

Figure 2 Potential curves for a mixed-valence dinuclear complex ($A^{+}\cdots A$) as functions of the energy gap reaction coordinate X. Broken lines (a), no electronic interaction; (b,b), (c,c), (d,d), successively stronger interactions, the last corresponding to $H_{AB} > \lambda/2$ (see text) so that the symmetrical structure is the most stable. The vertical arrow indicates an intervalence charge-transfer transition

The activated state $X^* = 0$ then corresponds to resonance of the donor and acceptor electronic levels at which electron tunneling may occur. The energy of the reacting system as a function of this coordinate is shown in Figure 2. The two intersecting curves (a) correspond to the fully localized wavefunctions ϕ_A, ϕ_B. The pairs of nonintersecting curves correspond to the mixed wavefunctions Ψ_1, Ψ_2, with different values of H_{AB}, the resonance integral or tunneling integral:

$$H_{AB} = \langle\phi_A|H|\phi_B\rangle \tag{9}$$

where H is the Hamiltonian of the dinucear complex $(A\cdots B)^+$. The separation between upper and lower curves at the point of resonance is $2H_{AB}$. The vertical arrow in Figure 2 also corresponds to an observable physical process, the optical transition whereby the electron localization is reversed, but by the Franck-Condon principle atomic positions remain unchanged. For larger values of H_{AB}, the lower curves take the form shown as (b) and (c), with two potential wells and a smooth energy barrier between them, and finally the single-well potential (d), in which the electron delocalized form is the stable form of the dinuclear complex.[6]

3 THE MARCUS THEORY

The model developed by Marcus[7] and Hush[8] assumes the transition state formalism

$$k_{ps} = \kappa_{el}\left(\frac{RT}{Lh}\right)\exp\left(\frac{-\Delta G^*}{RT}\right) \tag{10}$$

where ΔG^* is the free energy of formation of the transition state from the precursor complex, κ_{el} is the probability that the reactants, once assembled into this state, will go on to form products, and the other symbols have their usual meanings. The transition state is defined as the configuration at which the zero-order energy curves cross. Figure 3 shows the crossings of the curves for different values of the overall free energy change ΔG^o. Neglecting the resonance energy, and assuming that the curves are parabolic with equal curvature, the activation free energy is given by the Marcus equation:

$$\Delta G^* = \left(\frac{\lambda}{4}\right)1 + \Delta G^o \tag{11}$$

where λ is the intrinsic free energy barrier. The arguments showing that free energy is the relevant parameter here are discussed by Marcus and Sutin.[9] When $\Delta G^o = 0$, λ is the work required to be done to move the electron from the precursor to successor electronic state without changing the ligand and solvent coordinates.

Reactions with κ_{el} significantly less than 1 are called nonadiabatic. Reactions with $\kappa_{el} \sim 1$ are adiabatic. A convenient notation due to Sutin is

$$k_{ps} = \nu_n\kappa_n\kappa_{el} \tag{12}$$

where ν_n is called the nuclear frequency factor and κ_n is the nuclear rearrangement factor $\exp(-\Delta G^*/RT)$.

All of the above applies to the intramolecular reaction (equation 4b). For the bimolecular process with second-order rate constant k (equation 5), we have

$$\begin{aligned} k = K_{ip}k_{ps} &= K_{ip}\kappa_{el}\left(\frac{RT}{Lh}\right)\exp\left(\frac{-\Delta G^*}{RT}\right) \\ &= Z\kappa_{el}\exp\left(\frac{-w}{RT}\right)\exp\left(\frac{-\Delta G^*}{RT}\right) \end{aligned} \tag{13}$$

where w, the work term, is the reversible work needed to bring the reactants from infinity to the appropriate distance, and Z is a second-order rate constant that can be interpreted as the specific rate of collisions between reactant molecules having the same size and shape as the reactants in question, in the same solvent, but with no mutual attractive or repulsive forces.

The importance of the work term is shown by the observation of chiral recognition in some electron-transfer reactions. Differences in the rate of reaction of different optical enantiomers of the same complex, with a common chiral complex, are attributed to differences in the preequilibrium constant K_{ip} rather than electronic effects.[10]

The reorganization energy is usually considered as the sum of intramolecular ('in') and solvent ('out') contributions:

$$\lambda = \lambda_{out} + \lambda_{in} \tag{14}$$

The intramolecular part is assumed to come from changes in bond length, that is, for a self-exchange reaction,

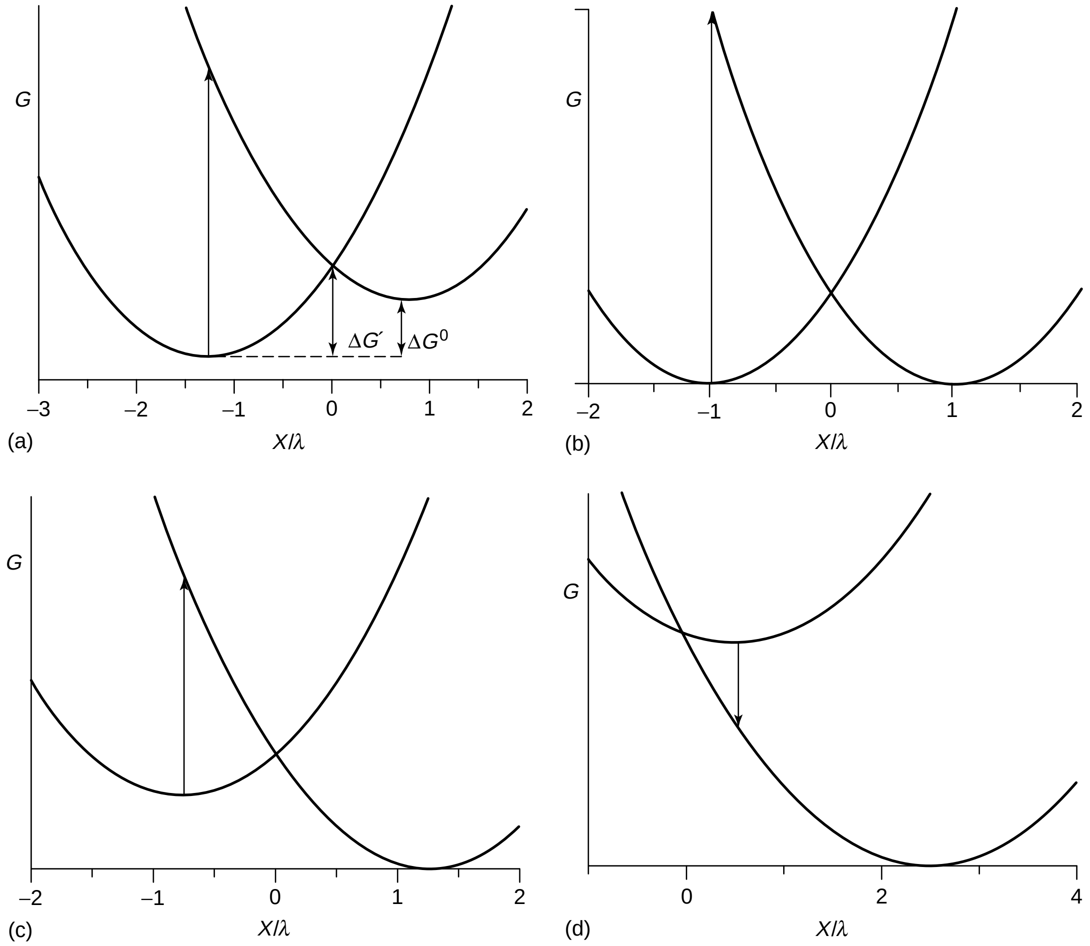

Figure 3 Plots of free energy of zero-order precursor and successor states versus reaction coordinate, for electron-transfer reactions $p(\mathrm{A}^{+}\cdots\mathrm{B}) \rightarrow s(\mathrm{A}\cdots\mathrm{B}^{+})$. (a) $\Delta G^{o} > 0$; (b) $\Delta G^{o} = 0$; (c) $0 > \Delta G^{o} > -\lambda$; (d) $\Delta G^{o} < -\lambda$. The upward-pointing arrows in (a), (b), and (c) indicate intervalence charge-transfer transitions; the downward-pointing arrow in (d) indicates a possible fluorescent transition from the precursor state $p(\mathrm{A}^{+}\cdots\mathrm{B})$

$\mathrm{ML_N}^{z+} + \mathrm{ML_N}^{(z-1)+}$

$$\lambda_{\mathrm{in}} = \left(\frac{LN}{2}\right)\left[\frac{f^{+}f^{-}}{(f^{+}+f^{-})}\right](\Delta r)^2 \tag{15}$$

where f^{+} and f^{-} are the bond force constants in the higher and lower oxidation states and Δr the change in bond length. For the solvent part, the polarization of the solvent fluctuates on two distinct timescales. If the solvent is subject to an instantaneously applied electric field, the immediate response is well approximated by the so-called optical dielectric constant, $\varepsilon_{\mathrm{op}}$, equal to the square of the refractive index of the medium. The slow polarization that follows is due to the atoms and molecules moving to new (average) locations. The sum of these two responses is what is measured by the ordinary 'static' dielectric constant ε_{s}. An argument involving hypothetical reversible charging processes, due to Marcus,[7] and an argument involving hypothetical transfers of molecules between media, due to Hush,[8] lead to the same result, which (in Marcus' formulation[1]) is

$$\lambda_{\mathrm{out}} = \left(\frac{L\varepsilon_0}{2}\right)(\varepsilon_{\mathrm{op}}{}^{-1} - \varepsilon_{\mathrm{s}}{}^{-1})\int_V (E_{\mathrm{c}}{}^{\mathrm{P}} - E_{\mathrm{c}}{}^{\mathrm{S}})^2 \mathrm{d}V \tag{16}$$

where $E_{\mathrm{c}}{}^{\mathrm{P}}$ and $E_{\mathrm{c}}{}^{\mathrm{S}}$ are the electrostatic fields due to the charges of the reactant ions in the precursor and successor complexes respectively, in a vacuum. The integral is taken over the volume occupied by the solvent. Applied to the case of two spherical reactants of radii a_1 and a_2, with central point charges, at distance R_{AB} apart, the formula integrates approximately to

$$\lambda_{\mathrm{out}} = \left(\frac{Le^2}{8\pi\varepsilon_0}\right)(\varepsilon_{\mathrm{op}}{}^{-1} - \varepsilon_{\mathrm{s}}{}^{-1})\left(\frac{1}{a_1} + \frac{1}{a_2} - \frac{2}{R_{\mathrm{AB}}}\right) \tag{17}$$

Refinements of this formula have been given that allow for 'image forces', for changes in radius during reaction,[1] and for cases where the shape of the precursor complex can be

better described as an ellipsoid or a sphere[11–14] rather than two spheres at close distance.

For the work term between charged ions in a polar solvent, the Fuoss equation is often used, giving

$$K_{ip} = \left(\frac{4}{3}\right)\pi a^3 L \exp\left(\frac{-z_1 z_2 s}{a}\right) \tag{18}$$

where z_1, z_2 are respective ionic charge numbers, a is the radius, and $s = e^2/4\pi\varepsilon_0\varepsilon_s k_B T$. (This constant has the value 6.94 Å for water at 25 °C.) For moderate ionic strength I, the extended Debye–Hückel formula leads to the modified Fuoss equation with $a(1 + \kappa a)$ in place of a, where $\kappa = \sqrt{(8\pi LsI)}$.

4 MICROSCOPIC PROPERTIES OF SOLVENT REORGANIZATION

Dielectric continuum approximation for the solvent may work in some cases, but fails when microscopic nature of the solvent is involved in the reaction activation. Such examples include H bonding interaction with ligands such as NH_3 and CN^- where donation of a lone pair leads to donor–acceptor interactions.[3] Even in the absence of specific interactions, dielectric continuum models are not reliable in application to properties obtained as thermodynamic derivatives of the activation Gibbs energy, for instance, the entropy[4] and volume[5] of activation. Both these properties are much more affected by the local solvent structure of the solvent around the donor–acceptor pair than by the long-ranged dielectric response. When the Gibbs energy of reorganization is concerned, a linear trend of λ_{out} versus the Pekar factor $c_0 = \varepsilon_{op}{}^{-1} - \varepsilon_s{}^{-1}$ predicted by equation (17) is often observed for a set of polar solvents.[15] However, there is one class of solvents for which the dielectric continuum approximation is completely inapplicable: nondipolar solvents. These solvents (e.g. benzene) lack any permanent dipole moment and possess only a quadrupole moment and higher multipolar moments. The existence of molecular quadrupole is not reflected by the macroscopic dielectric constant leading to $c_0 \rightarrow 0$ and, correspondingly, $\lambda \rightarrow 0$ for nondipolar solvents. In contrast, substantial reorganization energies are observed in experiment[16] and obtained from microscopic theories of solvent reorganization.[17]

5 THE CROSS RELATION

The above equations predict the absolute rates of electron-transfer reactions, but by far the most popular and useful aspect of the Marcus theory is comparison of rates of different, related reactions.

From equation (11) it follows directly that in a series of reactions, if the work terms and nonadiabaticity parameters are the same or similar, the rates will correlate with the thermodynamic driving force. For small differences, the relationship is linear:

$$\frac{d\Delta G^{\#}}{d\Delta G^{o}} = \frac{d\log k}{d\log K} = \frac{1}{2} \tag{19}$$

where K is the equilibrium constant of the overall reaction (equations 4a–c), and for larger differences it is quadratic. In Figure 4 this is expressed as a plot of log k against $-\Delta G^o$. Curve (a) represents the Marcus prediction. Curvature in the range of moderately negative ΔG^o has been verified many times.[1] The Marcus cross relation[18] expresses the rate constant in terms of those of the two self-exchange reactions involving the same couples:

$$A^+ + B \longrightarrow A + B^+ \qquad k_{12} \tag{20a}$$

$$A^+ + A \longrightarrow A + A^+ \qquad k_{11} \tag{20b}$$

$$B^+ + B \longrightarrow B + B^+ \qquad k_{22} \tag{20c}$$

In this context, equation (20a) is called the 'cross reaction'. Assuming that the reorganization energies are related by

$$\lambda_{12} = \left(\frac{1}{2}\right)(\lambda_{11} + \lambda_{22}) \tag{21}$$

then substitution into equation (11), with the further condition that the work terms are small or cancel, gives

$$\log k_{12} = \left(\frac{1}{2}\right)\log(k_{11}k_{22}K_{12}f_{12}) \tag{22a}$$

$$\log f_{12} = \frac{(\log K_{12})^2}{4\log(k_{11}k_{22}/Z^2)} \tag{22b}$$

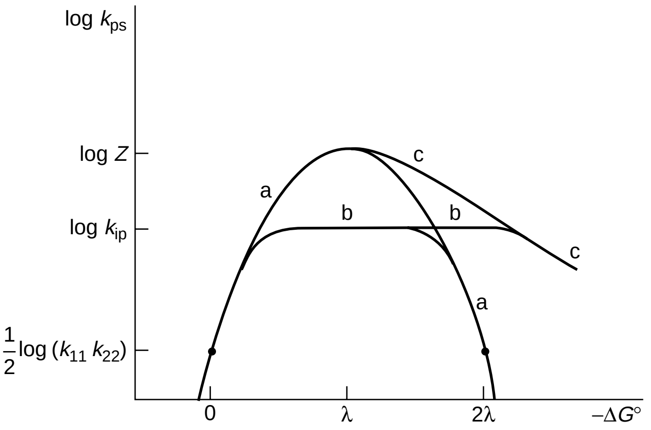

Figure 4 Variation of rate with standard free energy change: (a) as predicted by the classical Marcus equation; (b) with the higher rates limited by diffusion; (c) with nuclear tunneling in the range of highly negative ΔG^o

This result has been tested many times and often predicts values of k_{12} within a factor of two of the experimental result.[19] Deviations due to noncancellation of work terms are also understood,[1] and in some cases have actually been used to estimate the magnitude of the work terms, especially in nonaqueous systems where ionic interactions are strong.[20] Deviations due to nonadiabaticity (see next section) have also been proposed, but with less certainty.[21] When used in reverse to predict an unknown self-exchange rate constant k_{11} from known k_{22}, k_{12}, and K_{12}, the margin of error is greater because of the factor of 1/2 in equation (22a).

6 NONADIABATIC TRANSFER

As mentioned above, if the reactants are assembled with all nuclei in the positions required for the transition state, but the electron is artificially localized at one of the two sites, then released, it will oscillate between the sites. The probability κ_{el} of transfer thus depends on the time the reacting system spends in traversing this small region of reaction coordinate space, in relation to the frequency of oscillation of the wavefunction. Calculations developed by Landau and others give

$$k_{ps} = \left(\frac{4\pi^2}{h}\right) H_{AB}{}^2 (4\pi\lambda RT)^{-1/2} \exp\left(\frac{-\Delta G^*}{RT}\right) \qquad (23)$$

The resonance integral in equation (23) can be obtained from experimental data using the Mulliken-Hush relation

$$H_{AB} = \frac{\mu_{12}}{\Delta\mu_{AB}} \Delta E_{12} \qquad (24)$$

where μ_{12} is the transition dipole coupling the adiabatic states Ψ_1 and Ψ_2 separated by the adiabatic energy gap ΔE_{12}, and $\Delta\mu_{AB}$ is the dipole moment change between the diabatic states A and B. For the case of a well-resolved intervalence band of Gaussian shape, the area of the band gives a measure of the transition dipole moment and hence the mixing parameter ρ (equation 8),[22,23] (the transition dipole moment (in D) can be defined in terms of the molar extinction coefficient by the following relation: $m_{12} = 9.585 \times 10^{-2}(\sqrt{n_D}/f(n_D)) \left[\int \bar{\nu}\varepsilon(\bar{\nu})d\bar{\nu}\right]^{1/2}$, where n_D is the solvent refractive index, the function $f(n_D)$ accounts for the local field of the electronic polarization of the solvent, and $\bar{\nu}$ is the wave number (cm^{-1})).

Equations (23) and (24) presume a knowledge of the relevant electronic states, either the charge-localized diabatic states ϕ_A and ϕ_B or the adiabatic states Ψ_1 and Ψ_2 (equation 8). Typically, diabatic states are natural for studying electron transfer, whereas the adiabatic states are used for optical transitions. The generalized Mulliken-Hush approximation[24] adopts the definition of diabatic states that are diagonal with respect to the component of the dipole moment operator along the charge-transfer direction. The diabatic dipole moment shift is then given in terms of adiabatic parameters observable in optical experiment

$$\Delta\mu_{AB} = [(\Delta\mu_{12})^2 + 4(\mu_{12})^2]^{1/2} \qquad (25)$$

The calculation of H_{AB} according to equations (24) and (25) is in a good agreement with the corresponding values extracted from kinetic measurements at varying temperature.[25]

The present consensus is that most reactions of the outer-sphere type between simple metal complexes in solution are either weakly adiabatic or weakly nonadiabatic with κ_{el} in the range of perhaps 10^{-3} to 1; but that inner-sphere reactions are probably more adiabatic, and reactions such as equation (3) (above) are strongly adiabatic. Also, many electrochemical reactions proceeding via a direct contact between the reactant and the electrode are adiabatic.[26]

7 CONNECTION WITH OPTICAL SPECTROSCOPY

Spectroscopic charge transfer between the two centers of a mixed-valence or precursor complex, known as intervalence charge transfer,[2,22] has the energy E_{op} given by

$$E_{op} = Lh\nu_{CT} = \lambda + \Delta G^o_{ps} \qquad (26)$$

From equations (11) and (24) we have

$$\Delta G^* = \frac{E_{op}{}^2}{4(E_{op} - \Delta G^o_{ps})} \qquad (27)$$

and in the limit of $\Delta G^o_{ps} = 0$; in other words for intervalence transfer in a quasi-symmetrical mixed-valence complex, 'Hush's Law':

$$\Delta G^* = \frac{E_{op}}{4} \qquad (28)$$

This relation relies on the fact that the entropy is unchanged in the Franck-Condon transition, so that the energy difference measured by optical transitions can be connected to the free energy difference for the activations barrier.[13,27] The conclusion, that the rate of a thermal electron-transfer reaction can be estimated from relatively simple spectroscopic data, is remarkable. But it has been pointed out that cases in which an optical and thermal electron transfer have actually been measured on precisely the same system, free of doubts over the assignments, are still very few.[28,29]

It is actually much easier to measure λ spectroscopically than kinetically. The Marcus-Hush model of charge-transfer transitions predicts two fundamental relations between the kinetic parameters and spectroscopic observables. The first relations is between the reorganization energy and the Stoke

shift $h\nu_{st}$ equal to the difference in the first spectral moments for absorption and emission approximately equal to the corresponding maxima energies[30]

$$\lambda = \frac{h\nu_{st}}{2} \tag{29}$$

The second relation connects the intramolecular and solvent reorganization energies to the second spectral moments of absorption, $\langle(\delta\nu)^2\rangle_{abs}$, and emission, $\langle(\delta\nu)^2\rangle_{abs}$, spectral lines:[30]

$$L^2h^2\langle(\delta\nu)^2\rangle_{abs/em} = 2RT\lambda_{out} + Lh\nu\lambda_{in} \tag{30}$$

where ν is the characteristic frequency of bond vibrations. The dependence on the optical and static dielectric constants (equation 17, above) has been verified mainly by measurements of spectra of mixed-valence complexes in solution. Extrapolation of such data to the limit of $({\varepsilon_{op}}^{-1} - {\varepsilon_s}^{-1}) = 0$ also provides a way of separately measuring λ_{in} and λ_{out}.

The analytical expression for the upper and lower of each pair of energy curves in Figure 2 is:[1]

$$E = \left(\frac{\lambda}{4}\right)(x^2+1) \pm \left(\frac{1}{2}\right)[\lambda^2x^2 + 4H_{AB}^2]^{1/2} \tag{31}$$

where $x = X/\lambda$. Valence localization means that the lower curve has two minima and the criterion for this is $H_{AB} < \lambda/2$.[1] The energy curves shown in Figure 2 provide the semiclassical model of a dinuclear mixed-valence complex,[6] distinguishing Robin and Day Class I (distinct valencies with negligible interaction), Class III (indistinguishable metal centers with complete electron delocalization), and Class II (intermediate cases with structurally distinct centers but physical properties affected by the interaction).[31] As the limit of delocalization is approached, the minima also begin to be lowered in energy, and to become less separated on the horizontal axis. This corresponds to the onset of appreciable 'resonance stabilization' in the ground states of the precursor and successor complexes. A comprehensive discussion of the effect of tunneling and other factors on the character of the interaction in a well-studied series of ruthenium(III)–ruthenium(II) dimers has been given by Richardson and Taube.[32]

For all values of H_{AB} (within this first-order perturbation model), equation (27) remains valid, and also

$$\Delta G^* = \left(\frac{1}{4}\right)\lambda - H_{AB} + \frac{{H_{AB}}^2}{\lambda} \tag{32}$$

Analogous relationships have been derived and tested for trinuclear mixed-valence systems[33] such as the triangular-shaped $Fe^{III,III,II}$ complexes.[33c]

8 STATE-TO-STATE THEORIES

More rigorous treatments of nonadiabatic electron transfer have been developed by Levich, Van Duyne and Fischer, Hopfield, Jortner, and others.[34] These consider the full range of vibrational energy levels of the precursor and successor states, so that electron transfer is not restricted to the single crossing point of the zero-order curves (Figure 5). Transfer can occur between any two levels at the same energy, with a probability given by the overlap integral of the respective vibrational wavefunctions, the so-called Franck-Condon factor:

$$(\mathrm{FC})_{ij} = \langle\chi^o_{Si}|\chi^o_{Pj}\rangle \tag{33}$$

where χ^o_{Si} and χ^o_{Pj} are vibrational wavefunctions of the precursor complex and successor complex in vibrational energy levels numbered i and j from their respective zero-point levels. The result can be expressed as

$$k_{ps} = \left(\frac{4\pi^2}{h}\right){H_{AB}}^2(\mathrm{FCWD}) \tag{34}$$

where FCWD is the Franck-Condon weighted density of states:

$$\mathrm{FCWD} = \sum_{i,j}\langle\chi^o_{Si}|\chi^o_{Pj}\rangle^2 \exp\left(\frac{-E_{Rj}}{k_BT}\right) \times \left[\sum_j \exp\left(\frac{-E_{Rj}}{k_BT}\right)\right]^{-1} \delta(E_{Pi} - E_{Rj}) \tag{35}$$

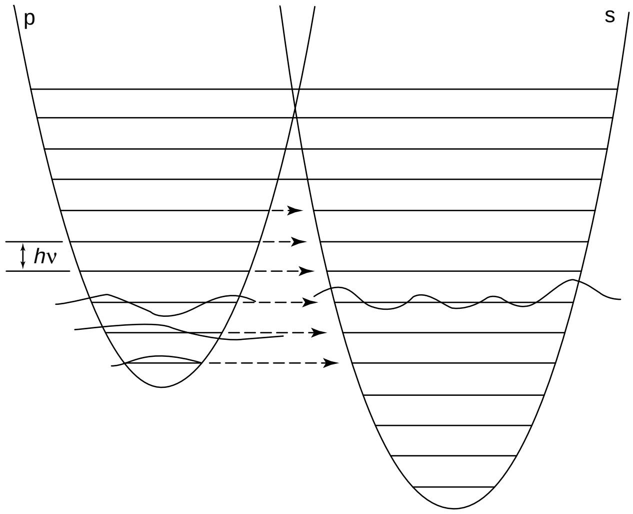

Figure 5 Potential energy curves for an electron-transfer reaction $p(A^+\cdots B) \rightarrow s(A\cdots B^+)$, showing vibrational quantization, assuming the same vibrational frequency ν in precursor and successor states. Some of the vibrational wavefunctions are indicated. The dotted arrows refer to electron transfer below the energy of the crossing of the two curves

the δ function indicating that the electron transfer can only take place with conservation of electronic energy. With the further simplifications that only one high-frequency mode ν effectively contributes to the electron transfer, and that the low-frequency solvent modes can treated by the Marcus-Hush model, this gives

$$k_{\text{ps}} = \left(\frac{4\pi^2}{h}\right) H_{\text{AB}}{}^2 (4\pi\lambda_{\text{out}} k_{\text{B}} T)^{-1/2} \times \sum_m \left[\frac{e^{-S} S^m}{m!}\right] \left[\exp - \frac{(\lambda_{\text{out}} + \Delta G^{\circ} + mh\nu)^2}{4\lambda_{\text{out}} k_{\text{B}} T}\right] \quad (36)$$

where $S = \lambda_{\text{in}}/h\nu$, which in the high-temperature limit reduces to the Marcus expression (equation 11). This type of model has been extensively used for the band-shape analysis of charge-transfer transitions with the goal of extracting the activation parameters from spectra.[2]

This approach makes it clear that electron transfer can occur at temperatures where the population of energy levels near the crossing point is negligible, and indeed the probability of transfer remains finite even at the limit of $T = 0$. In that limit, transfer is from the zero-point level of the precursor complex, and the activation energy is zero. Examples of activationless electron transfer at low temperature have indeed been reported, though it should be noted that there are sometimes difficulties of assignment. The most famous example is the cytochrome–chlorophyll transfer in the bacterium *Chromatium*. The facts are well attested, and the electron-transfer rate does tend to a low and temperature-independent value at low temperature, but detailed fitting to equations derived by Jortner does not yield a self-consistent model.[35] It is now considered that the implied nuclear frequency ν is too high to be physically reasonable, and an alternative suggestion (not necessarily the only possible one) is that two independent electron-transfer reactions take place with different activation energies. Other examples of efficient electron transfer at very low temperature (down to 10 K) have been reported, some of them in nonbiological systems,[36] and the whole area is still being debated.

Studies of the intervalence charge-transfer spectrum in solid-state inorganic materials and dinuclear mixed-valence complexes have given analogous information, less controversially. At low temperatures, the variation of spectral bandwidth is given by[37]

$$(\Delta v_{1/2})^2 (16 \ln 2) \lambda^2 (h\nu)^2 \coth\left(\frac{h\nu}{2k_{\text{B}}T}\right) \quad (37)$$

where $\Delta\nu_{1/2}$ is the full width at half-height. This has been verified experimentally in several cases, and reasonable values of the frequency have been found. For example, in the complex $[(NC)_5Fe^{III}(pz)Fe^{II}(CN)_5]^{5-}$, Felix and Ludi estimated $\nu = 490\,\text{cm}^{-1}$, which is close to the average of the Fe–C stretch frequencies of the complexes $[Fe^{III}(CN)_6]^{3-}$ and $[Fe^{II}(CN)_6]^{4-}$.[37b]

The most thorough-going state-to-state treatment is due to Piepho, Krausz, and Schatz (PKS).[38] Adapted from previous work on the dynamic Jahn–Teller effect, it covers the full range from nonadiabatic to strongly adiabatic. One method of approach starts from the analytical expressions for the double-well and single-well potentials (see equation 27) and uses the fact that, for these particular wells, exact solutions of the time-dependent Schrödinger wave equation are available. The energy wells for the lower surface are highly anharmonic, and the lower levels are grouped in closely spaced pairs, as shown in Figure 6.

Although the eigenvalues can be calculated exactly for these complicated wells, the PKS theory in its preferred form proceeds differently. This is because in the first method the upper and lower potential curves are treated as independent, so that a vibrating system would always be confined to one or the other. At sufficiently high energy and for an appropriate set of coupling parameters it should be possible for a system to spend time on either surface. In general, just as a single quantum oscillator has nuclear coordinates concentrated around two positions, corresponding to the stationary positions of a classical oscillator, so a mixed-valence molecule, or precursor/successor reacting system has nuclear coordinates concentrated around four positions, which it visits randomly by a process of simultaneous electron and nuclear tunneling. As a general basis for the calculation therefore, the original parabolic, zero-order potential curves are used and energy levels and transition probabilities are calculated without reference to the double-well potential as such. The concept of activation energy is avoided, though it reappears in the final results in the sense of the temperature dependence of the calculated rate constant. Plots of rate versus temperature show the expected transition from activated to activationless transfer at low temperature.[39] Other parameters calculated from the model include degrees of electron delocalization in mixed-valence dimers,[38] band shapes of

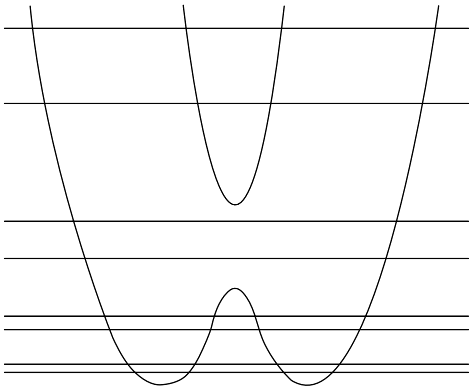

Figure 6 Potential curves for an electron transfer reaction $p(A^+ \cdots A) \rightarrow s(A \cdots A^+)$, or a mixed-valence molecule $(A \cdots A)^+$, with moderately strong electronic interaction, showing the lowest vibrational states split by tunneling through the activation barrier (not to scale)

intervalence charge-transfer spectra,[40] low-energy tunneling transitions,[41] and more recently, intervalence charge-transfer spectra of two-electron mixed-valence systems with one-electron excited states, such as $Sb^{V}\cdots Sb^{III} \rightarrow Sb^{IV}\cdots Sb^{IV}$.[42] The model has been applied to a series of ruthenium(III,II) complexes, calculating parameters such as the degree of valence localization, from the observed shapes of the intervalence charge-transfer bands.[43]

9 THE INVERTED REGION

A consequence of the Marcus-Hush model is the negative dependence of rate on total free energy change, when the latter is made highly negative. This corresponds to a crossing of the potential energy surfaces at the position shown in Figure 3(d). It is now accepted that the Marcus prediction is not likely to be followed in this highly negative range of ΔG^{o}. Two types of deviation have been discussed and can now be said to be understood.

Depending on the values of λ and w, the predicted maximum value of log k may exceed the diffusion-controlled limit for a bimolecular reaction. In that case, a flat-topped log $k - \Delta G^{o}$ profile is expected (Figure 4, curve b), though this in itself would not preclude a descending regime at sufficiently negative ΔG^{o}.[44] Early attempts to probe the inverted region, using positively charged inorganic complexes in polar media, did indeed reach a plateau region, at the level predicted for diffusion control when due allowance was made for the work terms.

In the inverted region, electron is transferred to acceptor vibrational levels well below the classical crossing point. This transition requires almost no activation barrier and thus nuclear tunneling is more favored than thermal activation along the classical activation mechanism. Equation (36), when applied to this situation, leads to a decrease of log k with increasingly negative ΔG^{o}, but not such a rapid decrease as the Marcus equation (Figure 4, curve c). This prediction appears to be supported by a considerable number of experiments, all involving electron transfer in rigid systems (precursor complexes with stiff organic bridging groups),[45,46] and redox centers in biological molecules[46,47] and glasses.[48] Experiments involving bimolecular electron transfer in solution have been much less supportive. Even though the earliest convincing demonstration of inverted behavior, by Creutz and Sutin, involved inorganic complexes in solution,[49] the effects were small; and in some other systems involving excited states of organic molecules as reactants, over much longer ranges of ΔG^{o}, constant, diffusion-controlled rates have been found.[50]

The extreme case of inverted behavior comes, again, from spectroscopy. Figure 3(d) can be applied to the electronic states of a fluorescent molecule as functions of a molecular vibrational coordinate. Fluorescence corresponds to the downward vertical transition, but competing with this is the radiationless transition, which is essentially transfer of an electron between different orbitals through vibrational coupling. The probability of this electron transfer decreases with increasing energy separation of the curves according to the linear energy gap law:[2]

$$k_{ps} \propto \exp\left[-S - \gamma\frac{|\Delta G^{o} - \lambda_{out}|}{h\nu}\right] \tag{38a}$$

$$\gamma = \ln\left(\frac{-\Delta G^{o}}{\lambda_{out}}\right) - 1 \tag{38b}$$

Most examples studied are organic molecules,[51] but an inorganic example is the nonradiative decay of the excited states of complexes such as $[Os(bipy)_3]^{2+}$, assigned to electron transfer from the coordinated radical $(bipy)^{-}$ to Os^{III}.[52]

10 BEYOND THE PARABOLAS

Figure 4 shows that there are several reasons contributing to the deviation of the energy gap law ($\log k_{ps}$ vs $-\Delta G^{o}$) from the inverted parabola of the Marcus-Hush theory. While the diffusion limit and effects of high-frequency vibrations can be sorted out, it is of fundamental interest whether the low-frequency nuclear modes follow the Gaussian statistics resulting in the picture of intersecting parabolas shown in Figure 3. This problem has been extensively studied in recent decades by computer simulations.[53] The quest for nonparabolicity effects predominantly aimed to understand the conditions at which linear solvation by the nuclear modes breaks down reflecting the onset of non-Gaussian statistics. It turned out, however, that solvation of fixed charges in high-temperature, dense molecular solvents is linear resulting in parabolic free energy surfaces for charge transfer.[53a] On the other hand, spectroscopic evidence indicates that relations between spectroscopic observables following from traditional theories may not stand the experimental test. An experimental test of the Marcus-Hush theory can be realized by combining equations (29) and (30). The resulting equation (39) contains only experimental observables

$$L^2h^2\langle(\delta\nu)^2\rangle_{abs/em} \cong RTh\nu_{st} + Lh\nu\lambda_{in} \tag{39}$$

In Figure 7, the absorption and emission second spectral moments are plotted against the Stokes shift obtained for coumarin-153 optical dye in 40 molecular solvents of varying polarity.[16] The slopes of $\langle(\delta\nu)^2\rangle$ versus ν_{st} have opposite signs for absorption and emission transitions in contrast to the prediction of equation (39).

The understanding of optical experiments demonstrating different optical widths (second spectral moments) for absorption and emission spectral lines requires an extension of the Marcus-Hush model that would incorporate different reorganization energies for forward and backward charge transfers

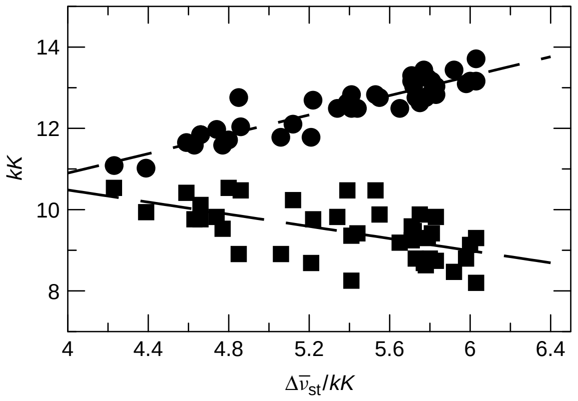

Figure 7 Absorption (circles) and emission (squares) widths $L^2h^2\langle(\delta\nu)^2\rangle/RT$ versus the Stokes shift for 40 molecular solvents according to Reynolds *et al.*[16] The dashed lines are regressions drawn as a guide for the eye. Q-model. Several physical reasons may be responsible for the difference in the reorganization energies; one of them is different polarizabilities of the $(A\cdots B)^+$ complex in the precursor and successor charge-transfer states. When $\lambda_p \neq \lambda_s$, the free energy of activation for the p → s transition changes from equation (11) to the following relation:[54]

$$\Delta G^* = |\alpha|\left(\sqrt{\left|\Delta G^o - \lambda_p\frac{\alpha^2}{1+\alpha}\right|} - \sqrt{|\alpha|\lambda_p}\right)^2 \quad (40)$$

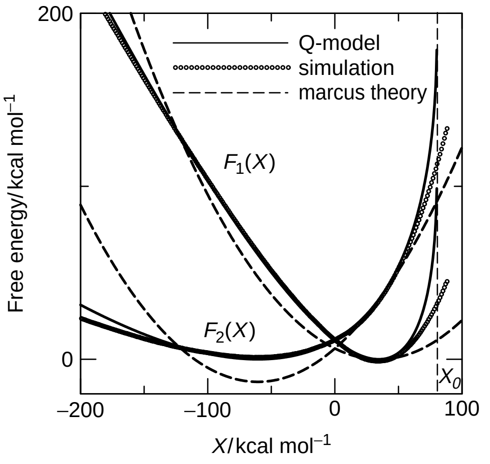

Figure 8 Free energy surfaces for the precursor and successor states of intramolecular electron transfer in a model charge-transfer system.[54] On the plot the dashed lines indicate the Marcus theory, circles are simulations, and solid lines refer to the Q-model. The vertical dashed line marked X_0 indicates the boundary of the energy gap fluctuation band predicted by the Q-model. (Reprinted with permission from Ref. 54, © 1989 American Chemical Society)

where α is the parameter on nonparabolicity of the free energy surfaces defined through the reorganization energies of the precursor and successor states

$$\alpha = \left(\sqrt[3]{\frac{\lambda_p}{\lambda_s}} - 1\right)^{-1} \quad (41)$$

When $\lambda_p \to \lambda_s$, the parameter α tends to infinity and equation (40) transforms into the Marcus equation (11).

Figure 8 shows an example of free energy surfaces for a charge-transfer transition when both the charge distribution and dipolar polarizability are allowed to change. The results of analytical theory agree well with computer simulations.[54] Change in the polarizability in the course of charge transfer leads to a significant deviation of the free energy surfaces from parabolas.

11 LONG-RANGE AND BRIDGED ELECTRON TRANSFER

The internuclear distance R_{AB} enters into the expression for the rate constant in two main ways: through the effect on reorganization energy (equation 7), and the effect on the tunneling integral H_{AB}. The two are difficult to distinguish experimentally.[55,56]

Most interest has centered on the variation of H_{AB}, which certainly becomes dominant at long range. For nonadiabatic transfer, with donor and acceptor sites connected through space, H_{AB} falls off rapidly with distance and most theories lead to an exponential formula:

$$H_{AB} = H_{AB}{}^o \exp\left[\frac{-\beta(R_{AB} - R_{AB}{}^o)}{2}\right] \quad (42)$$

where R^o_{AB} is the closest possible distance and H^o_{AB} is the value of H_{AB} at that distance, the factor of 2 being included because of the squared term in equation (23), so that the rate constant varies as $\exp(-\beta R_{AB})$. Endicott has reviewed the theories and collected experimental estimates of β, mostly in the range 0.8 to 1.5. ***Electron Transfer in Coordination Compounds*** Through-space interaction actually occurs in the gas phase, and distances of 10 to 20 Å are involved.[1] In condensed systems the intervening medium cannot be ignored and this leads to consideration of the effects of bridging groups.[57]

It is clear that in a bridged electron-transfer reaction the nature of the bridging group can profoundly affect the rate. Two aspects of this are immediately obvious, though they require careful analysis before they can be identified quantitatively.[1,53] One is that in a bimolecular reaction the bridging group may simply draw the reacting centers closer together than they would otherwise be, and hence facilitate the

reaction by increasing the direct electron tunneling parameter H_{AB}. The second is that, in a unimolecular or a bimolecular reaction, the strength of the metal–bridge bonds will affect the stabilities of both the final products and the transition state to different extents depending on the chemical nature of the metals and ligand atoms. When these effects have been correctly discounted, intrinsic differences between bridging groups still remain. In a series of bridging reactions such as equation (2), with different halogen atoms, rates increase in the order F $<$ Cl $<$ Br $<$ I, and there is a sense in which the iodine atom is the best 'conductor' of electrons. Theories of bridging groups all focus on this aspect and are therefore concerned with the first-order rate constant, k_{ps}, for intramolecular electron transfer.

It is useful to distinguish between 'chemical' and 'resonance' electron transfer.[58,59] In chemical transfer the electron is actually transferred from donor to bridge, and then from bridge to acceptor, in two distinct reaction steps (or conversely, a positive hole is transferred in two steps). Resonance transfer is a single concerted step. Experimentally, some clear examples of chemical transfer are known.[1,58b] However, even in a concerted process the effectiveness of a bridge can depend on its ability to accept or donate a mobile electron and this is shown by the fact that a particular type of bridging group may be effective only when the donor and acceptor redox potentials lie in a certain range.[60] It is claimed, for example, that in long-range electron transfer in biological systems, aromatic residues are effective bridges only when the oxidizing centers have $E°$ more positive than ca. 0.8 V.[61]

Most theories assume the superexchange mechanism,[58–60] according to which the wavefunctions $\Psi_{1,2}$ are modified by mixing in those of an excited state consisting either of the electron transferred from atom B to a bridging atom or molecule X, or an electron transferred from the bridge to atom A^+, depending on the relative energies of the orbitals involved. (The superexchange contributions to the mechanism can then be called 'electron transfer' or 'hole transfer' respectively.[60]) First-order perturbation treatments are used involving the tunneling integrals H_{AX} and H_{BX}. Such integrals may be calculated theoretically or derived from spectroscopic measurements of the relevant charge transfers.

Even outer-sphere reactions can be treated as bridged, by invoking the tunneling integral for transfer between the contacting ligands or through solvent molecules.[62] Thus, Newton has concluded that for the $[Fe(OH_2)_6]^{3+/2+}$ exchange reaction, hole transfer prevails, but for the reaction $[Ru(NH_3)_5(py)]^{3+/2+}$, electron transfer is dominant as a result of metal-to-pyridine charge transfer in the ruthenium(II) complex. In the latter case, expressions were calculated for a pathway with the pyridine rings in face-to-face contact, overlapping in the vicinity of their remote (C-3) carbon atoms.[63] Using spectroscopic data, Endicott has estimated nonadiabaticity for a series of reactions of the type $[Co^{III}(NH_3)_5L]^{2+}$ + $[Co(sepulchrate)]^{2+}$ and obtained κ_{el} in the range 10^{-3} to 1, increasing along the series $L^- = CN^-$, Cl^-, Br^-, N_3^-.[64]

All these calculations aim to provide a revised value of the single electron tunneling integral H_{AB}, so they are restricted to cases of resonance transfer in which the electron spends little effective time actually residing on the bridge. Reimers and Hush have discussed the conditions under which this approach can be justified.[65] They have provided a more general formalism for a three-level electron-transfer system that spans the regime from chemical to resonance transfer. As expected, the most effective transfer is predicted when the three orbital energy levels, for the electron located on donor, bridge, or acceptor, are equal.

For strongly coupled systems, molecular orbital theories are appropriate. Burdett has considered the energetics of M–X–M complexes, both homovalent and mixed-valent, and the relative stability of symmetrical and unsymmetrical structures, such as the nearly symmetric bridging in 'ruthenium red' $[(H_3N)_5RuORu(en)_2ORu(NH_3)_5]^{6+}$, and the asymmetric Cr^{III}–F–Cr^{II} units in solid Cr_2F_5 and Pt–Br–Br units in linear platinum(IV)–platinum(II) compounds. The question here is the shape of the potential well (see Figure 2). Calculations of the amount of charge located on the bridge in the transition state are used to distinguish chemical from resonance transfer, and for the Cr^{III}–Cl–Cr^{II} system, the latter is preferred.[66]

In the bioinorganic field, interest centers on extremely long-range electron transfer, over distances up to 20 Å in protein media. ***Long-range Electron Transfer in Biology*** Rates have been measured both in natural molecules and in artificially modified systems with ruthenium(III/II) centers coordinated to nitrogen atoms of the protein chain. Gray, Williams, and others have argued that aromatic residues and other polarizable units strategically located on the electron-transfer 'pathway' can strongly influence the rate. The opposite view is taken by Dutton and coworkers, who maintain that distance is overwhelmingly important, and that the electronic part of the rate expression is adequately given by equation (35), with a decay constant β that varies little from one medium to another.[57b,c]

12 SOLVENT DYNAMICS

The transition state theory assumes that as the reacting species proceeds over the energy barrier, the medium adjusts rapidly enough to stay in equilibrium. Classical electron-transfer theory takes the first step away from this idea by distinguishing rapid and slow polarization due to electronic and atomic motion, respectively. More recently, as faster reactions have been studied, interest has turned to the effects of rates of motion of solvent molecules. It is still possible to retain the notion of the solvent as a continuum, by introducing polarizations that respond at

different characteristic rates to an applied electric stimulus, in addition to the limiting fast and slow polarizations of the semiclassical model; or more generally by considering the dispersion of the relative permittivity over a spectrum of frequencies.

A model due to Debye that incorporates a single relaxation time τ_D gives

$$\varepsilon(\omega) = \varepsilon(\infty) + \frac{[\varepsilon(0) - \varepsilon(\infty)]}{(1 - i\omega\tau_D)} \tag{43}$$

where $\varepsilon(0)$ and $\varepsilon(\infty)$ are limiting relative permittivities at frequencies $\omega = 0$ and ∞ (replacing the previous ε_s and ε_{op}). The change in free energy of solvation of a dissolved species, in response to a sudden change in the charge distribution, is then given by an exponential function with time constant τ_L, the 'longitudinal' relaxation time, given by

$$\tau_L = \tau_D \frac{[\varepsilon(\infty)]}{[\varepsilon(0)]} \tag{44}$$

and more complicated expressions when processes with different time constants are involved.[67] Bulk dielectric loss measurements were the traditional method of measuring these times, but now microscopic techniques such as time-resolved emission spectroscopy are available.[68] The effect on the electron-transfer rate depends largely on the relaxation times compared with the nuclear vibration frequencies and resonant electron-transfer frequency in the transition state. In the last 10 years, there have been many detailed theoretical studies of these questions, and some good reviews.[17,69] Much of this work goes well beyond the continuum model and considers microscopic reorientation and translation motions of molecules in various regions of the solvation shell surrounding the reactants.[69d]

Hynes[67] uses the notion of 'friction' meaning that the motion of the reacting system along the reaction coordinate (Figure 3) is resisted by the solvent, and if the resistance is strong enough the motion may become a random process analogous to diffusion. As Endicott remarks in summary, 'this means that on the one hand, friction can lower the rate of reaction in the same way as nonadiabaticity, but on the other hand the effect of true nonadiabaticity [low κ_{el}] can be offset by the fact that the reacting system is forced to spend more time in the vicinity of the crossover point'. In one treatment, Hynes and coworkers have concluded that for nonadiabatic or weakly adiabatic electron transfer, if the solvent has a single relaxation time τ_d the rate constant k of equation (26) is changed to a new value k', given by

$$k' = (1 + 2\tau_d k)^{-1} k \tag{45}$$

To test these theories it is obviously necessary to concentrate on reactions that are both rapid and strongly controlled by solvent rather than intramolecular reorganization effects. Weaver and coworkers have measured self-exchange rates of metallocene couples such as $[Co(C_5H_5)_2]^{+/0}$ in various solvents and found that they can be rationalized on the basis of the measured relaxation times τ_L.[70]

There are a number of experimental systems for which the rate constant is higher than the frequency of longitudinal polarization relaxation. These systems indicate that here must be faster nuclear modes driving electron transfer. One possible source is the inertial component of solvent dynamics occurring on shorter timescales than diffusive polarization relaxation.[71] The participation of high-frequency vibrations rendering the reaction essentially barrierless is still another scenario.[72] Both mechanisms would obviate any correlation of the rate constant with the diffusional solvation timescale.

13 EFFECTS OF PRESSURE

Studies of reaction rates as a function of applied pressure lead to measures of the volume of activation $\Delta V^{\#}$, defined by

$$\Delta V^{\#} = -2.3RT \left(\frac{\partial \log k}{\partial P}\right)_{P=0} \tag{46}$$

Such measurements have been extremely useful in the study of substitution reactions, both organic and inorganic, and after a rather slow start, interest in pressure effects on electron transfer has now begun to pick up strongly. It is hoped among other things to obtain better evidence of adiabatic or nonadiabatic character in simple systems. Swaddle has discussed the factors that contribute to $\Delta V^{\#}$ in terms of the Marcus model.[73] He argues that since the tunneling integral H_{AB} is sensitive to distance, and since changes in pressure presumably directly affect the reaction distance in the transition state, there is a contribution due to nonadiabaticity. However, other systems have been less easy to interpret.[73,74] Once again, spectroscopy provides another approach. Intervalence charge-transfer spectra show small shifts with pressure, which have been interpreted as due in part to increases in the electron coupling,[75] though solvation changes are also a major factor.[14]

14 ELECTRON TRANSFER AND MAGNETISM

All one-electron transfers involve paramagnetic molecules, but this aspect was not much considered until recently. An early observation was that reactions between cobalt(III) and cobalt(II) complexes are often unexpectedly slow, and this is evidently related to the necessity of spin change from the $^1A_{1g}$ (low-spin d^6) cobalt(III) to the $^4T_{1g}$ (high-spin d^7) cobalt(II) state. Endicott and coworkers have provided, and analyzed, a mass of experimental data on this question.[76] The

most recent discussion invokes spin–orbit coupling in the transition state.[77]

More recently, interest has centered on electron-transfer reactions in which both reacting centers are paramagnetic, before and after the reaction. Anderson and Hasegawa treated the complex Mn^{III}–O–Mn^{IV} (a unit in the structures of certain mixed oxides) as a system with one mobile electron moving between two centers of local spin $S_1 = S_2 = 3/2$.[78] They pointed out that facile electron transfer requires the spins S_1 and S_2 to be parallel so that the mobile electron can couple parallel to both and so transfer without change of spin. The more common coupling scheme in a ligand-bridged paramagnetic complex is antiferromagnetic, and in that case electron transfer is spin forbidden. In other words, antiferromagnetic coupling favors localized mixed valency and slow electron transfer; ferromagnetic coupling favors delocalized mixed valency and rapid electron transfer. Examples of mixed-valence systems are known that support this view, including dinuclear molecular systems such as $Ni^{II} \cdots Ni^{I}$ (metal–metal bonded), delocalized and ferromagnetic; and $[(bipy)_2Mn^{IV}(\mu\text{-}O)_2Mn^{III}(bipy)_2]^+$ (anion-bridged), localized and ferromagnetic.[79] Several groups of workers have discussed the electronic energy levels in such systems, as functions of appropriate coupling constants. Closest to the subject of this article are those in which vibronic coupling is included.[80] Girerd and coworkers have made detailed predictions of energy levels in some dinuclear mixed-valence iron(III)–iron(II) molecules.[81] They have calculated electronic energy levels as functions of reaction coordinates, as for example in Figure 9. The diagram can be compared directly with the one-electron case illustrated in Figure 2. In the case illustrated, the total spin can range overall integral values from 1/2 to 9/2, and the localized precursor/successor complex is antiferromagnetic, while the transition state for electron transfer is ferromagnetic. In other words, if spin is conserved throughout the electron-transfer reaction the activation energy will be high, but if a mechanism for spin change exists, the activation energy will be much lower.

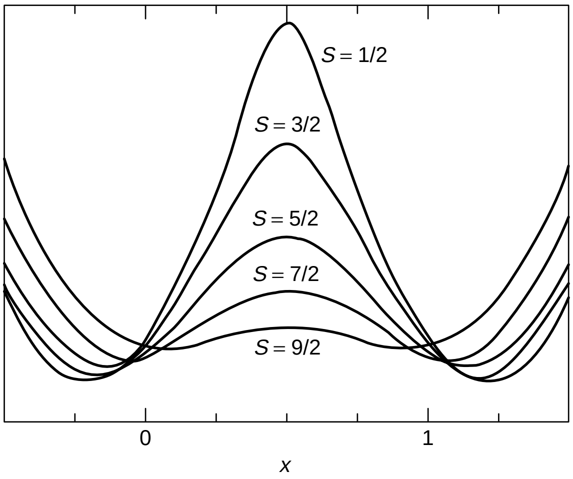

Figure 9 Potential energy curves for a mixed-valence iron(III,II) molecule, with various total spins S, and with coupling parameters such that the ordering of spin states is reversed in the electron-transfer transition state. 15 CONCLUSIONS

Perhaps unlike any other field of Chemistry the continuing progress in the understanding of the mechanisms and kinetics of electron-transfer reactions has been a result of fruitful collaboration between theory and experiment. The landmarks of experimental progress have been the discoveries of measurable self-exchange reactions, the bridging mechanism, long-lived precursor complexes, activationless transfer, and long-range electron transfer in solids and proteins. The theoretical predictions have lead to the recognition of the energy gap law, connection between spectroscopy and thermal activation, solvent dynamics control of transition rates, and the importance of inertial solvent dynamics. Electron transfer is only a part of many more complex mechanisms involved in reduction-oxidation reactions such as corrosion, dissociative electron-transfer reactions, atom transfer, proton-coupled electron transfer, and heterogeneous electrochemical reactions.[82] Intramolecular electron transfer is a promising line of approach to the synthesis of molecular electronic devices[83] and mimicking natural photosynthetic systems.[84] The rate of progress is healthy and there can be no doubt that electron-transfer studies will continue to be a leading edge of progress in chemistry for a long time to come.

DFT = Density Functional Theory; DSD = Diamond-Square-Diamond; HOMO = Highest Occupied Molecular Orbital; IR = Irreducible Representation; LCAO = Linear Combination of Atomic Orbitals; Ph = Phenyl; PSEPT = Polyhedral Skeletal Electron Pair Theory; SCF = Self-Consistent-Field; SDDS = Square-Diamond, Diamond-Square; TSH = Tensor Surface Harmonic.

1 INTRODUCTION

The first problem encountered in writing an article of this kind lies in deciding what a *Cluster* actually is, and which sorts of cluster are relevant to the audience in question. The former problem may be addressed in terms of size or number of constituent atoms; for example, Sugano[1] considers a classification in terms of molecules, microclusters, and fine particles. On the other hand, Berry has distinguished clusters as 'finite aggregates whose composition can be changed by adding or taking away units of the species that comprise them... they are finite bits of what, in composition but not necessarily in structure, constitute a tiny sample of bulk material, but more than a single molecule or even two atoms or molecules'.[2] Here, we must recognize that the domain of cluster chemistry extends beyond systems such as boranes, carboranes, and transition metal carbonyls, which are generally considered to be the stuff of inorganic cluster chemistry.[1,3–5] These are certainly the molecules of primary interest here, but it would be shortsighted to ignore the connections between these species and clusters bound, for example, by van der Waals forces. There is often much to be learned from making such comparisons: for instance, we may find analogous structures and rearrangement mechanisms in clusters bound by quite different forces. The converse is also true, and a better understanding of the dynamics of small inert gas clusters has been achieved partly by the application of ideas that originated in inorganic chemistry concerning rearrangement mechanisms.[6]

To appreciate the ubiquity of clusters in chemistry and physics, one need only consult the proceedings of one of the biennial International Symposia on Small Particles and Inorganic Clusters (ISSPIC).[7] These volumes include species ranging from hydrocarbon polyhedra, such as dodecahedrane[8] (*see also Dodecahedral*), to large carbon clusters,[9] and from small inert gas clusters to colloidal metal particles containing thousands of atoms. These systems are of interest for a variety of reasons, such as the investigation of fundamental processes including melting and freezing, and can sometimes provide insight into the behavior of larger systems at a more tractable level. Furthermore, small clusters may exhibit properties that are unique to the intermediate size regime, which may be of technological importance.[10]

The principal subject of this contribution is the electronic structure of clusters, and so we shall mainly be concerned with molecules in which the interatomic forces cannot be well described by simple empirical potential energy functions. Hence, the following section provides an overview of the progress that has been made in performing quantum mechanical calculations for clusters. Major difficulties remain to be solved in this field, particularly with regard to systems containing *Transition Metals*. However, although accurate calculations are certainly important, there are various patterns concerning the correlation between structure and electron count, which require a more general explanation. The latter are considered in Section 3, and the various models that have been developed to explain them are reviewed in Section 4. One of these, Stone's Tensor Surface Harmonic (TSH) theory, is then developed in Section 5, and some further applications to cluster rearrangements are described in Section 6.

2 COMPUTATIONAL APPROACHES

It is certainly not the purpose of this section to describe the mechanics of ab initio quantum chemical calculations on clusters.[11] However, some understanding of the problems

and achievements in this field is necessary to appreciate the simpler general models described in subsequent sections. Even if extensive and accurate calculations were possible for all the inorganic clusters of interest, the latter models would still be needed to explain the structural patterns that have been deciphered.

Most applications of ab initio quantum chemistry involve expanding the wavefunction using a basis set of atomic orbitals. As the many-body problem is not analytically tractable in either classical or quantum mechanics, we can never obtain the exact wavefunction. However, the variation principle[12] tells us that the more basis functions we use, the more accurate our calculation should become. Unfortunately, the computational cost of the most commonly employed self-consistent-field[12] (SCF) method increases roughly as N^4, where N is the number of basis orbitals. Hence, for clusters containing *Transition Metals*, for which even a minimal basis set of atomic orbitals requires many functions, the calculations rapidly become impossible. There is another problem as well: the usual Hartree–Fock SCF procedure neglects the instantaneous electron–electron interaction, replacing it instead with an average field[12,13] (*see Hartree–Fock Theory*). The error incurred by this treatment of the electron correlation problem generally becomes more significant for systems with low-lying electronic states, as are commonly found in transition metal compounds. Density functional theory[14] (DFT) can help deal with the correlation problem, but the reliability of such calculations is often subject to debate. This is particularly true for molecules containing heavy elements, where relativistic effects are also important.[15]

Given this background, it is not surprising that many different approaches, all introducing further approximations,[16] have been applied to inorganic clusters. The two most commonly encountered approaches in this area are the Extended Hückel[17] and Fenske–Hall[18] methods (*see also Extended Hückel Molecular Orbital Theory*). The former is the simplest approach, making use of empirical data, while the latter uses no experimental information, but instead approximates the quantum mechanical Hamiltonian so as to avoid many of the most time-consuming integrals. Despite the sweeping assumptions used in these methods,[19] they have often been found to give valuable insights, although DFT is now commonly used instead.

The early DFT studies of main group clusters by Jones and coworkers should be mentioned here.[20] However, as these are primarily concerned with clusters that are describable in terms of two-center, two-electron bonds, they will not be considered further. For similar reasons, no attempt will be made to survey the rapidly growing body of calculations on carbon–fullerene systems[9] (*see* ***Carbon: Fullerenes***). The σ-bonding framework of these molecules is again easily understood from the point of view of electron counting. Predicting for which geometries the delocalized π-system is especially favorable is a more interesting problem, but is beyond the scope of this review. Some other specific calculations on boranes, carboranes, metal, and silicon clusters will be considered in the following sections.

3 EMPIRICAL STRUCTURE–ELECTRON COUNT CORRELATIONS

With the explosion in size of the database of known cluster compounds, it is reassuring to note that a number of patterns were soon recognized and exploited by inorganic chemists. The most important relationships between geometry and the number of electrons in a cluster (‘electron-counting rules’, *see Counting Electrons*) are summarized in the Debor Principle[21] (or *Wade’s Rules*), Polyhedral Skeletal Electron Pair Theory[22] (PSEPT), and the Isolobal Principle.[23] These ‘rules’ (to which there are various exceptions) include three-connected clusters (By convention, the connectivity’ of a vertex is the number of nearest-neighbors in the cluster cage, not counting terminally bound ligands.), like prismane, deltahedral clusters (which have only triangular faces), such as *closo*-boranes; ‘naked’ clusters[24] like Sn_5^{2-} and Pb_5^{2-}; clusters with interstitial atoms, fused molecules, which can be decomposed into deltahedra that share vertices, edges, or faces, and even large multispherical transition metal clusters. Much of the rest of this article is devoted to rationalizing these patterns, whose importance can perhaps be appreciated by the example of $Au_{13}Cl_2(PMe_2Ph)_{10}{}^{3+}$. This compound was successfully synthesized several years after the stability of gold clusters $Au_{13}(PR_3)_{12}{}^{5+}$ was predicted on the basis of simple bonding considerations.[25]

Some of the historical development of the electron-counting rules is summarized in a review by Mingos and Johnston;[26] here, we will concentrate on the patterns themselves, beginning with the simplest cases – more details can be found elsewhere.[27] The most straightforward clusters commonly encountered in inorganic chemistry are those that can be described by essentially localized two-center, two-electron bonds, where all the atoms obey an effective atomic number rule EAN Rule. For main group atoms, this means that each one is associated with 8 valence electrons to give an ‘inert gas configuration’; for *Transition Metals*, 18 electrons are usually required to do this. Hence, such clusters are associated with

$$N_e = 8n - 2E \qquad \text{main group} \qquad \text{or}$$
$$N_e = 18n - 2E \qquad \text{transition metal} \qquad (1)$$

where N_e is the number of valence electrons, n is the number of vertices in the cluster, and E is the number of two-center, two-electron bonds, or edges. For ring compounds, $E = n$ and hence $N_e = 6n/16n$ for main group/transition metal clusters. Three-connected *Polyhedral* systems, such as prismane, have $E = 3n/2$ so that $N_e = 5n/15n$. To cover

mixed compounds, we note that replacement of a main group vertex atom by a transition metal should increase N_e by 10, while interstitial atoms are generally not associated with an increase in the number of occupied molecular orbitals,[27] and effectively act as electron donors. The relatively simple consequences of interchanging main group and transition metal atoms basically follow from the symmetries of the orbitals that these fragments provide for skeletal cluster bonding, as identified in the Isolobal Principle of Hoffmann and collaborators.[23]

Most clusters, however, cannot be described adequately in terms of two-center, two-electron bonds because the connectivity of the vertices exceeds the number of valence orbitals that are available for bonding. Early efforts to rationalize such systems, such as Lipscomb's styx approach[28] and Kettle's Topological Equivalent Orbital Method,[29] are described by Mingos and Johnston.[26] In these more difficult cases, the simple valence-bond picture is inappropriate; examples are deltahedral clusters composed of B−H vertices or conical $M(CO)_3$ fragments, both of which usually have only three orbitals available for skeletal bonding. Theoretical models for describing these systems will be discussed in the next section.

We find that four-connected clusters and *closo*-deltahedra have $N_e = 4n + 2/14n + 2$ for main group/transition metal clusters. *Closo*-deltahedra are clusters with entirely triangular faces; however, some four-connected clusters have one or more square faces.[27] When successive vertices are (notionally) removed from a *closo*-deltahedron, the resulting molecules are called nido, arachno, hypho, and so on. The Debor Principle[21] (or *Wade's Rules*) recognizes that the total number of valence electrons in such systems does not change, and in terms of the number of vertices remaining, n, this gives $N_e = 4n + 4/14n + 4$, $4n + 6/14n + 6, \ldots$ for main group/transition metal nido, arachno, ... clusters.

Most of the remaining patterns might be classified under the heading of 'condensation rules,' many of which were developed by Mingos and coworkers. The Capping Principle states that the number of skeletal bonding orbitals is unchanged when one face of a *Polyhedral* cluster is capped.[22,30] Hence, if the capping moiety is a conical $M(CO)_3$ fragment, then N_e increases by 12, this being the number of electrons in the nonbonding and metal−ligand bonding orbitals.[26] The Principle of Polyhedral Fusion deals with clusters that can be (notionally) decomposed into two polyhedra (A and B) that share a vertex, edge, or face.[31] In this case, N_e is usually equal to the sum of $N_e(A)$ and $N_e(B)$, regarded as complete, individual entities each containing copies of the fragments that are shared between them, minus the number of valence electrons expected for the shared unit.[26] The final one of these 'principles' is that of polyhedral inclusion, where high nuclearity multispherical systems are considered in terms of encapsulated polyhedra.[32] However, as a number of subcases must be considered for such systems, the reader is referred elsewhere for details.[27,32]

The remainder of this article is largely concerned with describing how some of the above observations can be rationalized using Stone's Tensor Surface Harmonic theory, and with the further implications of this model for dynamical processes such as cluster rearrangements. The number of example systems and electron count rationalizations will be kept relatively small in favor of explaining the theoretical foundations that underlie the method. Tables of examples and more detailed analyses of the various cases may be found elsewhere.[26,27]

4 MODELS OF CLUSTER BONDING

To achieve a general understanding of the patterns described in the previous section requires some sort of model for the energy of a cluster as a function of its geometry and the number of valence electrons. In this section, we focus upon the three most successful approaches, namely, jellium models, topological methods based upon graph theory, and Stone's Tensor Surface Harmonic (TSH) theory. In each case, the energetic problem is simplified by asking how many bonding, nonbonding, and antibonding orbitals are available for a given cluster geometry, and these orbitals may be delocalized, localized, or a mixture of both. In fact, TSH theory is more powerful than this, as it really defines an orbital transformation, which may be applied to the results of any calculation, as discussed below.

In each of the three approaches, we effectively guess the forms and energies of the solutions to the quantum mechanical many-body problem. Jellium models achieve this by solving a Schrödinger equation in which all the electron−electron and electron−nucleus interactions are replaced by a simple effective potential. The result is a set of spatially delocalized functions of increasing energy into which electrons are assigned by the usual Aufbau principle.[12] Although jellium methods are commonly found in the physics literature, they are of rather limited application in the present context, and are more appropriate for clusters of alkali or alkali earth metals, for which very large systems have been considered.

The topological or graph-theoretical approaches attempt to define the bonding and antibonding orbitals available to a cluster in terms of a sort of valence-bond description,[12] where hybridized atomic orbitals are directed in space to form either localized or multicenter functions. (*See also Hybridization*.) The analysis of a complex structure involving delocalized bonding may, however, require some seemingly subjective decisions about how the atomic orbitals overlap, where the multicenter bonds should be formed, and so forth.

How is it then, that organic chemists, armed only with pencil, paper, and some knowledge of basic molecular orbital theory and the Woodward–Hoffmann rules,[33] can often successfully predict the outcome of apparently complex organic reactions? The simple answer is that the bonding in such systems is generally rather easier to describe than in clusters, and relatively accurate calculations may often be used for guidance. However, with the advent of TSH theory, the inorganic chemist now has tools that are similar in many respects to those used in organic chemistry. The increased difficulty of the analysis in inorganic clusters may then be seen as a consequence of delocalization occurring in three dimensions, and of the presence of d valence atomic orbitals in *Transition Metals*.

TSH theory may be regarded as either a descent-in-symmetry approach, or, equivalently, as a method that exploits the existence of approximate quantum numbers in roughly spherical clusters. The idealized high-symmetry case in question is the free electron-on-a-sphere, for which the wavefunctions are the spherical harmonics, $Y_{LM}(\theta, \phi)$, and the angular momentum operators $\hat{L}^2$ and $\hat{L}_z$ have corresponding good quantum numbers L and M_L. In a finite cluster, the Hamiltonian has lower symmetry appropriate to the point group in question. TSH theory assumes that approximately good quantum numbers still exist for the angular momentum of an electron about the center of a roughly spherical cluster, and exploits this assumption to approximate the molecular orbitals. The resulting linear combinations of atomic orbitals (LCAOs) would be the true molecular orbitals of the cluster if it actually had spherical symmetry; they are known as cluster orbitals. (*See also LCAO Approximation*.) However, the usefulness of TSH theory goes beyond this construction, in providing a transformation of basis that may be applied to the results of any calculation in which identifiable atomic orbitals are used. Despite the fact that the ideal linear combinations of TSH theory actually mix in real clusters, it is often true that they are still recognizable. This is the essence of an approximate quantum number.

Before developing the TSH approach in Section 5 to explain some of the structure-electron count correlations described above, we will first consider the connections between the jellium, topological, and TSH methods in a little more detail. It is noteworthy that none of these models in their usual form includes any attempt to allow for electron correlation. Hence, it is important to ask, for example, why TSH theory can explain all the general structure-electron count correlations so successfully. The answer is presumably that the correlation energy is often not of primary importance in discriminating between different geometries with the same number of electrons. However, sometimes there exists more than one low-energy structure associated with a given electron count; in such cases, and in any case where the correlation energy exhibits a large variation with geometry, we should anticipate exceptions to the usual 'rules'.

4.1 The Jellium Model

The jellium model was first developed by Knight *et al.*[34] to explain the 'magic numbers' observed in mass spectra of sodium and potassium clusters produced by supersonic expansion in molecular beams.[35] The method was adapted from nuclear physics, where 'magic number' nuclear states have been successfully explained.[36] If the potential energy vanishes inside a sphere and is infinite outside it, then the energetic ordering of the solutions to the resulting Schrödinger equation is

$$1s < 2p < 3d < 2s < 3f < 3p < 4g < 4d < 3s < 5h \ldots, \qquad (2)$$

where 3d, for example, has no radial nodes and two angular nodes and is fivefold degenerate. The notation is analogous to that used for atomic orbitals, though different from that used in some of the literature,[34] and seems appropriate in this context. The wavefunctions for any potential energy function that depends only upon the distance from a fixed origin may be written as a product of spherical harmonics[12] and functions that depend only upon the distance. Hence, the same degeneracies arise, because of the assumed spherical symmetry, as for an atom. It is noteworthy that differences in the order of these energy levels with a deep potential well only occur for relatively high-lying solutions.[37] Experimentally, peaks in the mass spectra of sodium and potassium clusters are indeed found for 8, 18, 20, 40, ... atoms, corresponding to completed electronic shells in the above scheme.[38]

Various refinements of the above model have been proposed; for example, using alternative spherical potentials or allowing for nonspherical perturbations,[39–40] and these can improve the agreement of the model with the abundance peaks observed in different experimental spectra. For small alkali metal clusters, the results are essentially equivalent to those obtained by TSH theory, for the simple reason that both approaches start from an assumption of zeroth-order spherical symmetry. This connection has been emphasized in two reviews,[40,41] and also holds to some extent when considerations of symmetry breaking are applied. This aspect is discussed further below. The same shell structure is also observed in simple Hückel calculations for alkali metals, again basically due to the symmetry of the systems considered.[42] However, the developments of TSH theory, below, and the assumptions made in the jellium model itself, should make it clear that the latter approach is only likely to be successful for alkali and perhaps alkali earth metals. For example, recent results for aluminium clusters have led to the suggestion that symmetry-breaking effects are more important in these systems.[43]

These conclusions are not unexpected. Firstly, the free-electron approximation works best for the alkali metals, with significant deviations for divalent and trivalent metals.[44] Secondly, the LCAO-MO TSH treatment requires a more complicated treatment of p and d orbitals, involving tensor

spherical harmonics. The jellium model makes no allowance for these properties, and hence, the analogy to TSH theory breaks down here. An alternative way to think about this breakdown is in terms of the strength of the nonspherical potential due to the nuclei,[40,41] and its influence upon electrons that occupy effective single-particle states. As the orbital energy increases, so too does the de Broglie wavelength;[12] and the effect of the nonuniform distribution of nuclei becomes more significant. Splittings of the spherical symmetry degeneracies should therefore increase with the orbital energy, and will probably be greater for aluminium than, say, sodium, because for a given cluster geometry there are more valence electrons to accommodate. The former effect is apparent around the Highest Occupied Molecular Orbital HOMO and above in Hückel calculations on different cluster morphologies containing up to 1000 atoms.[45] One further viewpoint is obtained by considering the magnitude of matrix elements of the nuclear potential, expanded in terms of spherical harmonic components.[41]

Before leaving the jellium model, it seems appropriate to mention some results for sodium clusters of up to 22 000 atoms. The abundances observed can be explained in terms of the extra stability associated with both completed jellium shells (for less than about 3000 atoms) and with completed icosahedral or cuboctahedral geometric shells for larger sizes.[46] The results are especially interesting because of the observation of 'supershells' that occur because of an interference effect, which has been explained using semiclassical arguments.[47]

One further question that one might naturally ask of metal clusters is how large they need to be for bulk properties to manifest themselves.[48] However, as the answer to this question depends crucially upon the bulk property in question, and the answer is still somewhat subjective, such issues will not be pursued here.

4.2 Topological Approaches

In the most well-developed topological approach, the mechanics of algebraic graph theory[49] are applied to enumerate the bonding and antibonding orbitals of a given cluster. From the earliest work of King and Rouvray,[50] the method has been extended by King,[51] leading to a self-consistent framework for rationalizing the electron counts of many of the systems mentioned in Section 3, among others. Connections to TSH theory have been discussed in several studies.[27,52] Basically, the method analyzes structures in terms of edge-localized, face-localized, and core-delocalized bonds that arise in the middle of cluster polyhedra. Electron pairs are then assigned to the resulting bonding orbitals, rather like the construction of a valence-bond wavefunction[12] when multicenter orbitals are included as building blocks.

This approach is perhaps best illustrated by a simple example. Consider a deltahedral cluster where the vertex connectivity is greater than three, for example, $B_6H_6^{2-}$. One valence orbital per vertex is used to form a two-center, two-electron bond to a terminal ligand (hydrogen in this case), leaving three orbitals, which may be partitioned into two functions that are tangential to the sphere on which the vertex atoms lie, and one which points toward the center of the cluster. Rationalization of the cluster electron count ($N_e = 4n + 2$) proceeds as follows. We already have n bonding orbitals corresponding to B−H bonds in this example. Pairwise overlap of the $2n$ tangential orbitals then produces n bonding and n antibonding sets, while overlap of the inward-pointing hybrids gives rise to one particularly low-lying orbital,[51] giving a total of $2n + 1$ bonding orbitals, which are completely filled by $4n + 2$ electrons.

To describe edge-localized bonding, as in prismane, for example, the three valence orbitals left after terminal bonding are simply directed toward the three-neighboring vertices. This is not unreasonable, but for more complex systems, it may require some imagination to direct the various valence orbitals along edges, into faces or into cavities to obtain the required number of bonding orbitals. Furthermore, it can be a significant approximation to neglect mixing between the radial and tangential orbitals in some clusters.[53] The corresponding problem in TSH theory is the mixing of TSH σ- and π-type cluster orbitals, which is readily quantified by simply transforming the results of any MO calculation into a TSH theory cluster orbital basis (see below).

Teo's topological approach also deserves mention in this section.[54] It combines Euler's theorem with the idea of an effective atomic number rule for each cluster vertex, but involves a rather arbitrary parameter whose purpose is to correct for the formation of multicenter bonds.

4.3 Tensor Surface Harmonic (TSH) Theory

Stone's TSH theory is framed within LCAO-MO theory, whose power was first demonstrated in the field of cluster chemistry by Longuet–Higgins and Roberts[55] in providing the first satisfactory analysis of icosahedral $B_{12}H_{12}^{2-}$. (*See also LCAO Approximation*.) Here, it is perhaps worth mentioning that the popular nomenclature for such species, that is, 'electron deficient', is a misnomer. Although there are certainly not enough valence electrons in the cluster for all the nearest-neighbor contacts to represent two-center, two-electron bonds, it is not the case that there are unoccupied bonding orbitals. On the contrary, all the bonding molecular orbitals are precisely filled, as we shall see. (*See also Electron Deficient Compound*).

The closest forerunner to TSH theory was due to Hoffmann, Ruedenberg, and Verkade.[56] These authors used spherical harmonics at the center of the cluster to generate linear combinations of orbitals with particular symmetry and nodal characteristics. The energy of these orbitals could then be estimated by the number of angular nodes in the parent spherical harmonic. For alkali metal clusters, one could actually produce the same answers for the symmetries of

the bonding orbitals as for the spherical jellium model (above) or TSH theory. However, once again the method cannot work for systems, where p and d orbitals contribute to the bonding, because then there are valence orbitals that have intrinsic nodal planes containing the radius vector of the atom. Stone's principal contribution was to produce a remedy for this problem.[57]

Let us first consider how the π molecular orbitals of linear and cyclic conjugated polyenes may be obtained by a descent-in-symmetry approach. If the electrons moved in an average nuclear potential, the corresponding free-particle wavefunctions would be the solutions of the Schrödinger equation for a particle-in-a-box and a particle-on-a-ring, respectively. These are, of course, just sine and cosine functions,[12,27] and there are 'good' quantum numbers associated with the linear momentum and the angular momentum about the center of the ring, respectively. The corresponding linear combinations of p^π orbitals, which have the same transformation properties as the free-electron functions, are obtained by taking the coefficients to be the values of the latter functions evaluated at the atom positions.[27] In fact, if the boundary conditions are chosen appropriately, this procedure gives precisely the molecular orbitals of simple Hückel theory in both cases, as shown below. This result should not be taken to mean that TSH theory has its basis in Hückel theory. Rather, it is an illustration that the descent-in-symmetry results from the free-electron problem may be a very useful guide to the true LCAO-MO wavefunctions.

For a conjugated linear polyene with n atoms, it is not hard to show[27] that the normalized Hückel wavefunctions are given by

$$\psi_m = \sqrt{\frac{2}{n+1}} \sum_t p^\pi(t) \sin \frac{\pi t m}{n+1} \qquad (3)$$

where $1 \le m \le n$ and $p^\pi(t)$ is the π orbital at atom t. The solutions of the Schrödinger equation for a free particle-in-a-box of length L are

$$\psi_m = \sqrt{\frac{2}{L}} \sin \frac{\pi x m}{L} \qquad (4)$$

where $m > 0$. The (unnormalized) coefficients for each p^π orbital in the expansion are now obtained from the values of $\sin \pi x m / L$ at the atom positions if we identify x/L with $t/(n+1)$. For a cyclic polyene, the normalized Hückel wavefunctions are

$$\psi_{ms} = \sqrt{\frac{2}{n}} \sum_t p^\pi(t) \sin \frac{2\pi t m}{n} \quad \text{or}$$
$$\psi_{mc} = \sqrt{\frac{2}{n}} \sum_t p^\pi(t) \cos \frac{2\pi t m}{n} \qquad (5)$$

while for a free particle-on-a-ring the wavefunctions may be written as

$$\psi_{ms} = \sqrt{\frac{1}{\pi}} \sin m\phi \quad \text{and} \quad \psi_{mc} = \sqrt{\frac{1}{\pi}} \cos m\phi \qquad (6)$$

where ϕ is the angle that describes the particle's position on the ring. In this case, we may obtain the expansion coefficient for $p^\pi(t)$ from the above functions by setting $\phi = 2\pi t/n$.

Stone applied similar reasoning to the problem of a three-dimensional cluster. Here, the solutions of the corresponding free-particle problem for an electron-on-a-sphere are spherical harmonics.[12] These functions should be familiar because they also describe the angular properties of atomic orbitals.[27] Two quantum numbers, L and M, are associated with the spherical harmonics, $Y_{LM}(\theta, \phi)$, and these define the eigenvalues for the operators $\hat{L}^2$ and $\hat{L}_z$, which correspond to the square of the total orbital angular momentum and its projection on the z-axis, respectively. It is more convenient to use the real linear combinations of $Y_{LM}(\theta, \phi)$and $Y_{L-M}(\theta, \phi)$ (except when $M = 0$), and these are written as $Y_{LMc}(\theta, \phi)$ and $Y_{LMs}(\theta, \phi)$ because they are proportional to $\cos M\phi$ and $\sin M\phi$, respectively. Hence, the functions Y_{10}, Y_{11c}, and Y_{11s} are proportional to z, x, and y, respectively, as in p_z, p_x, and p_y atomic orbitals.

We now categorize the basis atomic orbitals in any, roughly spherical, cluster according to the number of nodal planes they possess that contain the radius vector. Hence, s atomic orbitals are classified as σ-type cluster orbitals, and so are p_z and d_{z^2} orbitals, where the local axes at each vertex are chosen with the x and y directions tangential to the surface of the sphere so that z points outwards along the radius vector. Radially directed hybrids, such as sp_z are also σ-type under this classification. Examples will be illustrated below. π-type cluster orbitals have one intrinsic nodal plane containing the radius vector, for example, p_x, p_y, d_{xz} and d_{yz} in the same axis system. d_{xy} and $d_{x^2-y^2}$ functions contain two such nodal planes, and are known as δ orbitals.[27,57]

A set of σ-type atomic orbitals transform amongst themselves under point group operations like scalar quantities. Hence, to construct descent-in-symmetry-type LCAO cluster orbitals, we simply follow the same reasoning as for the linear and cyclic polyenes, above, and define (unnormalized) σ-type cluster orbitals as

$$L^\sigma_\mu = \sum_t Y_{L\mu}(\theta_t, \phi_t)\sigma(t) \qquad (7)$$

where $\mu = Mc$ or Ms, $\sigma(t)$ is a σ-type basis orbital at atom t and θ_t and ϕ_t are the angular coordinates of atom t. We write $S, P, D, \ldots$ when $L = 0, 1, 2, \ldots$, by analogy with atomic orbitals. This is as it should be, for our assumption that the orbital angular momentum of an electron about the center

of the cluster provides approximate quantum numbers is not unlike describing the cluster as a pseudoatom.

σ-cluster orbitals transform like the parent spherical harmonics in any given point group, and these properties are easily determined from standard descent-in-symmetry tables.[58] Sometimes it may be more convenient to omit the μ subscripts from the cluster orbitals and give the transformation properties instead. For example, the six 2s orbitals in Li_6 form a basis for a representation that spans[12] $A_{1g} \oplus T_{1u} \oplus E_g$. When transforming to a basis of cluster orbitals, we generally start from functions with the smallest L and work up. In this case, the cluster orbitals are $S^\sigma(A_{1g})$, $P^\sigma(T_{1u})$, and $D^\sigma_{0,2c}(E_g)$ as illustrated in Figure 1, where the three $P^\sigma(T_{1u})$ functions transform like x, y, and z and correspond to the Y_{11c}, Y_{11s}, and Y_{10} spherical harmonics. Note that in this case, the energetic ordering is simply expected to follow the number of nodes in the cluster orbital.

π-type basis functions, however, transform like a set of unit vectors because the intrinsic nodal plane in each one defines a particular direction. Stone recognized that appropriate LCAO combinations may be formed using vector surface harmonics, which have both magnitude and direction at any given point in space. Hence, instead of LCAO expansion coefficients, which are just the values of spherical harmonics evaluated at the atom sites, the coefficients for π-type basis functions define not only an amplitude but also the *direction* in which the π-functions point.[27,57]

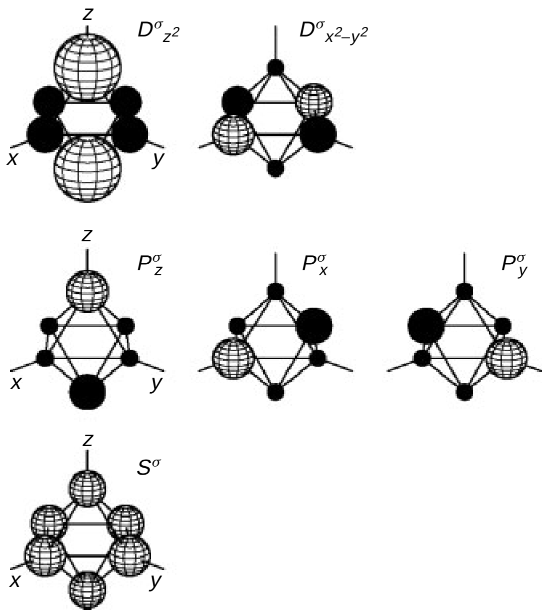

Figure 1 The (unnormalized) σ-cluster orbitals of an *Octahedral* cluster, such as Li_6 for which the basis functions are 2s orbitals.[27] The light and dark shading indicates the phase; the atoms are represented as small filled black circles. (This figure was produced using Mathematica 2.0 © Wolfram Research Inc., 1990.)

In fact, two types of vector function can be derived from the spherical harmonics, and these are defined by

$$\mathbf{V}_{LM} = \nabla Y_{LM} \quad \text{and} \quad \overline{\mathbf{V}}_{LM} = \mathbf{r} \times \mathbf{V}_{LM} = \mathbf{r} \times \nabla Y_{LM} \tag{8}$$

where $\times$ denotes the vector cross product and ∇ is the gradient operator, which is $(\partial/\partial x, \partial/\partial y, \partial/\partial z)$ in Cartesian coordinates. These vector functions are clearly orthogonal; $\mathbf{V}_{LM}$ has the same parity as the parent Y_{LM}; it is a *polar* (or even) vector surface harmonic. $\overline{\mathbf{V}}_{LM}$ has the opposite parity (i.e. it changes sign under inversion if L is even, and is unchanged if L is odd) and is an *axial* (or odd) vector surface harmonic. The first π-cluster orbitals are the P^π and $\overline{P}^\pi$ sets because the derivatives of $Y_{00}(\theta, \phi)$ are zero. We denote the even and odd sets generically by L^π and $\overline{L}^\pi$ respectively; the p^π cluster orbitals of an octahedron are given in Figure 7.

Linear combinations of radial p orbitals, or sp hybrids, may be used to construct σ-cluster orbitals as mentioned above. If we consider an n-vertex cluster, then there are $2n$ π-type p orbitals, that is, two at each vertex, and these correspond to the two independent directions at each site tangential to the surface of the sphere upon which all the atoms are assumed to lie. It is convenient to choose the two directions corresponding to the spherical polar coordinates θ and ϕ increasing, that is, along the unit vectors $\hat{\mathbf{e}}_\theta$ and $\hat{\mathbf{e}}_\phi$. Using the standard form for the gradient vector operator in spherical polars, this gives the two orthogonal vector functions

$$\mathbf{V}_{L\mu} = \frac{\partial Y_{L\mu}}{\partial \theta}\hat{\mathbf{e}}_\theta + \frac{1}{\sin\theta}\frac{\partial Y_{L\mu}}{\partial \phi}\hat{\mathbf{e}}_\phi \quad \text{and}$$

$$\overline{\mathbf{V}}_{L\mu} = -\frac{1}{\sin\theta}\frac{\partial Y_{L\mu}}{\partial \phi}\hat{\mathbf{e}}_\theta + \frac{\partial Y_{L\mu}}{\partial \theta}\hat{\mathbf{e}}_\phi \tag{9}$$

The θ component of $\overline{\mathbf{V}}_{L\mu}$, written $\overline{V}^\theta_{L\mu}$, is the same as the negative of $V^\phi_{L\mu}$ while $\overline{V}^\phi_{L\mu} = V^\theta_{L\mu}$. Hence, odd π cluster orbitals may be obtained from their even partners by rotating the p orbital components through 90° about the radius vector. These cluster orbitals may be written as

$$L^\pi_\mu = \sum_t \left(V^\theta_{L\mu}(t) \mathrm{p}^\theta(t) + V^\phi_{L\mu}(t) \mathrm{p}^\phi(t) \right) \quad \text{and}$$

$$\overline{L}^\pi_\mu = \sum_t \left(\overline{V}^\theta_{L\mu}(t) \mathrm{p}^\theta(t) + \overline{V}^\phi_{L\mu}(t) \mathrm{p}^\phi(t) \right) \tag{10}$$

where the functions are evaluated at the atom positions t as for the σ cluster orbitals. We could therefore sketch the π cluster orbitals from p^θ and p^ϕ orbitals at each vertex using the appropriate expansion coefficients. However, an alternative representation would take just one resultant p orbital, which is the superposition of these two, taking into account their relative weights in a given cluster orbital. This is just the same as choosing one p orbital at each site with the direction and magnitude of the tangential component of $\mathbf{V}_{L\mu}$ or $\overline{\mathbf{V}}_{L\mu}$

at that point. This fact was used to produce Figure 7 in Section 5.

As for σ cluster orbitals, the transformation of basis to give π cluster orbitals from π-type basis atomic orbitals is not unique. To define a transformation, we must first form and reduce the representation, $\Gamma_{\pi/\overline{\pi}}$, spanned by the $2n$ π orbitals of a given n-vertex cluster.[27] Conventionally, we start from $L = 1,\ M = 0$ and take the corresponding L^{π}_{μ} and $\overline{L}^{\pi}_{\mu}$ cluster orbitals until we have matched the irreducible representations contained in $\Gamma_{\pi/\overline{\pi}}$ in number and type. Usually, this gives a linearly independent set of cluster orbitals; if not, then functions of higher L or M with the appropriate symmetry are substituted to produce such a set. It is helpful to realize that L^{π}_{μ} orbitals transform in the same way as the parent $Y_{L\mu}(\theta, \phi)$ functions under operations of the point group; the corresponding odd functions $\overline{L}^{\pi}_{\mu}$ transform in the same way under pure rotations, but with a sign change under reflections, inversions, and rotation–reflections.[27] Detailed worked examples for the equilateral triangle and the octahedron may be found elsewhere.[27]

Transition metal clusters also have d_{xy} and $d_{x^2-y^2}$ atomic orbitals, which are classified as δ-type in TSH theory. To represent the transformation properties of these orbitals, we use second derivatives of the spherical harmonics, that is, tensor spherical harmonics – hence the name of the theory. As for the vector surface harmonics, there are again both odd and even δ cluster orbitals, denoted by $\overline{L}^{\delta}$ and L^{δ}, respectively. Usually, both sets are completely filled in transition metal clusters, and we will not consider their properties in any detail in this review. However, the cases of partial occupation are important and have been described in previous articles.[27,59]

Having provided an overview of the TSH theory cluster orbital transformation, it may be as well to emphasize once more the idea behind this approach, namely, to guess first approximations to the true molecular orbitals of the system. In this section, we have basically dealt with the mechanics of this transformation; to see how it leads to a general theoretical basis for structure-electron counting rules, we need to know the energies of the cluster orbitals. This problem is considered in the next section; for σ cluster orbitals, simple node-counting arguments suffice, while for clusters where π cluster orbitals are occupied, we must introduce the TSH theory 'pairing principle'.

There are, however, some other useful applications due to Mingos and coworkers that are based upon or framed within TSH theory, but will not be dealt with here. For example, the TSH theory pairing theorem may be generalized and used to analyze nonbonding orbitals in hydrocarbon polyenes, coordination compounds, and clusters.[60] The ligand and central atom valence orbitals may be classified using TSH theory to analyze the bonding and the stereochemistries of coordination compounds.[61] Finally, an alternative transformation framework has been developed in terms of edge-localized and face-centered equivalent orbitals.[62]

5 FURTHER DEVELOPMENT OF TSH THEORY

5.1 Clusters Involving Only σ orbitals

5.1.1 *Characteristics of σ cluster Orbitals*

In clusters where the contributions of p and d atomic orbitals can be neglected, the bonding is especially simple. In such cases, we need to only consider σ cluster orbitals, whose energies are basically defined by node counting. For such systems, the same qualitative energy-level pattern often results as for jellium models, because the angular parts of the jellium wavefunctions are also spherical harmonics. Hence, the same 'magic numbers' for precisely filled electronic shells are also found, as mentioned in Section 4.1 above. The σ cluster orbitals for an octahedron were illustrated in Figure 1.

For a cluster with n vertices, the cluster orbital transformation involves n functions. For deltahedral geometries, it is generally not necessary to use the cluster orbitals from the set with $L + 1$ until all the $2L + 1$ members of the set based upon the spherical harmonics $Y_{L\mu}(\theta, \phi)$ have been used. However, this is not possible for all systems, such as three-connected structures and bipyramids.[27] For example, if all the atoms of a particular cluster happen to lie on nodal planes of one of the spherical harmonics, then no σ cluster orbital can be constructed from that function.

The energies of the L^{σ}_{μ} depend principally upon the value of L, because this defines the number of angular nodes. The nodeless S^{σ} orbital always lies lowest, followed by $P^{\sigma},\ D^{\sigma}, \ldots$, and so forth. Furthermore, for a given value of L, the L^{σ} orbitals become more bonding as the number of atoms in the cluster increases, so long as all these atoms lie approximately on a single sphere.[57] The P^{σ} and D^{σ} orbitals usually become bonding when n is greater than about 6 and 16, respectively. Hence, filled bonding sets of orbitals are expected for 2 electrons, 8 electrons ($n > 6$), and 18 electrons ($n > 16$), and these correspond to the same 'magic numbers' for sodium clusters as predicted by the jellium model, above. However, in a finite cluster, the degeneracies associated with spherical symmetry are usually split, so this is by no means a complete explanation of why such magic number clusters are especially stable. Furthermore, one should really be more precise about whether it is kinetic or thermodynamic stability (or both) that is in question.

5.1.2 *Splitting of σ cluster Orbitals*

In radially bonded clusters, the bonding cluster orbital energy levels lie lower when the number of nearest neighbors per atom is maximized, and this usually corresponds to close-packed high-symmetry structures. However, in clusters that do not correspond to completely filled S^{σ}, P^{σ} and so on, shells, it may be more favorable for the cluster to distort and open up a significant *HOMO-LUMO* gap. The

splittings induced by symmetry-lowering distortions of an L^σ shell follow an approximate center-of-gravity rule,[63] and so stabilization of the occupied orbitals and a large *HOMO-LUMO* gap are synonymous at this qualitative level of theory. The sense of the splitting (i.e. which orbitals are stabilized and which are destabilized) depends upon the way in which the cluster is distorted and can be analyzed rather like the splitting of atomic d orbitals in transition metal complexes.[64]

Two different classes of distortion may be recognized, namely oblate and prolate.[63] A prolate molecule, like CH_3F, has two equal principal moments of inertia, which are greater than the third, while an oblate molecule, like NH_3, has two equal moments of inertia, which are less than the third. In each case, the unique axis corresponds to a rotational axis of order 3 or more. The classification may be loosely extended to less symmetrical species, where two of the principal moments of inertia are similar and different from the third.

If applied with due caution, these ideas may provide useful insight. In any planar structure, the P_0^σ cluster orbital vanishes if the z axis is taken perpendicular to the plane, and we cannot apply the barycentre principle. In the triangle and square, the $P_{1c,1s}^\sigma$ orbitals are antibonding and nonbonding, respectively, and Na_3, Na_4, Li_3, Li_4 are all found to be planar, albeit relatively unsymmetrical, structures.[11] In nonplanar clusters with more than around 6 atoms, the $P_{1c,1s}^\sigma$ pair are expected to lie lower than P_0^σ, as shown in Figure 2. In agreement with this observation, both Na_6 and Li_6 exhibit a low-energy oblate geometry, that is, a capped pentagonal structure, as well as a planar raft, and both are favorable according to ab initio calculations.[11] In contrast, both Na_8 and Li_8 are calculated[11] to adopt tetracapped tetrahedral geometries, where the P^σ orbitals are all degenerate and precisely filled.

Similar considerations apply to gold clusters of the form $Au_m(PPh_3)_m^{x+}$, where the 5d orbitals may be treated as a closed shell in the first approximation, and bonding occurs principally through inwardly directed s/p_z σ hybrids.[65] For example,

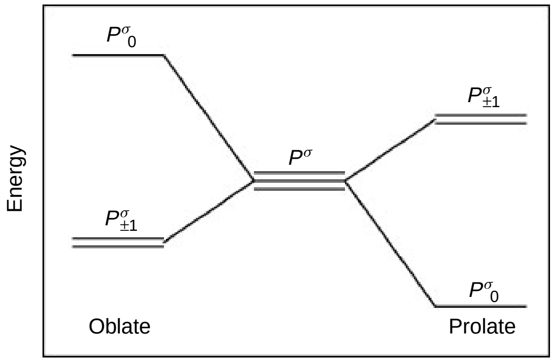

Figure 2 The idealized splitting of the P^σ orbitals in nonplanar oblate and prolate clusters

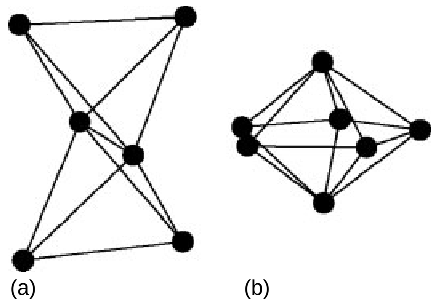

Figure 3 The gold skeletons of (a) $Au_6(PPh_3)_6{}^{2+}$ and (b) $Au_7(PPh_3)_7{}^+$

$Au_6(PPh_3)_6{}^{2+}$ has a D_{2h} pseudoprolate gold skeleton, in which the P_0^σ cluster orbital is preferentially stabilized. However, $Au_7(PPh_3)_7{}^+$ is an oblate pentagonal bipyramid, where the two $P_{1c,1s}^\sigma$ orbitals are occupied[27] (Figure 3).

5.2 The TSH Pairing Principle

In most clusters, the bonding is more complicated than for the systems discussed in the previous section, because π-cluster orbitals must be considered. One simplification is obtained from an energy-pairing relation[57] between even cluster orbitals L_μ^π and their odd partners $\overline{L}_\mu^\pi$.

The idea of a pairing rule may be more familiar in the context of conjugated alternant hydrocarbons (which are defined as those containing no odd-membered rings). Coulson and Rushbrooke[66] showed that the Hückel molecular orbitals of such systems occur in pairs with energy $\alpha \pm \lambda\beta$, where α and β are the usual energetic parameters of *Hückel Theory*.[12] The LCAO coefficients of either of the partner orbitals may be obtained from the other by changing the signs of alternate coefficients.

The TSH theory pairing principle plays a similar role in cluster bonding. It can be shown that the energies of partner L_μ^π and $\overline{L}_\mu^\pi$ cluster orbitals have the same magnitude but opposite signs with respect to an origin at α. Several approximations are made in the proof,[27] for example, all the atoms are assumed to lie on a sphere, and the β parameters for π orbitals interacting in σ- and π-fashion are assumed to be the same. Neglect of nonnearest neighbors is not necessary, however.[27] The usefulness of this result is probably best illustrated by the detailed analysis of $B_6H_6{}^{2-}$ in the following section.

5.3 Bonding in Deltahedral Clusters

5.3.1 *Analysis of $B_6H_6{}^{2-}$*

As mentioned in Section 3, the deltahedral *closo*-boranes, $B_nH_n{}^{2-}$, and carboranes, $C_2B_{n-2}H_n$, have $4n+2$ valence

electrons. In this section, the presence of $2n+1$ bonding molecular orbitals, of which $n+1$ may be identified with skeletal bonding, is explained using TSH theory. The structures of the *closo*-boranes from $B_5H_5^{2-}$ to $B_{12}H_{12}^{2-}$ are illustrated in Figure 4 (*see also* ***Boron: Polyhedral Carboranes***).

$2n$ of the valence electrons are associated with n two-center, two-electron B−H bonds, and will not be considered further. In deltahedra, we generally find that all the even π cluster orbitals are bonding in character, and all their odd partners are therefore antibonding, by the pairing principle. The $n+1$ skeletal bonding orbitals may be formally identified as S^σ and the n even L^π orbitals. However, the P^σ set may be bonding in character too, but these orbitals transform in the same way as the corresponding P^π orbitals, and hence the two sets mix to give strongly bonding and antibonding combinations. Because of this σ/π mixing, we are generally guaranteed to have $n+1$ skeletal bonding orbitals in deltahedral clusters.

A detailed analysis of the bonding in $B_6H_6^{2-}$ should help illustrate exactly how the TSH approach is applied; the labelling scheme for this cluster is illustrated in Figure 5. The six σ cluster orbitals, $S^\sigma(A_{1g})$, $P^\sigma(T_{1u})$, and $D^\sigma(E_g)$, generated by the s orbitals in Li_6 or Na_6 were shown in Figure 1. For $B_6H_6^{2-}$, it is more appropriate to form radial sp_z hybrids from the outset, and use these as the basis for the B−H bonds and the L^σ cluster orbitals. The same linear combinations are generated, and these are shown for the inwardly directed sets in Figure 6. Explicitly, the linear combinations are

Orbital	LCAO form	Energy
$S_0^\sigma(A_{1g})$	$\sqrt{\tfrac{1}{6}}(\sigma(1)+\sigma(2)+\sigma(3)+\sigma(4)+\sigma(5)+\sigma(6))$	$\alpha+4\beta$
$P_{0,1c,1s}^\sigma(T_{1u})$	$\left\{\begin{array}{l}\sqrt{\tfrac{1}{2}}(\sigma(1)-\sigma(6))\\ \sqrt{\tfrac{1}{2}}(\sigma(2)-\sigma(4))\\ \sqrt{\tfrac{1}{2}}(\sigma(3)-\sigma(5))\end{array}\right\}$	α
$D_{0,2c}^\sigma(E_g)$	$\left\{\begin{array}{l}\tfrac{1}{2}(\sigma(2)+\sigma(4)-\sigma(3)-\sigma(5))\\ \sqrt{\tfrac{1}{12}}(2\sigma(1)+2\sigma(6)-\sigma(2)-\sigma(3)-\sigma(4)-\sigma(5))\end{array}\right\}$	$\alpha-2\beta$

To form $P_{1c}^\sigma \equiv P_z^\sigma$, for example, we need only use the value of z at each vertex to obtain $P_z^\sigma \propto (\sigma(1)-\sigma(6))$. The energies have been evaluated in the Hückel approximation (*see Hückel Theory*), but this is simply to provide an idea of the bonding/antibonding character, and some more accurate calculations will be discussed below. (Note that the splitting obeys another center-of-gravity rule.) The normalization is simply $1/\sqrt{2}$, as overlap between the two σ orbitals has been neglected.[27]

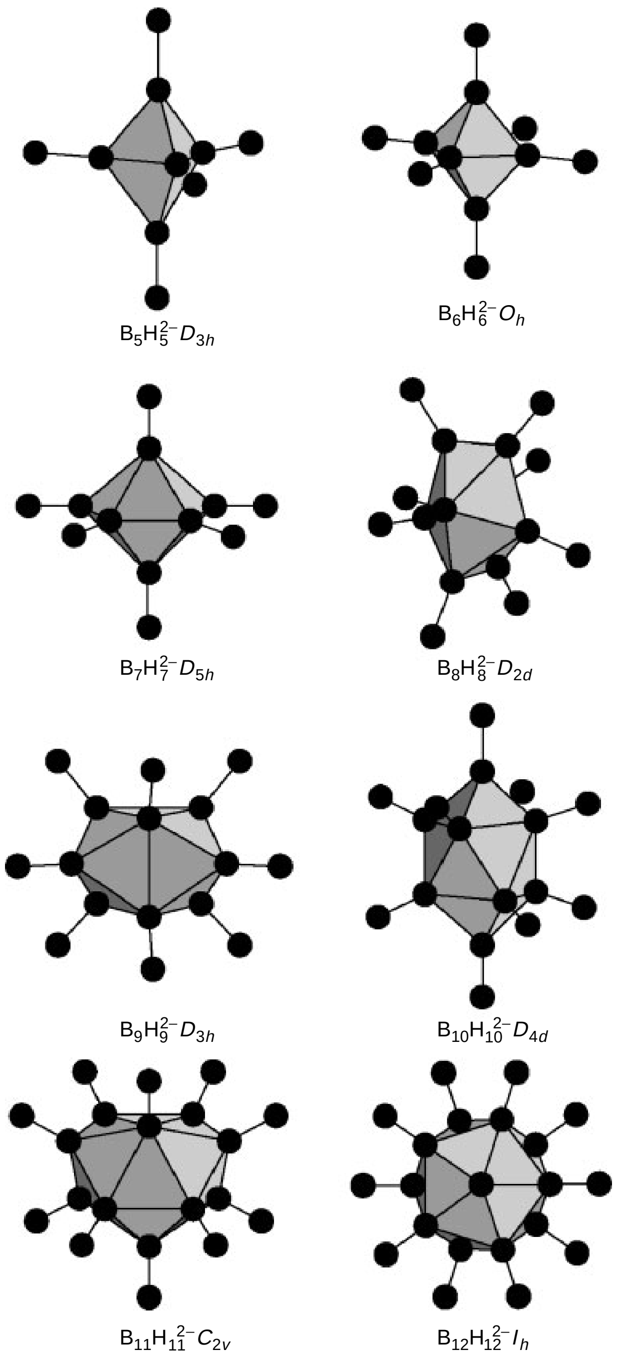

Figure 4 Structures of the *closo*-boranes from $B_5H_5^{2-}$ to $B_{12}H_{12}^{2-}$; these are the optimized geometries calculated with a minimal STO-3G basis. (This figure was produced using Mathematica 2.0 © Wolfram Research Inc., 1990.)

To find the linear combinations required for the π cluster orbitals, we must first form and reduce the representation spanned by the 12 tangential p^π atomic orbitals, $\Gamma_{\pi/\bar{\pi}}$. The result is[27] $\Gamma_{\pi/\bar{\pi}} = T_{1u} \oplus T_{1g} \oplus T_{2g} \oplus T_{2u}$, and the corresponding cluster orbitals are $P^\pi(T_{1u})$, $\overline{P}^\pi(T_{1g})$, $D_{1c,1s,2s}^\pi(T_{2g})$, and $\overline{D}_{1c,1s,2s}^\pi(T_{2u})$. Owing to the particular

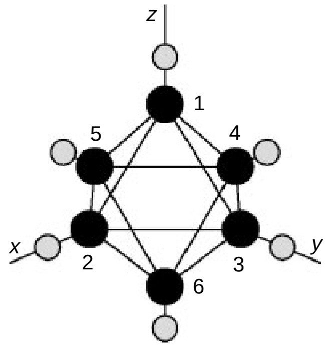

Figure 5 Structure and labeling scheme for the $B_6H_6{}^{2-}$ octahedron

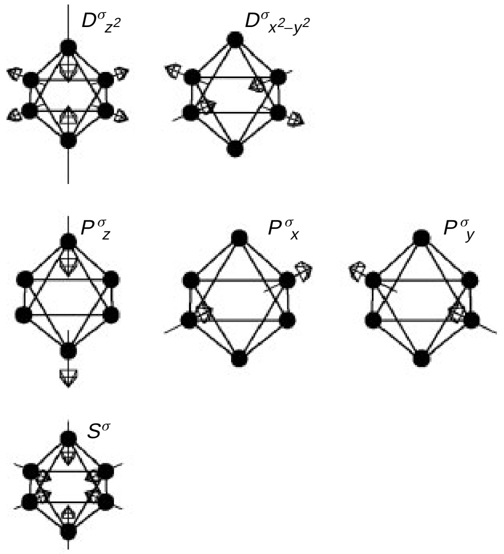

Figure 6 Unnormalized L^{σ} cluster orbitals for $B_6H_6{}^{2-}$ formed from inwardly pointing sp_z hybrids. Each arrow represents a hybrid valence orbital contribution to the molecular orbital in both magnitude and direction. (This figure was produced using Mathematica 2.0 © Wolfram Research Inc., 1990.)

symmetry of this cluster, it is quite convenient to express everything in Cartesian coordinates rather than spherical polars, that is, using p_x, p_y, and p_z instead of p^{θ} and p^{ϕ}. The only disadvantage is that the relationship between odd and even partner orbitals is more obvious when the latter basis functions are used, but this analysis may be found elsewhere.[27] In the following linear combinations, the x, y and z directions correspond to the global axes, as defined in Figure 5, not the local axes described previously. (Note that ∇z has no tangential components at vertices 1 and 6, and no radial components at the other atoms.) To form P_0^{π}, for example, we simply use the fact that $\nabla z = (0, 0, 1)$, so that $P_0^{\pi} = \frac{1}{2}(p_z(2) + p_z(3) + p_z(4) + p_z(5))$, where the normalization has been added as for the σ-cluster orbitals above. Hence, the full set of π orbitals is

Orbital	LCAO form	Energy
$P^{\pi}_{0,1c,1s}(T_{1u})$	$\frac{1}{2}(p_z(2) + p_z(3) + p_z(4) + p_z(5))$ $\frac{1}{2}(p_x(1) + p_x(6) + p_x(3) + p_x(5))$ $\frac{1}{2}(p_y(1) + p_y(6) + p_y(2) + p_y(4))$	$\alpha + 2\beta$
$\overline{P}^{\pi}_{0,1c,1s}(T_{1g})$	$\frac{1}{2}(-p_y(2) + p_x(3) + p_y(4) - p_x(5))$ $\frac{1}{2}(p_y(1) - p_y(6) - p_z(3) + p_z(5))$ $\frac{1}{2}(-p_x(1) + p_x(6) + p_z(2) - p_z(4))$	$\alpha - 2\beta$
$D^{\pi}_{1c,1s,2s}(T_{2g})$	$\frac{1}{2}(p_x(1) - p_x(6) + p_z(2) - p_z(4))$ $\frac{1}{2}(p_y(1) - p_y(6) - p_z(5) + p_z(3))$ $\frac{1}{2}(p_y(2) - p_y(4) - p_x(5) + p_x(3))$	$\alpha + 2\beta$
$\overline{D}^{\pi}_{1c,1s,2s}(T_{2u})$	$\frac{1}{2}(p_y(1) + p_y(6) - p_y(2) - p_y(4))$ $\frac{1}{2}(-p_x(1) - p_x(6) + p_x(5) + p_x(3))$ $\frac{1}{2}(p_z(2) + p_z(4) - p_z(5) - p_z(3))$	$\alpha - 2\beta$

Again, the Hückel energies are given simply as a guide to the bonding character and do not imply that the Hückel approximation must necessarily be used. (*See also Hückel Theory*.) These functions are illustrated in Figure 7; note that all of them contain nodes, but where these are only intrinsic to the atomic orbitals, they do not lead to antibonding interactions. The intrinsic nodes are not explicitly illustrated; they would, of course, bisect each arrow.

A qualitative energy-level diagram for the separate L^{σ} and L^{π} sets is shown in Figure 8. When the two sets are allowed to mix, we expect to find seven strongly bonding orbitals that may be written as $S^{\sigma}(A_{1g})$, $P^{\sigma/\pi}(T_{1u})$ and $D^{\pi}(T_{2g})$. To verify this result, one may perform any sort of standard MO calculation and transform to the cluster orbital basis.[27] For comparison, the energy-level spectrum resulting from a minimal basis set calculation is given in Figure 9. This analysis illustrates the general result that n-vertex deltahedra have $n + 1$ skeletal bonding orbitals, which may formally be identified with the S^{σ} and L^{π} cluster orbitals. Although the composition of the occupied orbitals may change when σ/π mixing is admitted, the symmetries of the occupied set do not.

5.3.2 *Symmetry-Forced Electron Count Deviations*

We may also use the TSH formalism to explain systematic deviations from the usual deltahedral electron count. Such cases arise when the two members of a pair of degenerate L^{π} orbitals are paired with one another, and must therefore both be nonbonding.[67] This will be the case in any cluster where $\Gamma_{\pi/\overline{\pi}}$ contains an odd number of E-type irreducible representations (IR's). Fowler[67] proved that any cluster with a rotation axis of order 3 or more, and a single vertex atom lying on that axis, would be forced to deviate from the usual skeletal electron count. These results were generalized by Johnston and Mingos,[68] who classified clusters as nonpolar, polar, or bipolar according to the number of atoms on the principal rotation axis, that is, 0, 1, or 2, respectively. For

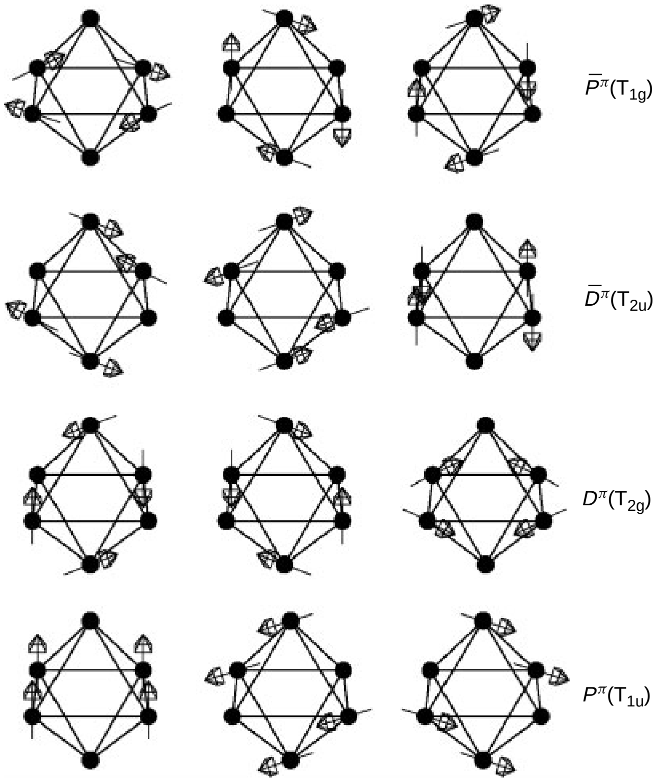

Figure 7 L^{π} cluster orbitals for $B_6H_6^{2-}$ formed from tangential p orbitals. Each arrow represents a p orbital contribution to the molecular orbital in both magnitude and direction, for example, all the arrow heads may be taken as the positive lobes. (This figure was produced using Mathematica 2.0 © Wolfram Research Inc., 1990.)

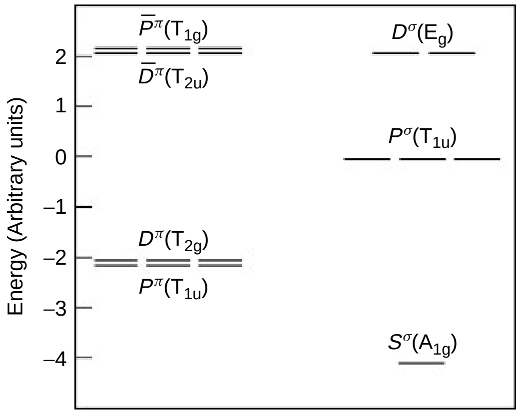

Figure 8 Qualitative energy-level diagram for the L^{σ} and L^{π} cluster orbitals of an octahedron, prior to mixing. The units are arbitrary, and the relative scales for the σ (right) and π (left) sets cannot be determined precisely without further calculation. $\overline{P}^{\pi}$ and $\overline{D}^{\pi}$ both lie at +2 units and P^{π} and D^{π} at −2 units

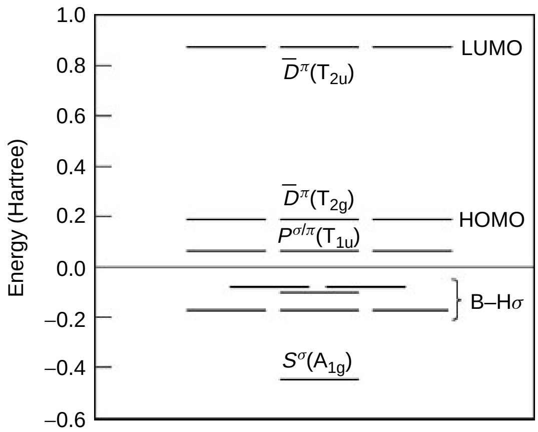

Figure 9 Energy-level diagram for $B_6H_6^{2-}$ calculated for the optimized geometry using a minimal STO-3G basis. The cluster orbitals have been picked out and labeled appropriately

polar deltahedral clusters, the principal axis can only have order 3, because all the faces must be triangular, and the axis passes through only one vertex, by definition. Hence, we expect deviations only for clusters with $3p + 1$ vertices. In fact, axes of order 2 are possible for a polar deltahedron if an edge is bisected, as in $B_{11}H_{11}^{2-}$, and in such systems the *HOMO-LUMO* gap may be small, depending upon the splitting of the idealized *e* pair of frontier orbitals. When there is a threefold axis, the π orbitals of each set of three equivalent atoms span precisely two E-type IR's. However, the p^{π} orbitals of the unique vertex atom also span an E symmetry IR, giving $2p + 1$ in total. Since all the even π cluster orbitals of E symmetry must find odd partners in this set, it follows that one pair must be paired with itself, and is therefore nonbonding[68] because of the energy-pairing principle described in Section 5.2. As this result depends critically upon the point group, it is hard to see how it could be derived by any other approach that does not consider symmetry explicitly.

Polar deltahedra with an approximately nonbonding *e* pair of orbitals might have either $4n$ or $4n + 4$ valence electrons, depending upon whether these orbitals are vacant or fully occupied. Here, as usual, we are assuming that intermediate occupation numbers would be unfavorable, since they would entail open shells and/or Jahn–Teller distortions. Both cases are known for $p = 1$, that is, $n = 4$ vertices, with B_4Cl_4 and P_4 tetrahedra having 8 and 12 skeletal valence electrons, respectively. The latter cluster can also be described in terms of two-center, two-electron edge-localized bonds, as discussed below. Examples for larger systems are found amongst the hypothetical *closo*-boranes investigated by Fowler;[67] some more complicated cases have also been considered and various examples are known for *Transition Metals*.[68,69]

In fact, it is also possible for nonpolar deltahedra to exhibit deviations from the usual electron-counting rules.[68] The D_{3h} tricapped trigonal prism provides an interesting example. In $B_9H_9^{2-}$ (see Figure 4), which has the usual

$n + 1 = 10$ skeletal electron pairs, the HOMO is actually odd in character ($\overline{F}_0^{\pi}$) and the *HOMO-LUMO* gap is rather small. Hence, it is perhaps not surprising that B_9Cl_9 and $Bi_9{}^{5+}$ have analogous structures, but 9 and 11 skeletal electron pairs, respectively.

5.3.3 *The closo, nido, arachno Debor Pattern*

TSH theory also provides an explanation for the number of bonding orbitals observed in related closo, nido, and arachno clusters.[21,57] Consider the notional formation of a nido cluster by removing a B−H vertex from a closo system. Now assume an idealized axial symmetry for the cluster such that the p^{π} orbitals of the vertex removed span an E-type IR. If the original closo cluster has a 'normal' electron count, that is, $n + 1$ skeletal bonding orbitals, then it must have been bipolar, that is, there were two vertices lying on the rotation axis on different sides of the cluster. It follows that the nido cluster is itself polar, and could exhibit n or $n + 2$ skeletal electron pairs, where n is now the number of vertices remaining in the nido cluster. Furthermore, the approximately nonbonding e pair of orbitals must have significant amplitude around the open face, because they would interact strongly with the corresponding orbitals of the missing vertex. Usually, the open face is protonated, thus stabilizing the frontier e pair and leading to $n + 2$ occupied skeletal orbitals that is, the same as in the parent closo cluster with $n + 1$ vertices. The loss of just one inwardly directed σ hybrid does not generally destabilize the S^{σ} orbital significantly.

An alternative explanation has been given within the topological graph-theoretical framework[50] using the 'Principle of Polyhedral Excision'. Here, it is argued that the atoms bordering each 'hole' left by removing a vertex would interact to give a core-type bonding orbital in addition to the usual core orbital and the n bonding orbitals resulting from pairwise overlap of the tangential orbitals at each vertex. However, this does not explain the presence of a nonbonding pair of e orbitals around the open face, which can be verified by calculation.

Of course, as with all these general structure-electron count correlation 'rules,' there is scope for deviation. For example, if the nido cluster does not have a threefold or higher-order axis (a higher-order axis is possible because the cluster is no longer deltahedral), then the idealized e pair will be split. The electron count will then depend upon the splitting, specific stabilization by protonation, and so on. Of course, as successive vertices are removed, the cluster may also deviate significantly from the assumed roughly spherical arrangement of atoms.

The TSH formalism may also be used to explain the electron counts of arachno clusters, why the 'missing' vertex in a nido cluster usually gives the largest possible open face, and why it appears to be most favorable to 'remove' two adjacent vertices to give an arachno cluster. Since the (possibly idealized) nonbonding e pair of orbitals has significant amplitude around the open face, each orbital must have a single nodal plane passing through this face. The consequent antibonding interactions are minimized if the open face is as large as possible, as then their contribution relative to the in-phase bonding interactions is minimized.[57] This also explains why neighboring vertices appear to be 'lost' to give arachno clusters. To rationalize the electron count of such an arachno cluster requires further idealizations.[57] The essential idea is that two e-type nonbonding pairs of orbitals are created; the details are omitted here.

5.4 Transition Metal Clusters

The analysis of these molecules is complicated by the presence of the d orbitals, which contribute one orbital of σ symmetry (d_{z^2} in local axes), two of π symmetry (d_{xz} and d_{yz}), and two of δ symmetry (d_{xy} and $d_{x^2-y^2}$). There are far more examples of deviations from the usual patterns in transition metal clusters than in main group clusters, and many of these must be treated specifically, although TSH theory may again provide a useful framework in which to perform the analysis. However, in this section the objective will simply be to understand the most common patterns, as set out in Section 3, which are typically found in clusters with π-acceptor ligands such as CO.

It is easiest to derive the number of inaccessible orbitals in this case, that is, the number of orbitals that are too high in energy to contain electrons, and we divide the ns, np, and $(n-1)$d orbitals (n here represents a principal quantum number, for example, 4s, 4p, 3d) into three sets. By suitable *Hybridization*, we may construct in-pointing and out-pointing σ and π orbitals, leaving one orbital of σ character and the two δ orbitals. The latter consist approximately of d_{z^2}, d_{xy}, and $d_{x^2-y^2}$, and are conveniently referred to as the 't_{2g}' set by analogy to the way they transform in *Octahedral* transition metal complexes. Similar divisions are made in the graph-theoretical approach.[51]

The t_{2g} set and the three out-pointing hybrids usually correlate formally with accessible orbitals, with varying ligand character, assuming that there are sufficient π-acceptor ligands to stabilize them. This is usually the case in clusters composed of so-called 'conical' $M(CO)_3$ vertices. However, deviations may occur for lower carbonyl to metal ratios. It follows that the detailed geometrical arrangement of the ligands is not of primary importance, so long as there are enough of them. This result is in agreement with the fluxionality commonly observed in transition metal carbonyls and with the view that the carbonyl arrangement is determined principally by packing considerations.[70] The remaining in-pointing σ and π orbitals then give rise to $n + 1$ bonding and $2n - 1$ antibonding orbitals, as discussed for main group deltahedral clusters in the preceding section. Indeed, this is actually the basis of the Isolobal Principle.[23] The antibonding orbitals are not stabilized by ligand interactions because they are inwardly directed, and hence they are termed 'inaccessible'. The result

is $7n + 1$ accessible orbitals and $14n + 2$ valence electrons, in agreement with calculations by Lauher[71] and Ciani and Sironi.[72]

It is noteworthy that the δ orbitals are always considered to be accessible in this analysis, and need not be considered further. Of course, this assumption is not always true, but clusters where the δ orbitals need to be analyzed in detail will not be treated here.[27,73] Furthermore, since the only inaccessible orbitals arise from the inwardly directed σ and π interactions, the same analysis for symmetry-forced electron counts involving one additional occupied (or unoccupied) orbital holds.[68] Closo, nido, and arachno relationships follow by analogy so long as no additional inaccessible orbitals arise.

5.5 Bonding in Three-Connected Clusters

Here, we deal with clusters such as prismane, C_6H_6, and cubane C_8H_8, which can simply be described in terms of edge-localized two-center, two-electron bonds. Why, then, is it necessary to devote any space to such molecules? The answer is that it was not initially clear how TSH theory can rationalize the electron counts of these molecules. Of course, this is not entirely surprising, as the *Hybridization* patterns used in the TSH model are not well adapted to cover this situation. However, the correct answer can be obtained without abandoning the framework developed in the preceding sections.

The reason why the TSH analysis of deltahedral clusters, with $n + 1$ skeletal bonding orbitals, is inapplicable is that the L^π and $\overline{L}^\pi$ cluster orbitals are not necessarily bonding and antibonding, respectively, in three-connected clusters. This result is basically due to the low coordination number and the relatively sparse manner in which the vertices in three-connected structures cover a sphere.[52]

An n-vertex three-connected cluster has $3n/2$ edge-localized bonds, that is, $3n$ skeletal valence electrons rather than the $2n + 2$ found in deltahedra. Johnston and Mingos considered the $3n/2$ skeletal bonding orbitals in terms of linear combinations of the localized bonds, identifying $n/2 + 2$ combinations that are 'face-bonding' and $n - 2$ that are 'face-antibonding'.[74] The face-bonding combinations have all the localized bonds in phase around each face, the face-antibonding (or nonbonding) combinations do not, and lie somewhat higher in energy, though they are, of course, bonding overall. A TSH analysis[52,74] identifies the $n/2 + 2$ strongly bonding combinations as S^σ and $n/2 + 1$ members of the L^π set. The more weakly bonding skeletal orbitals then consist of the remaining $n/2 - 1$ L^π orbitals, and their parity-related $\overline{L}^\pi$ partners.

5.6 Additional Examples

There is space to provide only a very brief mention of how TSH theory is able to rationalize some of the other bonding patterns mentioned in Section 3. TSH analyses of the bonding in cylindrical clusters[75] and the hyper−closo versus iso−closo discussion[76] may also be found in the literature.

5.6.1 *Interstitial Atoms*

For larger clusters, the central cavity may be big enough to accommodate additional atoms. For example, the distance from the shell to the center of a cuboctahedral cluster is the same as the nearest-neighbor distance within the shell, and the cavity at the center of an *Octahedral* transition metal cluster is typically large enough to accommodate first-row main group atoms such as boron, carbon, or nitrogen. The valence orbitals of such interstitial atoms will generally mix with inwardly directed L^σ and L^π orbitals of the shell that have the same symmetry, leading to strongly bonding and antibonding combinations.

For a main group atom in a radially bonded cluster (see Section 5.1), the analysis is especially simple, as the s and p orbitals of the interstitial transform in the same way as the S^σ and P^σ cluster orbitals. The net result is that the original energy-level spectrum is reinforced, with more strongly bonding s/S^σ and p/P^σ in-phase combinations and additional inaccessible antibonding combinations, as shown in Figure 10. Hence, the interstitial atom effectively acts as an electron donor, without producing any new bonding orbitals, and therefore represents a possible remedy for 'electron deficiency'. (*See also Electron Deficient Compound*.) However, this does not mean that a large charge is necessarily associated with the interstitial atom. A simple example is Na_6Mg in which the magnesium atom occupies the central position in a sodium octahedron. This cluster has 8 valence electrons, completely filling the bonding s/S^σ and p/P^σ orbitals.[27]

The same pattern emerges in simple transition metal carbonyls[27] such as $Ru_6C(CO)_{16}{}^{2-}$, which has 86 valence electrons as does $Ru_6(CO)_{18}{}^{2-}$. Some more complicated

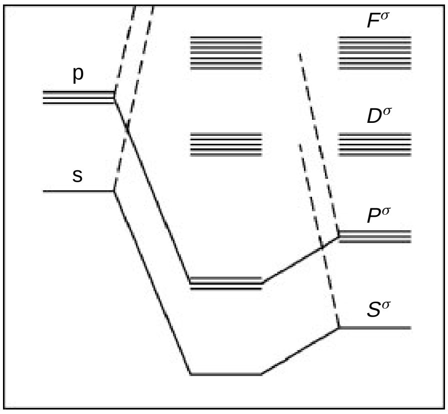

Figure 10 Schematic energy-level spectrum for a radially bonded cluster with a main group interstitial atom

examples[27] are provided by halide clusters with interstitial main group atoms, a wide variety of which have been characterized by Corbett and his coworkers.[77]

5.6.2 *The Capping,[22,30] Condensation,[31] and Inclusion[78] Principles*

Of these three ‘Principles’ mentioned in Section 3, the Capping Principle is the easiest to understand.[22,30] The others will only be mentioned briefly here; more details may be found elsewhere.[27] It should also be mentioned that King has proposed alternative visualizations of the bonding in such systems within his graph-theoretical approach.[51]

Consider a transition metal cluster that consists of an n-vertex deltahedron with m additional caps that are well separated so that they do not interact significantly with one another. Because the inaccessible orbitals of the deltahedron are all inwardly hybridized, they will only mix very weakly with orbitals on the capping atoms, and we do not expect to obtain any new bonding orbitals in this fashion. If the caps are also transition metal atoms, then we may again describe each one in terms of three inwardly directed orbitals (one σ plus two π), a ‘t_{2g}’ set and three outward-pointing hybrids (again one σ plus two π). The six orbitals consisting of the t_{2g} set and the outward-pointing hybrids will be accessible, but the inward-pointing hybrids mix with orbitals of the n-vertex deltahedron, which have already been formally identified as accessible. Hence, the addition of a single capping atom generally increases the valence electron count by just 12. However, additional accessible orbitals can occur if there are inwardly pointing $\overline{L}^{\pi}$ orbitals generated by a set of capping atoms that are not matched in symmetry by any accessible orbitals of the inner sphere. The tricapped trigonal prism may be analyzed in this way.[27]

5.6.3 *Silicon Clusters*

A short discussion of the bonding in small silicon clusters will demonstrate how the TSH framework may be useful in considering the structures of less familiar molecules. These species have received much attention in recent years, partly because of the technological significance of silicon as a semiconductor. Calculational strategies fall into two camps, namely, ab initio quantum mechanical treatments of some kind and analyses that employ analytic empirical atom−atom potentials.[79]

Slee, Lin, and Mingos[80] have analyzed the geometries of small silicon clusters, exploiting a connection with the deltahedral boranes and carboranes. A silicon atom with an out-pointing lone pair and three in-pointing hybrids is isolobal to a B−H vertex. However, Si_n clusters have $4n$ valence electrons, two fewer than the corresponding boranes, $B_nH_n^{2-}$. Hence, we should not expect the two series of clusters to be isostructural, but it may be helpful to start from the corresponding borane deltahedron and consider how the structure might distort to destabilize one of the skeletal bonding orbitals.[80] Of course, Si_n clusters could adopt structures analogous to C_n, with two-center, two-electron bonds and delocalized π systems. However, this is probably not favorable because carbon is unusual in its ability to form strong π bonds. Silicon clusters therefore tend to exhibit delocalized bonding and higher coordination numbers.

The $P_z^{\sigma/\pi}$ orbital, where the z-direction defines the principal rotation axis of the cluster, may be destabilized by contraction along this axis.[80] The D_{3h} minimum-energy structure found for Si_5 in ab initio calculations by Raghavachari[81] may be viewed in this way as a squashed trigonal bipyramid. Alternatively, application of the Capping Principle discussed in the previous section shows that $2n$ skeletal electron pairs can also result through capping, and both Si_6 (capped trigonal bipyramid) and Si_{10} (tetracapped octahedron or trigonal prism[82]) appear to exploit this fact.

The empirical interatomic potentials cannot really account for the detailed geometries of clusters such as these, where the structure depends critically upon the molecular orbital spectrum. For example, a high binding energy has been predicted[83] for Si_{13} in a centered icosahedral geometry. However, the 52 valence electrons in this cluster would require 12 lone pair orbitals and 14 skeletal bonding orbitals to accommodate them, whereas the centered icosahedron has only 13 skeletal bonding orbitals. A distortion is therefore predictable, although Si_{13}^{2+} might adopt a centered icosahedral geometry.

6 CLUSTER REARRANGEMENTS

Lipscomb[84] first proposed his diamond-square-diamond (DSD) mechanism for skeletal rearrangements in clusters in 1966, but in 1975 he commented that ‘few reaction pathways in rearrangements of boron compounds are well understood’.[85] A general theory to rationalize the relative rearrangement rates of boranes and carboranes did not, in fact, emerge until 1987, when Wales and Stone[86] used TSH theory to deduce some orbital symmetry selection rules. An equivalent description was provided by Mingos and Johnston,[87] and subsequently the theory was further developed and various predictions made.[88] Combining the new theoretical tools provided by TSH theory with modern ab initio calculations now puts us in a significantly more optimistic position than in 1975.

In the DSD process (Figure 11), an edge common to two triangular faces breaks while a new edge is formed perpendicular to it. Hence, the idealized transition state geometry would have a square face. Degenerate rearrangements, in which the rearrangement leads to the same cluster skeleton, aside from possible permutations among atoms of the same element, are particularly important in small

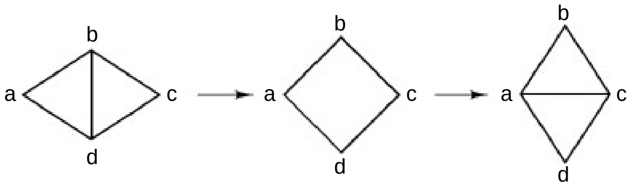

Figure 11 Lipscomb's DSD process

clusters where there may only be one stable minimum-energy structure. The boranes, and associated carboranes, provide a good example. King[89] used topological considerations to deduce which *closo*-boranes $B_nH_n^{2-}$ have geometrically possible single DSD processes available. If the connectivities of the vertices are α, β, γ, and δ, then a general DSD process may be written as $\alpha\beta(\gamma\delta)$, where the edge is broken between the vertices of connectivity α and β and made between the two with connectivities γ and δ.[89] For a degenerate single DSD process to be possible, there must therefore be vertices satisfying $\alpha + \beta = \gamma + \delta + 2$, and of the *closo*-boranes this condition is only satisfied for $B_5H_5^{2-}$, $B_8H_8^{2-}$, $B_9H_9^{2-}$ and $B_{11}H_{11}^{2-}$ (see Figure 4). However, of these four molecules only $B_8H_8^{2-}$ and $B_{11}H_{11}^{2-}$ appear to be readily fluxional;[86] in the other two clusters, the geometrically feasible single DSD process turns out to be 'forbidden' by orbital symmetry.[33] (*See also Fluxional Molecule*.)

Gimarc and Ott first noticed that the single DSD processes in $B_5H_5^{2-}$ and $B_9H_9^{2-}$ would result in crossings of filled and vacant molecular orbitals, and would therefore be expected to have high activation energy barriers.[90] (The hypothetical single DSD process in $B_5H_5^{2-}$ is, in fact, directly analogous to the *Berry Pseudorotation* in PCl_5.) Subsequent computational studies have confirmed the result[91] for $B_5H_5^{2-}$ (and the corresponding carborane) and suggest that the orbital symmetry–'allowed' double DSD process may account[92–93] for the experimental results obtained by Onak and coworkers for B, B′-disubstituted $2,4\text{–}C_2B_5H_7$ derivatives.[94] Group theoretical analysis framed within TSH theory leads to two important theorems that enable orbital crossings to be easily identified:[86,88]

(1) A crossing occurs if the proposed transition state has a single atom lying on a principal rotation axis of order 3 or more.
(2) A crossing also occurs if a mirror plane, which must pass through two atoms in the critical face, is retained throughout a DSD process.

Theorem 1 immediately reveals that the single DSD processes in $B_5H_5^{2-}$ and $B_9H_9^{2-}$ are forbidden. The result follows from the same considerations of nonbonding orbitals and symmetry-forced deviations in electron count that were discussed in Section 5.3.2. The polar transition state in question must have a nonbonding *e* pair of *Frontier Orbitals*, which are absent in

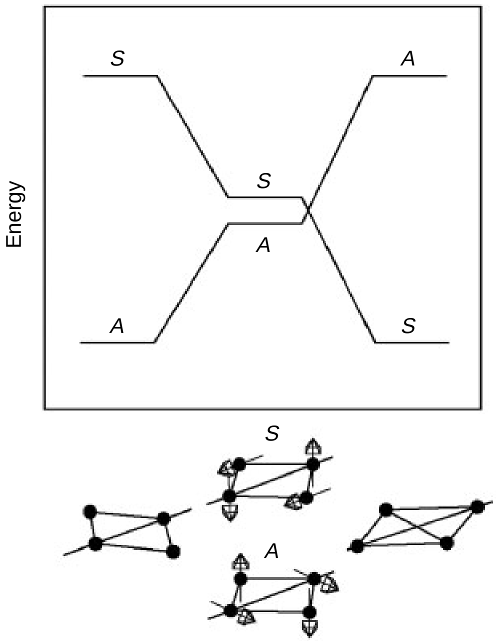

Figure 12 Splitting of the frontier orbitals in the open face of a DSD transition state. One function is symmetric (S) with respect to the conserved mirror plane, the other is antisymmetric (A). Their energies change in opposite senses and lead to an orbital crossing

the starting and finishing structures, and therefore correspond to an orbital crossing.

Theorem 2 is a more subtle result of the TSH pairing principle, and may be deduced[88] by considering the number of occupied orbitals with a given parity under reflection. The frontier orbitals, which need not be strictly degenerate, are sketched in Figure 12. They have different parities under reflection through a mirror plane that includes either pair of opposite vertices. Hence, one orbital rises in energy and the other falls when the square face contracts along a diagonal, but the splitting is in the opposite sense for the other diagonal. If only a C_2 rotation axis is preserved throughout, then there is an avoided crossing, for the two frontier orbitals are both antisymmetric under this operation.[88]

Using the above results, and the premiss that double DSD processes are less favorable than single DSD processes, and so on, (on the grounds that a single DSD process produces the smallest structural perturbation), Wales and Stone were able to rationalize the available experimental evidence for borane and carborane rearrangement rates.[86] The archetypal single DSD mechanism in $B_8H_8^{2-}$ has since been studied by accurate ab initio calculations[95] and is shown in Figure 13. Calculations for $C_2B_4H_6$ have also characterized a high-energy rearrangement mechanism based upon 'local bond rotation'.[96] The case of icosahedral $B_{12}H_{12}^{2-}$ and the associated carboranes (of which there are three isomers) is also interesting. There is no geometrically

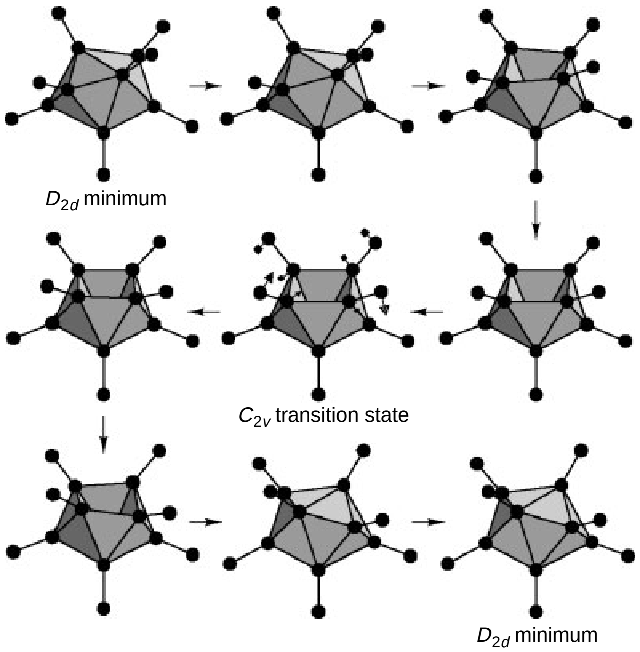

Figure 13 Calculated reaction mechanism for $B_8H_8^{2-}$. The arrows superimposed upon the transition state represent appropriately scaled normal mode displacements for the mode with the unique imaginary frequency. Structures were selected along the reaction path so as to include all three stationary points plus three geometries at regular intervals on either side of the transition state. The structures were triangulated using distance cutoffs of 2.1 Å. (This figure was produced using Mathematica 2.0 © Wolfram Research Inc., 1990.)

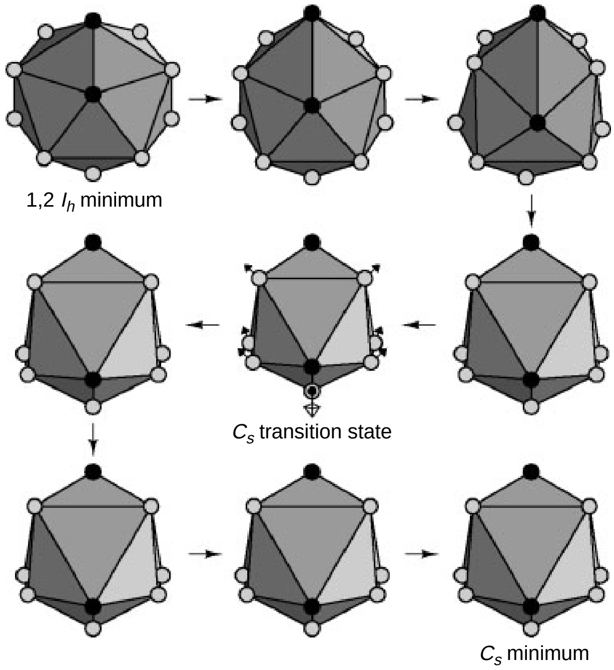

Figure 14 Concerted double DSD process (calculated at the SCF level with an STO-3G minimal basis set) linking 1, $2-C_2B_{10}H_{12}$ with C_{2v} symmetry to a high-energy local minimum with C_s symmetry. The diagram is arranged as for Figure 13 except that the terminal hydrogen atoms are omitted for clarity and the distance cutoff for triangulation is 2.8 Å. The calculated barriers are 311 and 13 kJ mol^{-1} for the forward and reverse processes, respectively. (This figure was produced using Mathematica 2.0 © Wolfram Research Inc., 1990.)

feasible single DSD process for this cluster, and earlier work[86] has shown that concerted hextuple and pentuple DSD processes are probably not responsible. Possible high-symmetry intermediates were investigated by Gimarc *et al.*,[97] but more recent results suggest that the interconversions probably occur via a complex series of rearrangements involving low-symmetry minima and transition states.[98] These pathways confirm previous suggestions made on the basis of orbital symmetry selection rules.[88] The highest barrier encountered on the pathway between the 1,2 and 1,7 carboranes involves a concerted double DSD process, as shown in Figure 14.

Of the other predictions concerning cluster rearrangement mechanisms using TSH theory, only one more will be mentioned here. This is the square-diamond, diamond-square (SDDS) mechanism that may occur in a cluster with a square face, such as square-based pyramidal $C_5H_5^+$. The TSH theory prediction is that a concerted mechanism should be orbital symmetry allowed if the edges that are made and broken lie in the same mirror plane. If one edge lies in a mirror plane and the other lies across it, then two crossings are predicted.[27,88] The mechanism is unlikely to occur in *nido*-boranes, because of the additional bridging hydrogen atoms around the open face; however, recent ab initio calculations[95] have confirmed that it does indeed occur in $C_5H_5^+$, as shown in Figure 15.

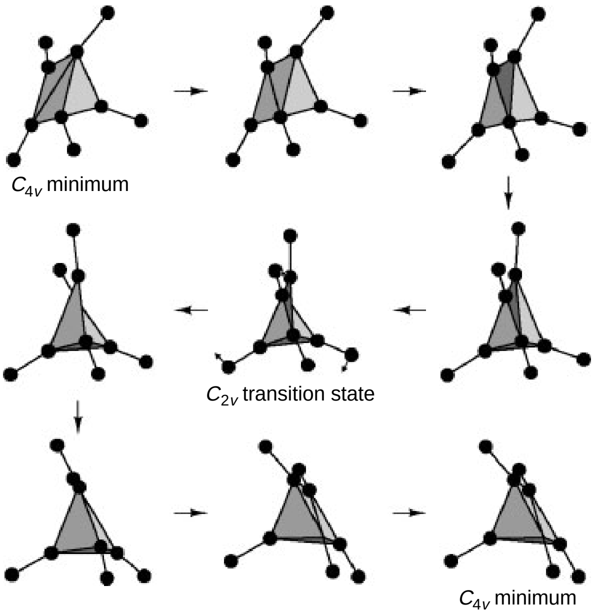

Figure 15 The SDDS rearrangement of square-based pyramidal $C_5H_5^+$, which proceeds through a C_{2v} symmetry transition state.[95] The diagram is arranged as for Figure 13 and the triangulation cutoff is 2.1 Å. (This figure was produced using Mathematica 2.0 © Wolfram Research Inc., 1990.)

1 INTRODUCTION

The electronic structure and bonding situation in main-group compounds is usually introduced and discussed in textbooks of inorganic chemistry with heuristic bonding models which have been proven to be helpful ordering schemes and to provide plausible explanations for the experimental findings. The most widely used approach for describing the electronic structure of molecules is the Lewis paradigm of electron-pair bonding, which was introduced into chemistry before quantum chemistry was developed.[1] A quantum theoretical reasoning of the Lewis electron-pair model was later suggested by Pauling who employed valence bond theory as a basis for chemical models.[2] A complimentary and equally important approach uses molecular orbitals for explaining the geometries and reactivities of molecules. Another frequently used concept is the valence shell electron-pair repulsion (VSEPR) model.[3] The advantage of the heuristic models is that the rather complicated molecular electronic structure that is determined by quantum theoretical laws of interatomic electrostatic interactions becomes expressed in terms of comparatively simple pictures and rules that are very useful for a qualitative interpretation of experimental observations. Chemistry would be a scientific pandemonium without the ordering power of chemical models.

Much effort has been devoted to the connection between the heuristic chemical models and the quantum theory of molecular electronic structure in theoretical chemistry in recent years. It is important to understand why and where the models are valid descriptions of experimental results and why and where they fail. It is also possible to examine the validity of the explanations that are given to understand the reactivity, geometry, and other properties of molecules. This article deals with important chemical models and recent quantum chemical studies, which shed light on the electronic structure and bonding situation in main-group compounds.

2 THE NATURAL BOND ORBITAL METHOD

The most popular and currently most widespread method that connects the qualitative Lewis model for writing molecular structures in terms of electron pairs with the results of quantum chemical calculations is the natural bond orbital (NBO) approach developed by Weinhold.[4] The NBO method is a charge partitioning analysis of the electronic structure that maximizes the electronic charge that can be localized in occupied orbitals that are either core orbitals, one-center (lone-pair) orbitals, or two-center (bonding) orbitals. A special option considers also delocalized three-center two-electron bonds. The set of occupied MOs indicates the best Lewis structure of the molecule. The remaining electrons, which cannot be localized into the three types of orbitals, occupy MOs, which are called Rydberg orbitals. The population of the usually weakly occupied Rydberg functions is a sensitive probe that shows how well the electronic structure of the molecule is described by the 'Lewis' occupied orbitals. A significant occupation of Rydberg orbitals suggests that the molecule has a nonclassical bonding situation, which should be described with more than one resonating Lewis structure. The NBO method also makes it possible to enforce a particular Lewis structure during the calculation. The comparison of the amount of localized electronic charge of a selected Lewis structure with the best (i.e. unconstrained) NBO solution indicates the weight of this structure.

The NBO method can be used for ab initio calculations at the HF and any correlated levels as well as for DFT methods. The results do not strongly depend on the size of the basis set, which is one reason that the NBO method has replaced the outdated Mulliken population analysis, for example, for the calculation of atomic partial charges. But there is a price that has to be paid for the advantages. Like any orbital-based method for partitioning the electronic charge into atomic and bonding domains, the choice of the selection procedure has some arbitrary character that needs to be known in order to judge the quality of the results.

The NBO method uses the one-electron density matrix, which can be obtained from any quantum chemical method as starting point for the partitioning procedure. The first step is the diagonalization of the one-center (atomic) blocks, which yields the pre-Natural Atomic Orbitals (pre-NAOs). This is a straightforward procedure. The second step is crucial in the NBO method. The pre-NAOs at the different atoms that are not orthogonal to each other are then orthogonalized yielding the natural atomic orbitals (NAOs). The pre-NAOs are first divided into two sets. One set consists of the strongly occupied minimal basis set, which describes the atomic electron density in the ground state. The other set consist of the remaining weakly occupied Rydberg orbitals. The subsequent sequence of orthogonalization steps treats the minimal functions and the Rydberg functions in different ways. The 'occupancy-weighted symmetric orthogonalization' (OWSO transformation), which was developed with the goal to preserve maximum resemblance of the NAOs with the pre-NAOs, strongly favors the minimal basis set in the description of the NAOs. Another reason for introducing the weighting factor was to ensure the stability of the orthogonalization procedure toward basis set enlargement. It is important to recognize that the weighting factor automatically disfavors atomic basis functions that are empty in the atomic ground state in the description of the chemical bond. Thus, the NBO method excludes a priori the outermost d orbitals of the heavier main-group elements and the outermost p orbitals of the transition metals from the valence space! Thus, the results of the NBO method cannot be used to investigate the question whether the d functions of main-group elements and the p functions of the TMs are true valence orbitals or polarization functions, because the answer is already enforced by the preselection of the orbitals belonging to the valence space in the occupancy-weighted orthogonalization.

The third step of the NBO algorithm is the calculation of the natural hybrid orbitals (NHOs), which form the two-center (sometimes three-center) NBOs. The density matrix in the NAO basis is first partitioned into one-center and two-center subblocks. Each one-center block is searched for NAOs, which have an occupancy $\geq$1.90 e. These one-center orbitals are labeled as core or valence lone-pair orbitals. The latter are deleted from the two-center subblocks, which are then orthogonalized (again via the OWSO transformation) yielding the final orthogonal set of NHOs. This leads to a set of N/2 (N being the number of electrons) NBOs. The search for NBOs is then repeated with lower occupancy thresholds than 1.90 e in steps of 0.1 e up to 1.50 e. The set of NBOs that accommodates most electrons is then given as the optimal Lewis structure of the molecule.

The information that becomes available from a NBO calculation shall be demonstrated by the analysis of the chemical bonds between carbon and hydrogen and the first-octal row elements Li–F. Table 1 gives the results for the C–H and C–E bonds of $H_3C\text{-}EH_n$ (EH_n = H, Li, BeH, BH_2, CH_3, NH_2, OH, F).

The calculated atomic partial charges agree with the expected trend, which follows the electronegativites of the atoms. The high occupation of the orbitals of the classical Lewis structures shows that the standard textbook description of the molecules $H_3C\text{-}EH_n$ as methyl substituted species having C–H, C–E, E–H single bonds and lone-pair orbitals at $EH_n = NH_2$, OH, F is a faithful representation of the electronic structure. The polarisation of the C-E (E = Li–F) bonds follows smoothly the trend of the electronegativity of atom E, that is, the bonds become more strongly polarized toward E when E becomes more electronegative. The hybridization of the C–H bond in CH_4 is perfectly sp^3 while the other C–E bonds deviate from this value. The %p character at the carbon end increases from boron to fluorine, which is in agreement with Bent's rule, which states that 'Atomic s character concentrates in orbitals directed towards electropositive substituents'.[5] However, the C–Be and C–Li bonds also have a very large %p character at carbon. This comes from the diffuse 2s orbitals of beryllium and particularly of lithium, which have large overlaps with the 2p AOs of carbon. The C–Li bond has the highest %p value at carbon while lithium has a nearly pure s AO in the C–Li bond. The beryllium atom is ~sp-hybridized in the C–Be bond while the heavier atoms have a much higher p character. There is

[b]Reference 6.

little variation in the polarization and hybridization of the C–H bonds.

The NBO analysis may be used to address the question if a molecule should be written with a bonding line between two atoms or not. Table 2 shows the NBO results of donor–acceptor complexes of group-13 Lewis acids EF_3 and ECl_3 (E = B–In) with the Lewis bases NH_3, CO and $C(NH_2)_2$ as examples.[6] The NBO analysis suggests that the very weakly bonded complexes F_3BCO ($D_e = 3.2$ kcal mol^{-1}) and Cl_3BCO ($D_e = 2.3$ kcal mol^{-1}) should not be written with a bonding line between the donor and acceptor moiety but rather with a lone-pair orbital at CO. The NBO calculations of the remaining complexes of CO, which have bond dissociation energies between $D_e = 9.7$ kcal mol^{-1} and 15.1 kcal mol^{-1}, give E–CO bond orbitals that are highly polarized towards the carbon donor end (Table 2). The hybridization at the C(CO) atom in the donor–acceptor bonds is always s > p while for the other donor molecules NH_3 and $C(NH_2)_2$ the hybridization at the donor atom is s < p.

There is no correlation between the polarization of the donor–acceptor bond and the bond strength. This becomes obvious, for example, by comparing the F_3Ga–NH_3 bond with F_3Ga–CO. The latter complex has a much weaker bond (D_e = 12.5 kcal mol^{-1}) than the former ($D_e = 38.5$ kcal mol^{-1}) but the donor–acceptor bonds are polarized to the same extent. There is also no correlation between the calculated charge transfer from the donor to the acceptor moiety. The charge transfer Δq(D → A) of the most strongly bonded complex Cl_3Al–$C(NH_2)_2$ ($D_e = 61.6$ kcal mol^{-1}) is only 0.26 e while the weaker bonded complex F_3B-NH_3 ($D_e = 23.5$ kcal mol^{-1}) has a charge transfer of 0.29 e.

Another important point concerns the calculated atomic charges at the donor and acceptor atom. Table 2 shows that the partial charges at the donor and acceptor atoms have positive values. A naive interpretation would suggest that there is Coulomb repulsion between the donor and acceptor atoms. This is not correct because even the positively charged donor atom carries an occupied lone-pair orbital, which is directed toward the acceptor atom. There is always a *local area of negative charge concentration at the overall positively charged donor atom* that yields strong *Coulomb attraction* with the positively charged acceptor atom. The nonspherical charge distribution at the bonded atoms becomes analyzed in paragraph 6, Topological Analysis of the Electron Density Distribution, using Cl_3B–CO as an example. The energetic aspects of the interatomic interactions must be analyzed in order to understand the nature of the chemical bond. This will be shown in the next section.

3 ENERGY DECOMPOSITION ANALYSIS OF THE CHEMICAL BOND

Like the charge distribution in a molecule can be partitioned into domains that may be used for a chemically meaningful interpretation of the bonding situation, the electronic energy of a molecule can also be divided up into quantities that are helpful for an understanding of the molecular structure and reactivity. Because the geometry and reactivity of molecules are driven by the associated energy changes, it is even more important to understand the factors that make a molecular structure energetically favorable. The energy of a chemical bond has been the subject of theoretical research for a long time.

There are some fundamental concepts and quantities that are used by chemists to characterize a chemical bond. For example, a bond is considered as covalent when the attractive interactions arise from the mixing of the wave functions of the fragments, which yields a chemical bond. This type of chemical bonding is conceptually different from ionic bonding, which can be rationalized in terms of classical Coulomb attraction that arises when two charges of opposite sign attract each other. It is important to recognize the carrier of the charges, which are the electrons and protons but not the atoms. While the protons may be reasonably described as a point charge, the electronic charge distribution in a molecule is usually highly anisotropic, which means that a point charge description is not appropriate. Atomic partial charges may therefore be a misleading guide for estimating classical Coulomb interactions between atoms in a molecule. It is also important to recognize that ionic bonding and classical electrostatic attraction are not identical quantities. Theoretical studies have shown that there are strong classical electrostatic attractions between atoms in nonpolar bonds that are not ionic. This will be discussed in more detail below.

Covalent bonding is usually described in terms of orbital interactions. If the molecule has a mirror plane, the bonding orbitals have σ symmetry when they are symmetric with regard to the mirror plane, or they have π symmetry when they are antisymmetric. This definition leads to the familiar concept of single and multiple bonds in molecules. It must be emphasized that covalent and ionic interactions do not establish different types of elementary forces. The driving force of chemical bonding is electrostatic interaction. The difference is that covalent bonding is associated with quantum theoretical laws of electrostatic interactions whereas ionic bonding is associated with the classical description of electrostatic forces.

The question if the bonding interactions in a molecule are covalent or ionic (electrostatic) cannot be answered in a definite way neither by experiment nor by theory because covalency and ionicity are conceptual quantities but no observables. The same holds true for the strength and the existence of σ and π bonds. Any statement about single or multiple bond character in a molecule depends on the theoretical method that is used to analyze the electronic structure. The situation is easy for molecules such as ethylene or acetylene but for complicated bonding situations it can be more difficult to determine the multiplicity of a bond.

A powerful method that addresses both the question about the covalent and electrostatic character of a bond and the strength of the σ and π bonding contributions is the energy decomposition analysis (EDA), which was developed by Morokuma[7] and Ziegler.[8] The focus of the bonding analysis is the instantaneous interaction energy ΔE_{int} of a bond A – B, which is the energy difference between the molecule AB and the fragments A and B in the frozen geometry of the compound. Note that ΔE_{int} is not the same as the bond dissociation energy D_e. The difference between D_e and ΔE_{int} is the preparation energy of the fragments ΔE_{prep}, which is necessary to promote the fragments from their equilibrium geometry in the electronic ground state into the geometry and electronic state in the molecule:

$$-D_e = \Delta E_{int} + \Delta E_{prep} \qquad (1)$$

The advantage of using ΔE_{int} and not the bond dissociation energy as a starting point for a bonding analysis is that the actual interatomic interactions of the bond are considered. In the EDA, the bond formation A–B is considered to be the result of a three-step process for which individual energy terms are calculated, which can be interpreted in a physically meaningful way. In the first step, the fragments A and B with the frozen electron densities are superimposed in the geometry of A–B. This is a quasi-classical approach that gives the classical Coulomb interaction energy ΔE_{elstat}. The electronic structure that is yielded in the first step violates the Pauli principle, which states that two electrons having the same spin must not occupy the same region in space. The Pauli repulsion ΔE_{Pauli} between two electrons with the same spin (which is much stronger than the Coulomb repulsion at short distances) is calculated in the second step of the EDA. This is done by enforcing the wave function of the superimposed fragments to obey the Pauli principle by antisymmetrization and renormalization. The latter interaction is rather strong for most chemical bonds but its contribution to the interatomic interactions is frequently neglected in bonding models.

In the final step of the EDA, the wave function of the molecule relaxes to its optimal form yielding the orbital interaction term ΔE_{orb}. This term can be further partitioned into contributions by the orbitals belonging to different irreducible representations of the point group of the interacting system. Thus, it is possible to give energy contributions of the σ and π bonding contributions to a bond that has a mirror plane. More details about the EDA method in the framework of DFT can be found in a recent review article.[9]

$$\Delta E_{int} = \Delta E_{elstat} + \Delta E_{Pauli} + \Delta E_{orb} \qquad (2)$$

The calculated values for ΔE_{elstat} and ΔE_{orb} may be used to classify a bond in terms of electrostatic and

covalent interactions, because the two terms are the attractive contributions to the chemical bond.[10] However, the orthodox view that nonpolar bonds such as the C–C bond in ethane are purely covalent must then be revised because the bonding contributions of ΔE_{elstat} are rather large.

3.1 Isoelectronic Diatomic Molecules N_2, CO, BF

Table 3 gives the EDA results for the isoelectronic diatomic molecules N_2, CO and BF.[11] The contribution of the electrostatic interaction $\Delta E_{elstat} = -308.5\,\text{kcal mol}^{-1}$ to the N–N bond is *larger* than the total interaction energy $\Delta E_{int} = -232.2\,\text{kcal mol}^{-1}$, which gives directly the bond dissociation energy because there is no relaxation energy of the fragments, that is, the nitrogen atoms. This result is surprising for most chemists, because the bonding in N_2 is usually considered to come from the σ and the degenerate π bonds. Table 3 shows that the bonding contributions from σ orbitals ($\Delta E_\sigma = -470.0\,\text{kcal mol}^{-1}$) and π orbitals ($\Delta E_\pi = -245.4\,\text{kcal mol}^{-1}$) are rather large, indeed. However, there is strong repulsion from the Pauli term ($\Delta E_{Pauli} = 791.7\,\text{kcal mol}^{-1}$), which compensates the attractive orbital interactions. If N_2 would be held together by classical electrostatic forces, the bond energy would be $\sim$450 kcal mol^{-1} at an equilibrium distance of $\sim$0.85 Å. This is shown in Figure 1, which displays the energy terms of N_2 as a function of the internuclear distance.

The important role of quasi-classical electrostatic bonding in molecules has been recognized as early as 1974.[13] In 1986, Spackman and Maslen published the calculated results for 148 diatomic molecules, which showed that, in 147 diatomics, the ΔE_{elstat} term contributes a significant portion of the binding energy.[14] The only diatomic molecule among the 148 species where the electrostatic attraction is negligible is H_2. Dihydrogen is an atypical molecule for learning about the principal bonding contributions in a molecule.

It is well known that CO has a larger bond dissociation energy (BDE) than N_2. Table 3 shows that the

[a]The percentage values in parentheses give the contribution to the total attractive interactions $\Delta E_{elstat} + \Delta E_{orb}$. [b]The percentage values in parentheses give the contribution to the orbital interactions ΔE_{orb}. [c]Experimental values are given in brackets.[12]

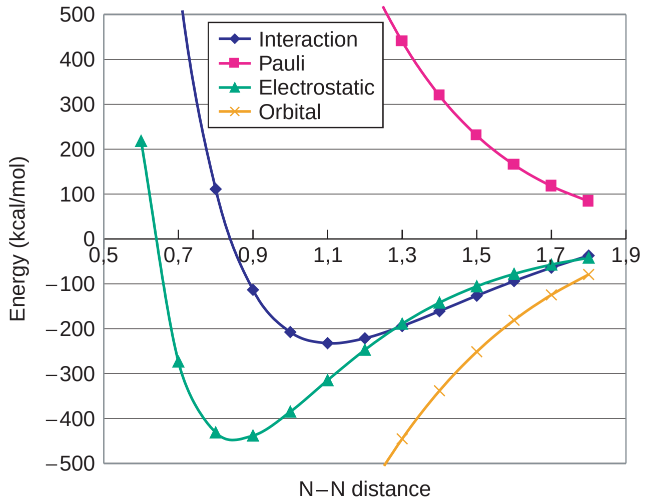

Figure 1 Energy contributions ΔE_{elstat}, ΔE_{Pauli} and ΔE_{orb} to the total interaction energy ΔE_{int} in N_2 as a function of N–N interatomic distance. (Ref. 11. Reproduced by permission of Springer Verlag)

attractive components of the C–O bonding energy ($\Delta E_{elstat} = -240.0\,\text{kcal mol}^{-1}$; $\Delta E_{orb} = -594.2\,\text{kcal mol}^{-1}$) are weaker than in N_2. The larger BDE of CO is caused by the weaker Pauli repulsion ($\Delta E_{Pauli} = 575.8\,\text{kcal mol}^{-1}$) compared with CO. This can be explained with the smaller orbital overlap in heteroatomic CO than in homoatomic N_2, which yields a smaller ΔE_{orb} term. But also the ΔE_{Pauli} term becomes smaller when there is less overlap! The EDA results also show that the π bonding in CO has nearly the same strength as the σ bonding that supports the Lewis structure (−)C≡O(+) with a triple bond as the most important one. BF, however, should be written with a single bond. Table 3 shows that the most important difference between BF and the isoelectronic diatomics N_2 and CO is the much weaker contribution of the π orbitals, which provide only 11.2% of the total orbital interaction term. If π bonding in BF would be as strong as in N_2 and CO, it would have an even bigger BDE.

3.2 Dihalogens $F_2 - I_2$

Table 4 gives the EDA results for the dihalogens E_2(E = F–I). The BDE of E_2 increases for the lighter elements except for F_2, which has a weaker bond energy than Cl_2. The standard textbook explanation for the relatively weak F–F bonding is given in terms of strong Pauli repulsion between the lone-pair electrons at the equilibrium distance of F_2, which is much shorter than that of Cl_2. However, also the radius of the valence orbitals of fluorine is much smaller than the radius of the chlorine valence orbitals because of the higher electronegativity of F. Inspection of the energy components to the interatomic interactions in E_2 (Table 4) shows that the absolute values of ΔE_{Pauli} and ΔE_{orb} increase from I_2 to F_2 but

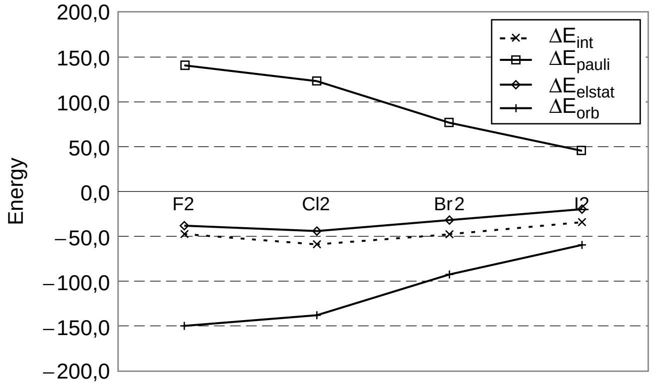

Figure 2 Energy contributions ΔE_{elstat}, ΔE_{Pauli} and ΔE_{orb} to the total interaction energy ΔE_{int} in the dihalogen molecules E_2 at the equilibrium bond length

the increase of the Pauli repulsion from Cl_2 to F_2 is not very steep. This becomes obvious from Figure 2, which displays a plot of the energy components and the total interaction energy from I_2 to F_2. The trend of ΔE_{Pauli} and ΔE_{orb} exhibits a regular behavior from the right to the left. What is unregular, however, is the trend of ΔE_{elstat}. The electrostatic attraction increases from iodine to chlorine, but then it decreases for fluorine. Figure 2 shows that the ΔE_{int} and ΔE_{elstat} correlate nicely over the whole range of dihalogen molecules. It becomes obvious from the EDA results that the weak bond of F_2 is *not* because the Pauli repulsion becomes very strong, but rather because the electrostatic attraction is unusually weak, weaker than in Cl_2. If the trend of ΔE_{elstat} would show a regular increase from Cl_2 to F_2, its value would be ∼56 kcal mol^{-1}, which would yield a total interaction energy of ∼65 kcal mol^{-1}.

3.3 Dipnicogens $N_2 - Bi_2$

Another set of diatomic molecules that reveals interesting information about the strength of π bonding in heavy main-group compounds is the pnicogen series E_2 (E = N–Bi). Table 5 shows the EDA results of the E–E bonding situation. The percentage contribution of the orbital interaction to the total bonding decreases from nitrogen to bismuth where only 41.7% of the attractive energy comes from ΔE_{orb}. The most important information concerns the strength of the σ and π bonding in the diatomics. Compounds with multiple bonds between heavy main-group elements are much less stable than

molecules that have multiple bonds between first-octal row elements. It is sometimes stated that π bonding is weak in the former species because their bonds are longer than in the latter molecules. However, the π overlap between heavier main-group elements does not become much smaller when one goes down in the periodic table because the orbitals have also large radii.[15] The size of the overlap integral is not a reliable probe for estimating the strength of the orbital interactions because it does not give any information about the energy of the electrons that occupy the orbital.

Table 5 shows that the overlap integral of the σ orbitals in N_2 (0.18) is only about one half of the overlap of the π orbital (0.37). This is because the 2p(σ) AOs of the nitrogen atoms overlap at short distance partly in an antibonding fashion with each other. The binding contributions of the σ orbitals are still much larger than those of the π orbital because the 2s AOs of nitrogen are lower in energy and, therefore, contribute strongly to the attractive orbital term.

Table 5 shows also that the percentage contribution of ΔE_π to the orbital interaction term in P_2, As_2 and Sb_2 is even slightly higher than in N_2, and the relative π bonding in Bi_2 is not much smaller. The trend of the σ and π orbital overlap does not show the important energy contribution of the π orbitals although the size of the π orbital overlap remains quite large. Molecules with multiple bonds between heavier main-group elements are not intrinsically unstable because of weak π bonding. The electronic structure of heavy main-group molecules containing multiple bonds will be discussed below.

3.4 Single and Multiple Bonds in First-row Molecules $H_nE–EH_n$ (E = Li–F)

Table 6 gives the EDA results of a complete ‘first-row sweep’ of nonpolar single bonds $H_nE–EH_n$ (E = Li–F), which gives important information about the electronic structure and bonding situation in the molecules.[48] The covalent contribution decreases and the electrostatic bonding increases from F–F to HBe–BeH. The Li–Li bond is a special case as it is the dihydrogen bond H–H. The 2s orbital of Li is very diffuse, and the long Li–Li bond yields only a very weak electrostatic attraction (Table 6). Although the valence orbital of Li_2 is bonding, removal of one electron from the 3σ HOMO that leads to Li_2^+ gives a Li–Li bond that is stronger (33.2 kcal mol^{-1}) than in Li_2 (26.4 kcal mol^{-1}). The Pauli repulsion in Li_2 prevents shortening of the bond.[9] Removing one-electron reduces Pauli repulsion and the increase in electrostatic attraction at shorter distances compensates for the loss of orbital interaction. H_2 and Li_2 are atypical molecules for discussing the electronic structure of main-group compounds.

The contribution of π bonding interactions in classical multiple bonds to the bond strength becomes obvious from the EDA results of the HB=BH, $H_2C=CH_2$, HN=NH, and HC≡CH bonds, which are shown in Table 7.[48] The covalent contributions to the attractive interactions are stronger than the electrostatic contributions in the above molecules. The relative contribution of ΔE_π decreases for the double bonds in the order HB=BH > $H_2C=CH_2$ > HN=NH. The degenerate π bond in acetylene contributes 44.4% to the orbital interactions, which means that it is not much weaker than the σ bond. Note that the absolute values of ΔE_σ in acetylene (−215.5 kcal mol^{-1}) and ethylene (−212.2 kcal mol^{-1}) are nearly the same while ΔE_π in acetylene (−172.4 kcal mol^{-1}) is more than twice as strong as in ethylene (−79.2 kcal mol^{-1}).

3.5 Single Bonds in Group-14 Molecules $H_3E–EH_3$ (E = C–Pb)

Table 8 gives the EDA results for the heavy-atom analogs of ethane $H_3E–EH_3$ (E = Si–Pb).[48] The calculated data suggest that the nature of the E–E bonding changes little when one goes from carbon to the heavier group-14 atoms. The covalent contributions decrease slightly from C to Sn, but the changes are not very big. The increase of ΔE_{orb} from Sn to Pb is caused

by relativistic effects. The weaker bonds for heavier elements can be explained with the fact that the electrons in the ns and np valence orbitals are higher in energy when n becomes larger because they are farther away from the nucleus.

3.6 Chemical Bonding in $XeF_6$and SF_6

The nature of the chemical bonding in noble gas compounds has been a challenge to chemical bonding theory since the first synthesis of a xenon compound by Neil Bartlett in 1962.[19] Textbooks of inorganic chemistry employ either resonance structures in terms of three-center four-electron bonds[20] or molecular orbital correlation diagrams, which are discussed in the following section for explaining the electronic structure in noble gas compounds. A particularly difficult case for qualitative models of the chemical bond is XeF_6.[21] The six unpaired electrons of the fluorine atoms yield six Xe–F σ bonds, which leaves two nonbonded electrons at xenon. If the latter electrons occupy the 6s orbital, it would become a stereochemically inactive electron pair and XeF_6 should have an octahedral geometry where only the 6p AOs of Xe are used for the bonds. Experimental studies have shown, however, that xenon hexafluoride has a fluxional structure based on a trigonally distorted octahedron.[22] High-level quantum chemical calculations suggest that the energy difference between the O_h form of XeF_6 and the distorted equilibrium geometry is very small ($<$2 kcal mol^{-1}).[21]

There are various ions valence-isoelectronic with XeF_6 like ClF_6^-, BrF_6^-, and $BiCl_6^-$, which have a regular octahedral structure, while others like SeF_6^{2-} and IF_6^- are trigonally distorted and still others like $SeCl_6^{2-}$, $SeBr_6^{2-}$, $TeCl_6^{2-}$, $TeBr_6^{2-}$, and TeI_6^{2-} are either octahedral or distorted, depending on the counter ion. It becomes obvious that the equilibrium geometry of the above molecules is controlled by a very delicate balance of various competing effects. Simple explanations using qualitative models should be met with caution. The a posteriori rationalization of the distorted structures in terms of a stereochemically active electron pair as it is suggested by the VSEPR model has more a character of a tautology than a true explanation because the model does not say in the beginning if an electron lone pair is active or not.

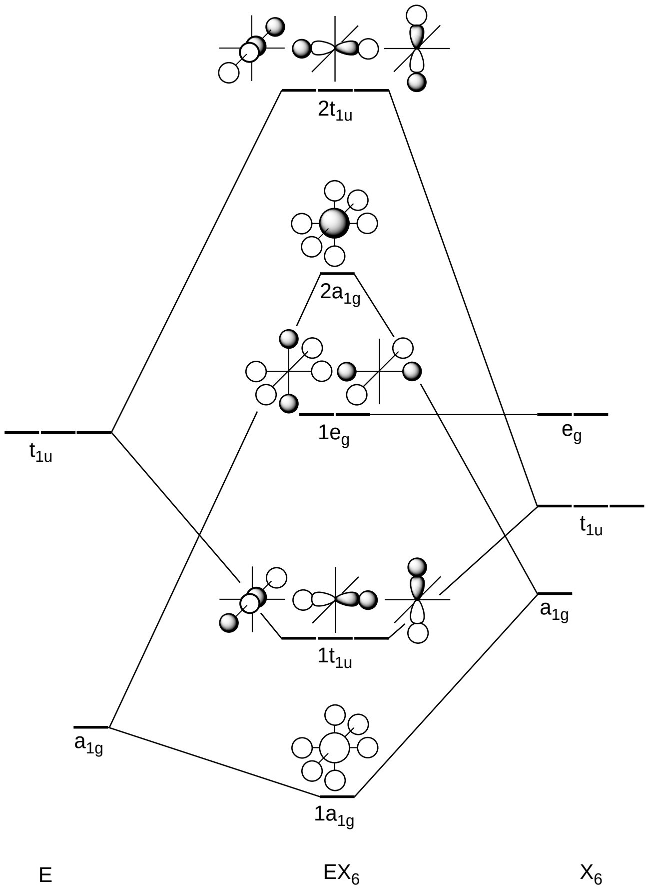

Figure 3 Orbital correlation diagram between a main-group atom E and six σ bonded ligands X in octahedral EX_6

Because the octahedral form of XeF_6 is only slightly higher in energy than the distorted equilibrium structure the O_h form may be used for the energy decomposition analysis. The results of the EDA calculations shall be used to compare the calculated orbital interactions with the qualitative MO model. Figure 3 shows a typical MO diagram for the σ orbital interactions in a molecule EX_6 in octahedral symmetry. π Orbitals between are not shown because in XeF_6 there are only Xe–F single bonds. The σ orbitals of the X_6 cage split in an octahedral field into three sets of a_{1g}, e_g, and t_{1u} symmetry. There are 14 electrons available for the σ bonding in XeF_6 (8 electrons from Xe and 1 electron from each F). Figure 3 shows that according to the aufbau principle, the 14 electrons occupy four sets of orbitals in the order 1a_{1g}, 1t_{1u}, e_g, and 2a_{1g} where the latter is the antibonding HOMO (Highest Occupied Molecular Orbital). The nonbonding e_g orbital is completely localized at the ligand atoms while the bonding contribution of the 1a_{1g} MO is compensated by the antibonding contribution of the 2a_{1g} MO. Thus, the MO correlation diagram suggests that the xenon−fluorine bonding in XeF_6 should mainly come from the t_{1u} (σ) orbital interactions. However, the MO correlation diagram is only a qualitative model. The strength of the orbital interactions can be quantitatively estimated through the EDA.

Table 9 shows that the latter prediction is supported by the EDA results as far as the contributions of the orbitals with different symmetry to the ΔE_{orb} term is concerned.[50] 90.4% of the latter come from the t_{1u} orbitals. The d orbitals of Xe do not play a role for the Xe–F bonds. The contributions of the e_g and t_{2g} orbital interactions are negligible. However, the EDA results show also that the attractive orbital interactions are compensated by the repulsive Pauli term. Xenon hexafluoride is stable because there is strong quasi-classical Coulomb attraction between Xe and F_6. The sum of the quantum theoretical expressions (ΔE_{orb} and ΔE_{Pauli}) is destabilizing.

The same valence orbital interaction diagram as for XeF_6 may also be used for a qualitative discussion of the sulfur−fluorine bonding in SF_6. The difference between the two molecules is that the antibonding HOMO of the former molecule is empty in SF_6. It may therefore be expected that the ΔE_{orb} term in SF_6 is more stabilizing than in XeF_6, and that the stabilizing contribution of the a_{1g} MOs should become larger in the former molecule than in the latter. Table 9 shows that this is indeed the case. The orbital interactions in SF_6 contribute 78.7% of the total attraction while in XeF_6 the ΔE_{Orb} term contributes only 69.3%. The strength of the a_{1g} orbital interactions in SF_6 is $-197.2\,kcal\,mol^{-1}$ while in XeF_6 it is only $-7.8\,kcal\,mol^{-1}$. The general picture of the bonding situation in SF_6 and XeF_6, which comes from the EDA results, is very similar though. The most important orbital interactions in both molecules come from the t_{1u} orbitals. The sum of ΔE_{Orb} and ΔE_{Pauli} in SF_6 is also repulsive. Without the significant stabilizing contribution of the classical Coloumb attraction ($-820.2\,kcal\,mol^{-1}$), sulfur hexafluoride would not be stable.

The distortion of some EX_6 molecules, which have 14 valence electrons from octahedral symmetry to C_{3v} or C_{2v},

has been explained using MO models with the small energy gap between the $2a_{1g}$ HOMO and the $2t_{1u}$ LUMO (Figure 3), which makes the system prone to second-order Jahn–Teller distortion.[23] Like the VSEPR explanation in terms of stereochemically active lone pairs this is not a satisfactory explanation because there is no a priori information if a given HOMO–LUMO gap is small enough to yield a distortion from O_h symmetry. The MO model predicts correctly (as does the VSEPR model) that a 14-electron system like SF_6 has octahedral symmetry because the HOMO–LUMO gap between the $1e_g$ HOMO and the $2t_{1u}$ LUMO is much larger (Figure 3).

4 MOLECULAR ORBITAL MODELS

The last example XeF_6 in the section about the energy decomposition analysis introduced already the MO correlation model, which is a very powerful and widely used method for the explanation of the structure and reactivity of molecules. The MO models are based on the assumption that the geometry of a molecule and its reactivity are mainly determined by the molecular orbitals of appropriately chosen interacting fragments. In particular, the HOMO and LUMO (Lowest Unoccupied Molecular Orbital), which are called frontier orbitals, play an important and dominating role in the MO models. The frontier orbital theory has been developed by Fukui with the goal to explain the stereoselectivity of chemical reactions.[24] MO models can be used not only for explaining and predicting molecular properties in the electronic ground state, they are also useful for molecules in electronically excited states.

Walsh suggested already in 1953 that the energetic behavior of the HOMO on distortion determines the molecular geometry.[25] The generalizations concerning the shapes of molecules as a function of the number and arrangement of valence electrons are known as Walsh's rules. They are derived from MO diagrams (Walsh diagrams) where the orbitals in a reference geometry are correlated in energy with the orbitals in another geometry.[26] A related qualitative approach uses the orbitals of molecular fragments for the construction of the MOs of the whole molecule.[23] An example is shown in Figure 3 where the σ valence MOs of XeF_6 are built from the valence orbitals of Xe and F_6. The scope and limitations of the MO model shall be discussed in this section.

An important aspect of the MO model is the choice of the molecular orbitals that are used for discussing the properties of molecules. Early work considered either qualitative sketches of MOs or molecular orbitals, which came from EHT calculations. Later work used Hartree-Fock (HF) orbitals for the MO models. The latter have the disadvantage that the correlation energy is not considered although correlation effects can be very important for the structure and reactivity of molecules. The advent of DFT calculations introduced also the use of Kohn-Sham (KS) orbitals for MO models.[9] The advantage of KS orbitals is that correlation effects are intrinsically included in the orbital energy. In general, HF and KS orbitals have a similar shape and the energy ordering of the orbitals is in most cases the same, but the absolute values of the energy levels are quite different.

MO models may be used for molecules that have covalent bonds. Ionic bonds having little orbital overlap between the bonded atoms are less influenced by the stereochemical guidance of the valence orbitals. The geometry of ionic compounds is mainly determined by the electronic repulsion between the nonbonded atoms. A bonding model that considers the latter interaction as the dominant factor for determining molecular geometries is the VSEPR approach, which is discussed further below.

4.1 Walsh Diagrams for EH_2 and EX_2

Figure 4 shows the Walsh diagram for the energy changes of the valence orbitals on bending linear EH_2 (E = main-group element). The Walsh rules predict that molecules with 2 valence electrons such as LiH_2^+ have a bent geometry in the electronic ground state. Molecules with 3 and 4 valence electrons where the $1\sigma_u$ MO is singly or doubly occupied should be linear. Table 10 gives examples that support the Walsh rules. EH_2 molecules, which have 5 or 6 valence electrons, should be bent. The same holds true for systems with 7 or 8 electrons because the energy level of the $1b_1$ MO does not change when the molecule is bent, which means that the $2a_1$ MO determines the bond angle. Table 10 shows that the shapes of the EH_2 molecules are in agreement with predictions made by using the Walsh rules.

A strength of the Walsh diagrams is that predictions can also be made for geometries of molecules in electronically excited

[a]Reference 26.

states. An example is BH_2. The electronic configuration in the ground state is $(1a_1)^2(1b_2)^2(2a_1)^1$ yielding a bent geometry because the singly occupied $(2a_1)^1$ orbital becomes strongly stabilized upon bending (Figure 4). If the unpaired electron is excited to the stereochemically inactive $1b_1$ orbital, BH_2 in the $(1a_1)^2(1b_2)^2(1b_1)^1$ configuration becomes linear because the lower-lying $1b_2$ orbital becomes stabilized. Another example is the ground and first excited state of NH_2, which have the electron configurations $(1a_1)^2(1b_2)^2(2a_1)^2(1b_1)^1$ and $(1a_1)^2(1b_2)^2(2a_1)^1(1b_1)^2$. With only one electron in the $2a_1$ orbital, the molecule is less bent than in the ground state. The behavior of the energy levels of the MOs shown in Figure 4 upon bending makes it possible to predict qualitatively the geometry of EH_2 in any electronically excited state.

The Walsh diagram for the valence orbitals of EX_2 where E and X are main-group elements becomes a bit more complicated than for EH_2 (Figure 5). The predictions about the geometry of EX_2, which are made by looking at the energy change of the HOMO upon bending, are still in remarkably good agreement with experimental observations, but there are some exceptions (Table 11). The equilibrium geometries of the 12 electron compounds SiC_2 and CSi_2 and the 21 electron molecule ClF_2 are bent but the Walsh diagrams predict a linear structure.[27] It becomes obvious that the stereochemical influence of the orbitals that are energetically lower lying than the HOMO may not always be neglected. It is important to recognize that the molecular properties are determined by the interactions of all electrons and nuclei of the compound.

An interesting class of compounds EX_2 that shows the limitations of the MO model but also the pitfalls of the VSEPR approach described below are the alkaline earth dihalides where E = Be – Ba and X = F–I. The Walsh rules predict that the 16 electron systems should have a linear geometry (Figure 5). The E–X bonds are highly polar because of the large differences between the electronegativities of E and X and thus, an ionic description of the bonding situation (X^-)-(A^{2+})-(X^-) might be more appropriate. The geometry may therefore be determined by the repulsion between the X^- anions, which, however, would also lead to the prediction that the alkaline earth dihalides should be linear. But high-level ab initio calculations show that some EX_2 molecules have a bent equilibrium geometry! Table 12 shows that bending occurs for the heavier earth alkaline species SrF_2, BaF_2, $BaCl_2$, and $BaBr_2$. The molecules CaX_2, SrX_2 (X = Cl–I) and BaI_2 are called quasilinear because the computed energy changes for angle deviation of 20° is $<1\,kcal\,mol^{-1}$.[28]

The electronic structures of a series of monomeric alkaline earth EX_2 compounds have been analyzed in order to explain the bent equilibrium geometry of some species. Several factors that have an influence on the bending angle could be identified. One factor is the core polarization of the positively charged metal cation by the negatively charged X^- atoms (Figure 6(a)), which allows stabilizing charge-dipole and dipole–dipole interactions in bent structures. Another factor that favors a

[a]Reference 26. [b]Molecule is not linear.

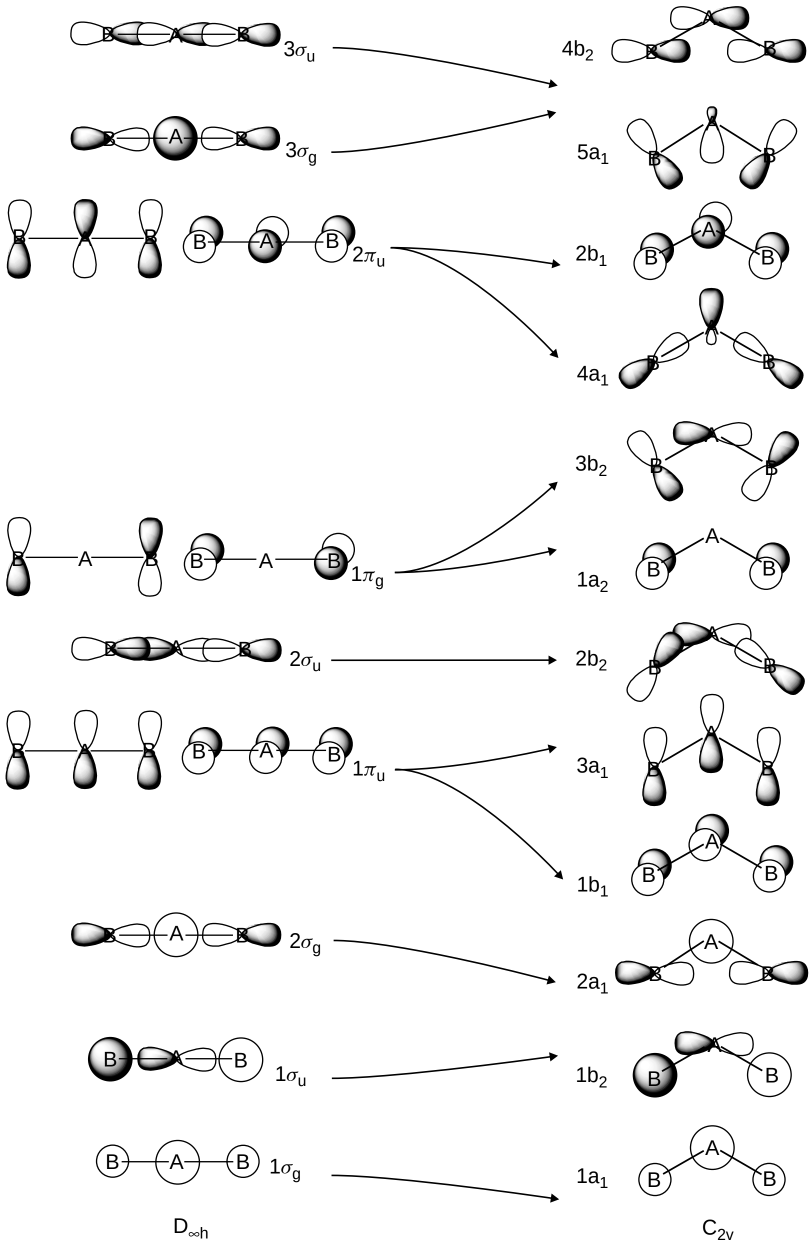

Figure 5 Qualitative MO correlation diagram for linear and bent AB_2 molecules. (Ref. 26. Reproduced by permission of Elsevier)

bent geometry is the participation of the outermost $(n-1)$d orbitals in the HOMO of the EX_2 molecules (Figure 6(b)). Note that this d orbital participation is different from the spd-hybridization model for hypervalent compounds. The d orbital participation shown in Figure 6(b) is small but relevant for the bending of EX_2. Theoretical studies showed that both core polarization and d orbital participation act simultaneously to favor bent structures in these systems. However, the two factors cannot be strictly separated from each other.[28]

A third factor that has a significant influence on the geometry of EX_2 molecule is the π interaction between the lone-pair orbitals of X and the empty orbitals of E. The NBO analysis showed that the empty nd(π) AOs of the heavy atoms Sr and Ba are important for the degenerate π bonding in linear EX_2 (Figure 6(c)).[26] Upon bending, the degenerate π bonding splits into in-plane and out-of-plane components of the E–X_2 interactions, which are further enhanced by π interactions using the nd AOs of E, which are not possible in the linear structure because of its higher symmetry. The bottom line of the analysis of the nontrivial orbital interactions in bent EX_2 is that, π bonding favors a linear structure but the π interactions are important for the actual geometry. This becomes obvious when the optimized geometries of $Ba(NH_2)_2$ with planar and perpendicular amino groups are compared with

(b) Participation of the outermost $(n-1)$d orbitals of E in σ bonding. (c) Degenerate π bond in linear EX_2, which become the in-plane π_{ip} (b_2) and out-of-plane π_{op} (a_2) components in bent (C_{2v}) EX_2. (d) Calculated structures of the planar and perpendicular forms of $Ba(NH_2)_2$. (Ref. 28c. Reproduced by permission of Wiley-VCH)

each other (Figure 6(d)). The strongly bent planar structure **1** is the global energy minimum. It is 3.8 kcal mol^{-1} lower in energy than structure **2**, which has longer Ba–N bonds and a less acute bending angle than **1**. The difference can be explained with the influence of the out-of-plane π (a_2) and in-plane π (b_2) interaction on the electronic structure of $Ba(NH_2)_2$. The b_2 component is more angle dependent than the a_2 component because the π overlap of the former decreases more when the bending angle becomes more acute. A fourth factor that needs to be considered at small bending angles of EX_2 molecules is the Pauli repulsion between the atoms or groups X.

4.2 MO models for E_2H_4 and E_2X_4

Ethylene and acetylene are model compounds for the description of double and triple bonds in terms of σ and π bonding. The MO correlation diagram for the carbon–carbon bonding in C_2H_4 uses the CH_2 fragments in the $^3B_1$ triplet ground state for the construction of the molecular orbitals (Figure 7, E = C). The HOMO of ethylene is the well-known out-of-plane π orbital, which explains why the molecule has a D_{2h} equilibrium geometry. Rotation about the C–C axis would break the π bond, which, according to the EDA results (Table 7), contributes 79.2 kcal mol^{-1} of the total orbital

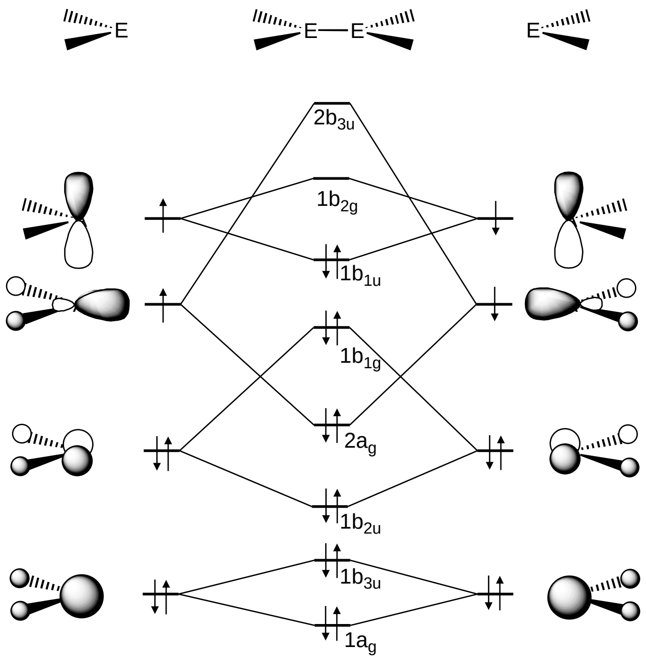

Figure 7 Qualitative MO correlation diagram for the orbital interactions between two EH_2 molecules with 6 valence electrons in the $^3B_1$ state yielding closed-shell E_2H_4

interactions. The latter value must not be confused with the rotational barrier of ethylene. The value of 79.2 kcal mol^{-1} for the out-of-plane π orbital interactions is calculated in the framework of the electronic structure of ethylene in D_{2h} symmetry. Rotating ethylene about the C–C bond changes the electronic structure significantly.

If the out-of-plane π orbital in E_2H_4 is empty like in B_2H_4 and in $C_2H_4^{2+}$, the molecule adopts a D_{2d} equilibrium geometry where the EH_2 fragments are rotated by 90°. Figure 8 shows the Walsh diagram for the $D_{2h} \rightarrow D_{2d}$ interconversion of E_2H_4. The rotation affects mainly the in-plane and out-of-plane π orbitals while the σ orbitals change little. It becomes obvious that molecules with 12 valence electrons should prefer a planar (D_{2h}) structure while species with 10 valence electrons should prefer a perpendicular (D_{2d}) geometry because of the energetically high-lying 2e HOMO (Figure 8). This is in agreement with quantum chemical calculations, which show that the D_{2d} structure of B_2H_4 is 17.7 kcal mol^{-1} lower in energy than the D_{2h} form.[29] The perpendicular structure of $C_2H_4^{2+}$ is even 31.0 kcal mol^{-1} more stable than the planar form.[30]

The MO models are also very helpful for explaining the effect of substituting hydrogen by halogen atoms yielding

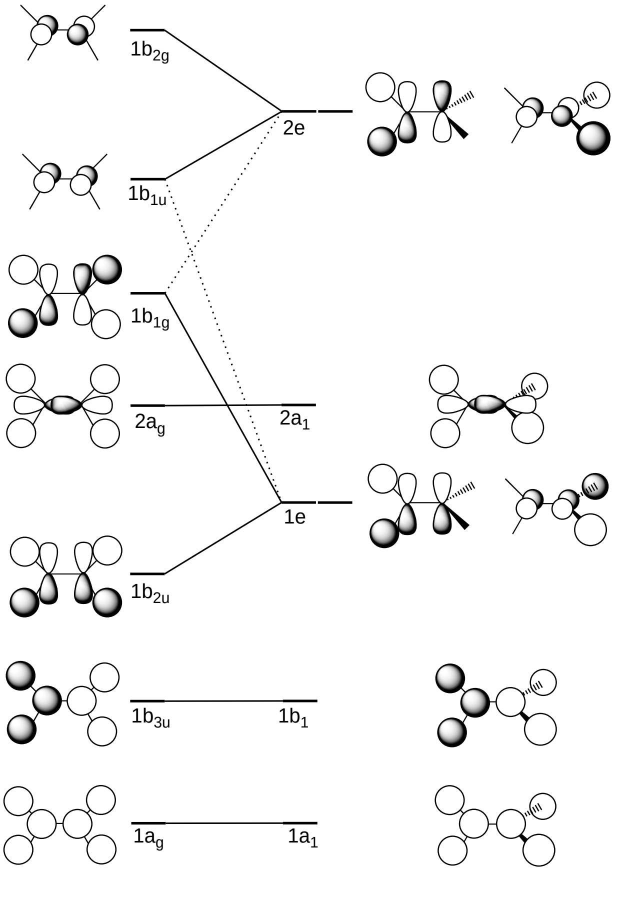

Figure 8 Qualitative MO correlation diagram for planar and staggered E_2H_4

C_2X_4 species. Dihalocarbenes have a $^1A_1$ singlet ground state. It is not possible to build E_2X_4 with a planar geometry in the electronic ground state using EX_2 fragments in the ($^1A_1$) singlet state where the HOMO is the $2a_1$ lone-pair MO (Figure 7). The latter species must be excited to the $^3B_1$ state, which is the first excited state of CX_2. The excitation energy for the process ($^1A_1$) $\rightarrow$ ($^3B_1$) of the two CX_2 species (Table 13) is the price that has to be paid for the formation of the $X_2C{=}CX_2$ double bond. This explains why the bond dissociation energies of C_2X_4 are significantly smaller than the BDE of C_2H_4 (Table 14). The very low BDE of C_2F_4 (74.1 kcal mol^{-1}), which is less than one half of the value of C_2H_4 (178.9 kcal mol^{-1}) is caused by the big excitation energy of CF_2 (52.4 kcal mol$^{-1)}$.[31]

The orbital interaction diagram shown in Figure 7 for C_2H_4 may not be used for the heavier analogs E_2H_4 (E = Si–Pb) because the latter species adopt a trans-bent (C_{2h}) geometry.[32] The bending angle increases from E = Si (20.4°) to E = Pb (37.6°) (Table 15). Trans-bent structures with rather larger bending angles are also calculated as equilibrium geometries for the halogen substituted heavier homologs E_2X_4. The preference for a trans-bent geometry rather than a planar form can be straightforwardly explained with the MO model given above. The heavier diylenes EX_2 (X = H, F–I) have singlet ground states. Table 13 shows that the ($^1A_1$) $\rightarrow$ ($^3B_1$) excitation energies are quite large, particularly for the dihalogen species where the calculated values are between 39.1 and 91.5 kcal mol^{-1}. This means that it may not be energetically favorable for two EX_2 molecules to bind through the excited $^3B_1$ state yielding a σ and a π bond in planar E_2X_4 but rather engage in two donor–acceptor type bonds between EX_2 in the $^1A_1$ state. This is shown in Figure 9. Table 14 shows that the planar tetrahalogen substituted molecules E_2X_4 with E = Si, Ge, and Sn are energetically higher lying than, or in case of Si_2I_4, are nearly degenerate with two EX_2 species. Calculation of the vibrational frequencies shows that the planar species are no minima on the PES. If the symmetry is relaxed toward C_{2h}, the molecules adopt trans-bent structures, which are slightly lower in energy than the sum of the EX_2 fragments. In the case of Sn_2X_4 (X = F, Cl, Br), the molecule rearranges towards a halogen-bridged geometry. Neither a planar nor a trans-bent structure of the tetrahalogen lead molecules Pb_2X_4 could be

^{a}Relativistic effective small-core core potentials with triple-zeta valence orbitals augmented by two sets of polarization functions were used for Sn and Pb. ^{b}Calculated with respect to the ($^1A_1$) singlet ground state of EX_2 except for CH_2, which has a ($^3B_1$) triplet ground state. ^{c}The trans-bent form (C_{2v}) is not a minimum on the PES (Potential Energy Surface). The structure rearranges during geometry optimization toward a halogen-bridged geometry. ^{d}The planar structure dissociates during geometry optimization into 2 EX_2 fragments.

located as stationary point on the PES. Halogens prevent the formation of planar E_2X_4 (E = Si–Pb) molecules because they yield very large ($^1A_1$) → ($^3B_1$) excitation energies in EX_2 and they weaken the donor–acceptor bonds between two EX_2 species in the singlet ground state because the electronegative halogens render the diyls to become poor donors. Halogen-bridged structures are the global minima on the PES of all tetrahalogen compounds E_2X_4.

The MO model given in Figure 9 explains nicely why the bending angle of E_2X_4 becomes in most cases larger for heavier atoms E. There is a correlation between the ($^1A_1$) → ($^3B_1$) excitation energy and the calculated bending angle. Note that, according to the MO model, there are two E–E bonds in the trans-bent structures. Unlike the classical σ/π bonds such as in ethylene, the two bonds in the former species are donor–acceptor bonds.

The MO model also explains the effect of halogen atoms on the structure of $C_2X_4{}^{2+}$ and B_2X_4. The halogen atoms have p(π) lone-pair orbitals, which can donate electronic charge into the empty p(π) AO of C^+ and B (Figure 10), which means that the out-of-plane p(π) orbital of the planar form becomes partially occupied. The partial occupation in $C_2F_4{}^{2+}$ is large enough that the D_{2h} form becomes now 3 kcal mol^{-1} lower in energy than the D_{2d} form.[30] The energetic effect of fluorine in B_2F_4 is less dramatic but still significant. The D_{2d} form of B_2F_4 is still lower in energy than the D_{2h} form but the latter is only <1 kcal mol^{-1} less stable than the former.

The strength of the π bonding interactions in planar and perpendicular B_2X_4 can be estimated using the EDA method.

[a]The value in parentheses gives the percentage contribution to the total attractive interactions. [b]The value in parentheses gives the percentage contribution to the total orbital interactions. [c]Energy difference between the planar and perpendicular form.

Table 16 gives the calculated data, which may be compared with the orbital correlation diagram shown in Figure 8. Note that the orbital contributions can only be given for MOs having different symmetry within C_{2v} constraint because the interacting BX_2 fragments have C_{2v} symmetry. The calculated data indicate that the strength of the out-of-plane π interactions increases from X = F (1.9 kcal mol^{-1}) to X = I (8.0 kcal mol^{-1}), that is, the π-donor strength increases with F < Cl < Br < I. The strength of the total π interactions in planar B_2X_4 increases in the order H < F < Cl < Br < I. The order changes in the perpendicular structures where the π bond strength (which is also called hyperconjugation) in the parent compound B_2H_4 becomes rather large (16.0 kcal mol^{-1}). Only B_2I_4 has a stronger hyperconjugation (18.0 kcal mol^{-1}). Note that the rotational barrier cannot be used to estimate the strength of hyperconjugation in B_2X_4 because the planar form of the halodiborenes(4) are significantly stabilized by π interactions.

4.3 MO Model for E_2H_2 (E = C–Pb)

Heavy-atom homologs of acetylene show very peculiar structures, which are at first sight difficult to explain with orthodox bonding models (Figure 11). The linear structure E, which is the global energy minimum on the C_2H_2 potential energy surface, is not even an energy minimum but a second-order saddle point for the heavier species E_2H_2 (E = Si–Pb). The most stable form of the latter species is the doubly-bridged butterfly structure **A**. The energetically next low-lying isomer

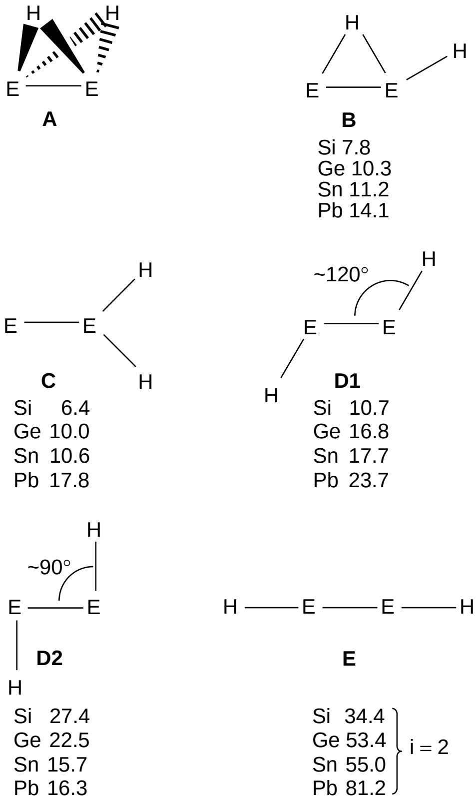

Figure 11 Stationary points and relative energies [kcal mol^{-1}] of E_2H_2 (E = Si, Ge, Sn, Pb) isomers calculated at CCSD(T)/TZ2P//B3LYP/6−31G(d)

is the singly bridged planar structure **B**. Both structures **A** and **B** are not known for C_2H_2. Isomer **C** is energetically nearly degenerate with structure **B** (Figure 11). The former structure resembles vinylidene CCH_2, which is a shallow minimum on the C_2H_2 potential energy surface being ~55 kcal mol^{-1} higher in energy than acetylene.

There are two trans-bent forms of E_2H_2 **D1** and **D2**, which are the only species for which substituted analogs E_2R_2 could be characterized by X-ray structure analysis. The difference between the electronic structures of the two trans-bent forms is that **D1** has an occupied π orbital, which is the out-of-plane component of the degenerate π orbital of planar HE≡EH. The out-of-plane p(π) AOs of E in **D2** are empty while each atom E has an occupied in-plane lone-pair orbital. The latter electronic structure corresponds to an excited state of linear HEEH where one component of the degenerate π orbital is empty, while for the other component both π and π^* orbitals are occupied, that is, the molecule has only a E–E single bond. E_2R_2 compounds with very bulky substituents having structure **D1** have been characterized with X-ray structure analysis for E = Ge, Sn while the isolated compound Pb_2R_2 has the structure **D2**.[33] The parent compounds E_2H_2 have been synthesized in low-temperature matrices. The comparison of the experimental vibrational spectra with high-level quantum chemical calculations shows clearly that structure **A** is the most stable form followed by **B**, which is in agreement with predictions that had previously been made using quantum chemical calculations.[34]

The puzzling results of theoretical and experimental research about the unusual structures of E_2H_2 can be explained using the MO model, which was introduced in the previous section.[49] The starting point of the MO approach is the electronic configuration of the interacting species EH, which are considered as the building block for the E_2H_2 isomers **A**, **B**, **D**, and **E**, while **C** would better be discussed in terms of interactions between E and EH_2. Figure 12 shows qualitatively the electronic structure of EH in the $^2\Pi$ ground state and in the $^4\Sigma^-$ first excited state.

It becomes obvious that the $^2\Pi$ ground state of EH is not the electronic reference state for the acetylene-type structure **E**, which has a triple bond HE≡EH. The latter form can only be built from the interactions between two EH molecules in the $^4\Sigma^-$ first excited state. Figure 12 shows also the experimental and calculated ($^2\Pi$) → ($^4\Sigma^-$) excitation energies. The excitation energies of the heavier diatomics are significantly larger than for CH. Table 17 compares the calculated bond dissociation energies of the linear species HE≡EH (**E**) with the energies that are necessary to promote two fragments EH from $^2\Pi$ to $^4\Sigma^-$. The calculated data show that the promotion energy for two CH molecules (40.8 kcal mol^{-1}) is much smaller than the BDE of HC≡CH (D_e = 271.3 kcal mol^{-1}).

The situation for the heavier homologs EH is quite different from the carbon system. The excitation energy of two SiH molecules (85.6 kcal mol^{-1}) is not much less than the BDE of the hypothetical HSi≡SiH species (121.0 kcal mol^{-1}). The difference is only 35.4 kcal mol^{-1}. If the binding interactions between two SiH fragments in the $^2\Pi$ ground state exceed this value it is energetically not favorable that the binding occurs through the $^4\Sigma^-$ excited state. The $^2\Pi$ ground state has one singly occupied orbital (Figure 12). Coupling the unpaired electrons yields a Si–Si single bond, which is typically stronger than 35.4 kcal mol^{-1}. Thus, two SiH molecules will prefer to bind through its $^2\Pi$ ground state, which does not yield an acetylene-type structure **E**. The situation is even more simple for the heavier species where E = Ge – Pb. Table 17 shows that the BDE of the linear form **E** is less than the ($^2\Pi$) → ($^4\Sigma^-$) excitation energy of the EH fragments. This means that two separated fragments EH are lower in energy than HE≡EH. The conclusion is that it is energetically favorable for the heavy-atom homologs E_2H_2 with E = Si–Pb to bind through interactions between EH in the $^2\Pi$ ground state.

The structures **A**, **B**, **D1**, and **D2** can be easily constructed using the electronic configuration of the $^2\Pi$ ground state in conjunction with simple MO models. Figure 13 shows three possible arrangements of two EH fragments where the unpaired electrons yield a E–E σ bond. Figure 13(a) shows the least favorable combination because the E–H bonds and the lone-pair electrons are in an eclipsing conformation. Rotation

[a]Relativistic effective small-core core potentials with triple-zeta valence orbitals augmented by two sets of polarization functions were used for Sn and Pb.

about the E–E bond by 90° (Figure 13(b)) leads to a much more favorable conformation because the E–H bonds are facing the empty p(π) AO of the other EH fragments yielding two donor–acceptor bonds (hyperconjugation) in addition to the σ bond. The E–H bonds tilt toward the empty orbitals of the other fragment and vice versa, which leads to the doubly-bridged butterfly structure **A**. The MO model explains nicely why the bridging hydrogens are not trans to each other. Figure 13(c) shows that a conformation where the E–H bonds are in a trans position does not allow any other attractive interactions between the EH fragments. However, such a conformation may become favorable when hydrogen is substituted by a very bulky group R. Figure 13(c) shows that the electronic configuration that comes from the shown interactions gives structure **D2**, which was reported for the molecule RPbPbR where R is a substituted mesityl group.[33a] Note that atom E in **D1** has only an electron sextet in the valence shell.

The unpaired electron in the $^2\Pi$ ground state of EH may also be used to form a π bond between two EH molecules. Figure 14 shows that again three different conformations may be envisaged. The conformation shown in Figure 14(a) leads directly to the singly bridged structure **B**. Besides the π bond

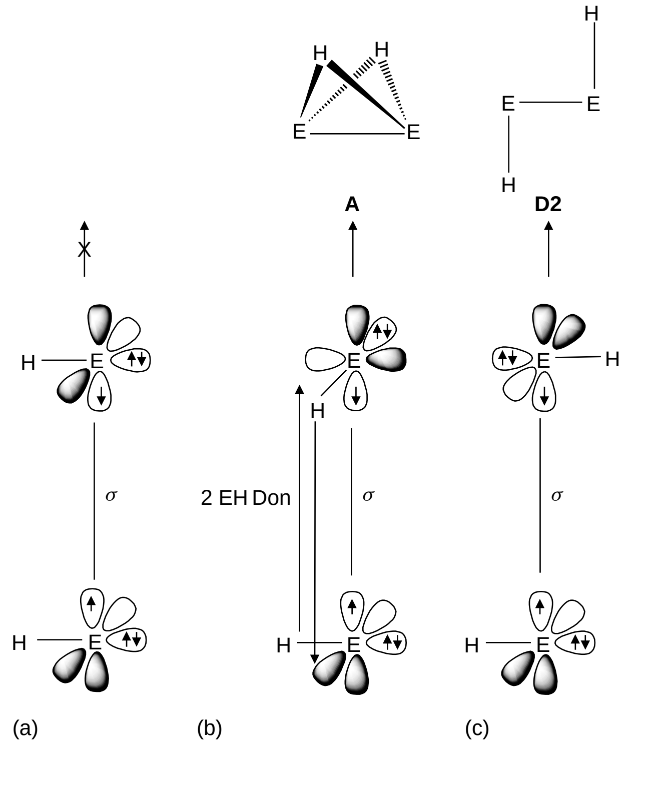

Figure 13 Qualitative orbital model for the bonding between two EH fragments (E = C–Pb) in the $^2\Pi$ ground state via σ coupling of the unpaired electrons showing three different conformations, which lead to different isomeric forms of E_2H_2. (a) Syn-conformation of the E–H bonds which does not yield an energy minimum structure. (b) Perpendicular orientation of the E–H bonds yielding structure **A** with two additional E–H donor–acceptor bonds. (c) Anticonformation of the E–H bonds yielding structure **D2**

there is a donor–acceptor bond between the lone-electron pair of one fragment and the empty orbital of the other. A third bonding component comes from donor–acceptor interaction (hyperconjugation) between a E–H bond from the fragment that serves as acceptor for the lone-electron pair and the empty orbital of the other EH fragment. The donor and acceptor orbitals of the latter interactions are tilted to each other in order to maximize the attractive interactions. The tilting of the empty orbital leads to a bending of the terminal E–H bond towards the bridging E–H bond. Thus, the MO model shown in Figure 14(a) explains nicely why the bridging and the terminal hydrogen atoms of **B** are on the same side of the E–E axis and why the molecule is planar. Note that the MO model suggests that there are three binding components in **B**: One π bond, one lone-pair donor–acceptor bond, and one E–H donor–acceptor bond (hyperconjugation).

The conformation shown in Figure 14(b) is unfavorable because there are no further binding interactions besides the π bond. The bonding interactions are enhanced by two donor–acceptor bonds between the lone-pair electrons and the empty orbitals of EH in addition to the π bond by tilting of the E–H bonds. The lone-pair orbitals are tilted towards the empty acceptor orbitals of the other EH fragment. The E–H bonds follow the tilting in the other directions towards a planar antiarrangement. This leads straightforwardly to structure **D1**. Note that the latter structure has also three bonding components: One π bond and two donor–acceptor bonds. The question if the trans-bent structure **D1** has a triple bond or not can be answered by referring to three bonding components that, however, are not the same and not as strong as one σ bond and a degenerate π bond.

5 THE VALENCE SHELL ELECTRON-PAIR REPULSION MODEL AND THE LIGAND CLOSE-PACKING MODEL

The VSEPR model for predicting the geometries of molecules is a simple and popular approach that has been developed by Sidgwick, Powell, Nyholm, and Gillespie.[3] The starting point of the VSEPR model is the assumption that the electron pairs in the valence shell of an atom E in a molecule EX_n adopt arrangements that keep them as far apart as possible. This approach is very different from the valence bond model, which suggests that the geometry of a covalently bonded molecule is determined by the angles between the sp^n hybridized bond orbitals (180° for sp, 120° for sp^2, 109.8° for sp^3). According to the VSEPR model, the driving force for the geometry of EX_n does not come from the attractive interactions between E and X but rather from the Pauli repulsion between the electron pairs of the E–X bonds. A nonbonding electron pair is treated like a E–X bonding pair but the former occupies

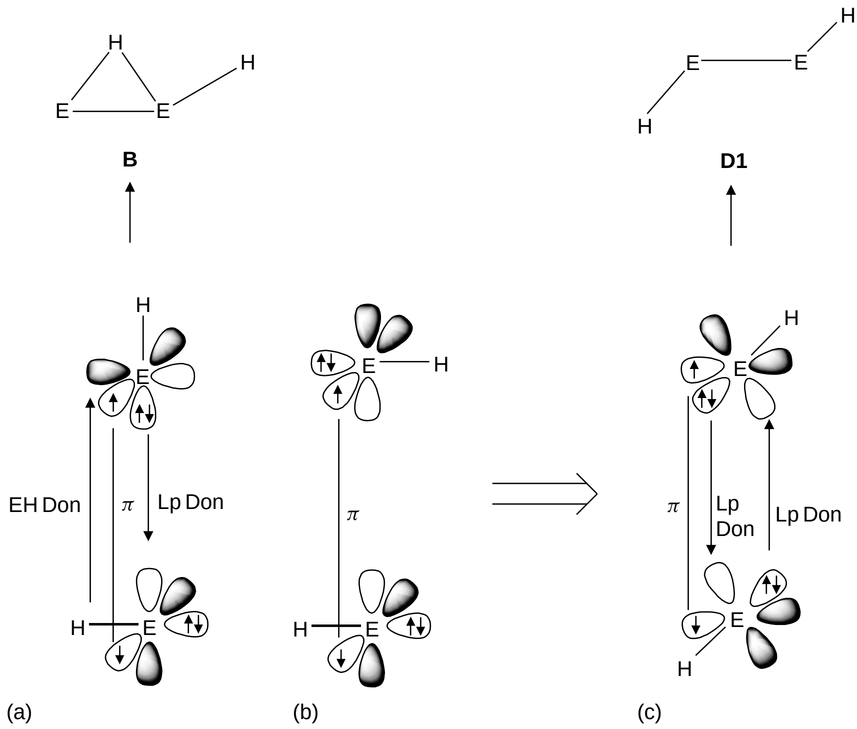

Figure 14 Qualitative orbital model for the bonding between two EH fragments (E = C–Pb) in the $^2\Pi$ ground state via π coupling of the unpaired electrons showing three arrangements, which lead to different isomeric forms of E_2H_2. (a) Top-to-side arrangement yielding structure **B** with additionally one lone-pair and one E–H donor–acceptor bond. (b) Antiarrangement of the E–H bonds which does not yield an energy minimum structure. Tilting of the E–H bonds gives the arrangement (c) with two lone-pair donor–acceptor bonds yielding structure **D1**

more space than the latter. Furthermore, the two-electron pairs of a double bond or the three electron pairs of a triple bond occupy more space than the electron pair of a single bond.

Figure 15 shows the molecular shapes that are predicted for molecules with up to six ligands in EX_nLp_m (Lp = electron lone pair). For each principal shape, there is one example shown in Figure 15. The VSEPR model explains nicely why compounds like SF_4 have a sawhorse geometry. The molecule has the formal structure SF_4Lp where the electron lone-pair occupies an equatorial position because it is considered being larger than the S–F bonding pair. The T-shaped structure of ClF_3, the square pyramidal geometry of IF_5 and the planar structure of XeF_4 are also in agreement with the predictions made by the VSEPR model. Problematic cases are molecules like XeF_6. There are six Xe–F bonding pairs and one-electron lone pair at Xe, which gives seven ligands. The VSEPR model would predict that the equilibrium geometry of XeF_6 should be distorted from O_h symmetry, which is correct. XeF_6 has a trigonally distorted octahedral structure.[22] However, there are various ions valence-isoelectronic with XeF_6 like ClF_6^-, BrF_6^-, and $BiCl_6^-$, which have a regular octahedral structure. This means that the electron lone pair is stereochemically active in some EX_6Lp molecules while it is inactive in others. The a posteriori rationalization of the distorted structures in terms of a stereochemically active electron pair as it is suggested by the VSEPR model has more a character of a tautology than a true explanation because the model does not say in the beginning if an electron lone pair is active or not. The conformation of N_2H_4 is another molecule where the VSEPR model fails, because the most stable form of hydrazine is not the anti but the gauche conformation where the lone-electron pairs are close to each other. It is obvious that the sole consideration of repulsive inter-ligand electron-pair interactions neglects other factors, which may be important for the geometry of a molecule.

The VSEPR model makes also predictions about the changes of the bond angles in molecules EX_n when E or X is substituted by other atoms or groups. It is predicted that bond angles decrease with increasing electronegativity of the ligand or decreasing electronegativity of the central atom E. Table 18 gives a list of bond angles in some trigonal pyramidal EX_3Lp molecules. The trend of the bond angles agrees in many cases with the VSEPR model but there are several exceptions. For example, the bond angle in NF_3 (102.2°) is smaller than in NH_3 (107.3°) but the bond angles in the phosphorus analogs PF_3 (97.8°) and PH_3 (93.8°) do not agree with the VSEPR approach. The prediction also fails for the series EMe_3 and ECl_3 (E = P, As, Sb) because the latter compounds have larger bond angles than the former. The VSEPR model is very useful for qualitatively predicting the geometry of

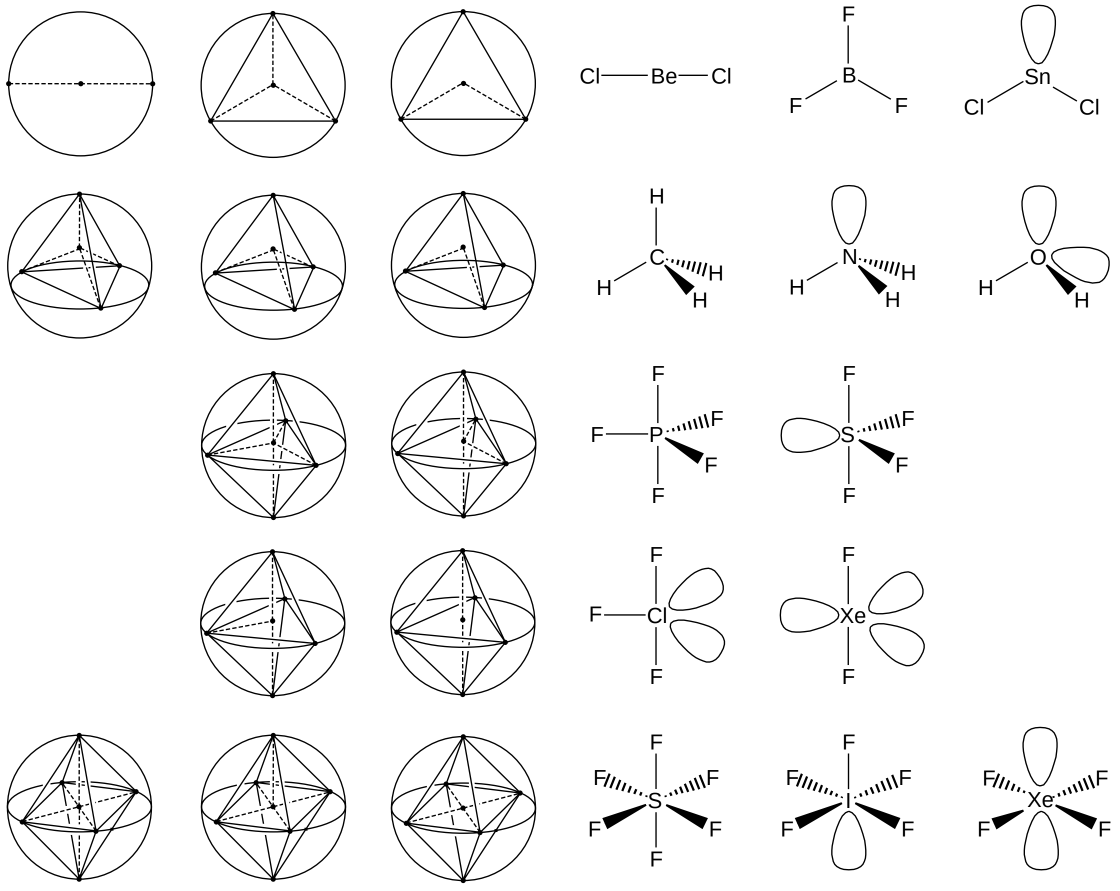

Figure 15 Molecular shapes based on the arrangement of 2–6 valence electron pairs

molecules that have a normal bonding situation. It is not useful for explaining molecular structures at a quantitative level because of its crude approximation.

A model that was introduced as an extension and a refinement of the VSEPR approach is the Ligand Close-packing (LCP) model.[35] The LCP model considers the ligand–ligand repulsion in molecules rather than bond pair-bond pair repulsion. The starting point of the LCP model was the observation that the inter-ligand distances of atoms X, which are bonded to a common central atom E, exhibit very nearly constant values X···X in related molecules EX_nL_m where L is another ligand group or atom. Examples for X = F are shown in Table 19.

Table 18 Bond angles (degrees) in some trigonal pyramidal AX_3Lp molecules[a]

[a]Reference 35.

The F···F distances of the beryllium, boron, and carbon compounds of fluorine are remarkably close to the mean values of 2.56, 2.26 and 2.16 Å, independent of the coordination number and the E–F bond length. The LCP model suggests that the fluorine atoms in the molecules EF_nL_m listed in Table 19 are squeezed together to their limit of compressibility. Each ligand is considered to be touching its neighbors, which makes it possible to assign the value of a nonbonded radius, which is called ligand radius. The value of the ligand radius of an atom depends on the nature of the atom to which it is bonded. Table 20 gives a list of ligand radii that have been suggested for the LCP model.[35]

The LCP model like the VSEPR approach thus suggests that the geometry of a molecule EX_n is primarily determined by the Pauli repulsion between nonbonded ligands X

[a]Reference 35.

rather than by the attractive interactions between E and X. Some predictions are made based on the LCP model. One prediction suggests that bond lengths in EX_n molecules increase with increasing coordination number n. For heavier elements E of periods 3–6 it is necessary to consider the coordination number for the assignment of the ligand radii in molecules EX_n, because higher-coordinated compounds have frequently shorter bond length E–X than lower-coordinated species. For example, the S–F distance in SF_6 (1.561 Å) is shorter than in SF_2 (1.589 Å). Another point that needs to be considered is the atomic charge of the central atom E. A large positive charge means that the radius of E shrinks. The LCP model has been used for a posteriori explanations of the geometries of main-group compounds.[35] It needs to be seen how the LCP model accounts for the structures like those of heavy-atom E_2H_2 homologs (see above).

6 TOPOLOGICAL ANALYSIS OF THE ELECTRON DENSITY DISTRIBUTION

The topological analysis of the electron density distribution has been developed by Bader into a powerful method that gives important information about the electronic structure of molecules.[36] The name of the method has lately changed to Atoms In Molecules (AIM) and more recently to Quantum Theory of Atoms in Molecules (QTAIM) emphasizing the fact that atomic domains in a molecule can be defined such that they agree with fundamental theorems of physics like the virial theorem and the Hellman-Feynman theorem. The strength and the very nature of the QTAIM is that many concepts and models that are important and interesting in chemistry are derived using only the electron density distribution $\rho(\mathbf{r})$ as starting point, which is an experimentally observable quantity. There is no direct reference to the wave function or to orbitals in the QTAIM. Much insight into the electronic structure is obtained from the first and second derivatives of $\rho(\mathbf{r})$ with respect to the spatial coordinates, that is, the gradient vector field $\nabla\rho(\mathbf{r})$ and the Laplacian distribution $\nabla^2\rho(\mathbf{r})$.

The most important aspects of the QTAIM that are relevant for questions of chemical bonding shall be discussed using the first neutral argon compound HArF as an example,[37] which was recently synthesized.[38]

Figure 16 shows contour line diagrams of the Laplacian distribution $\nabla^2\rho(\mathbf{r})$ of ArF, Har, and HArF at the equilibrium distance. Solid lines show areas of electron concentration where the values of $\nabla^2\rho(\mathbf{r}) < 0$ while dashed lines show areas of electron depletion where $\nabla^2\rho(\mathbf{r}) > 0$. Figure 16(a) shows that the electronic structures of the atoms Ar and F are nearly undisturbed by the presence of the other atom. This is reasonable because ArF is a weakly bonded van der Waals complex. The spherical shape of $\nabla^2\rho(\mathbf{r})$ of argon shows nicely the shell structure of the atom where regions of electron concentration and electron depletion are surrounding the nucleus. The shape of $\nabla^2\rho(\mathbf{r})$ of fluorine indicates that the density of the valence electron in the direction that is perpendicular to the Ar–F internuclear axis is higher than along the bonding line. This is because the 2p-shell of F, which has the electronic configuration $(p_x)^2(p_y)^2(p_z)^1$, is aligned in such a way that the doubly occupied orbitals $(p_x)^2(p_y)^2$ become the p(π) orbitals while the singly occupied $(p_z)^1$ AO is the p(σ) AO.

The solid line in Figure 16(a), which connects the atomic nuclei, is the bond path. The definition of the bond path comes from the topological analysis of $\rho(\mathbf{r})$. Between the atoms Ar and F there is a point in space called the bond critical point $\mathbf{r}_b$ where the first derivative $\nabla\rho(\mathbf{r}) = 0$ and the value of the second derivative along the internuclear axis is positive. It

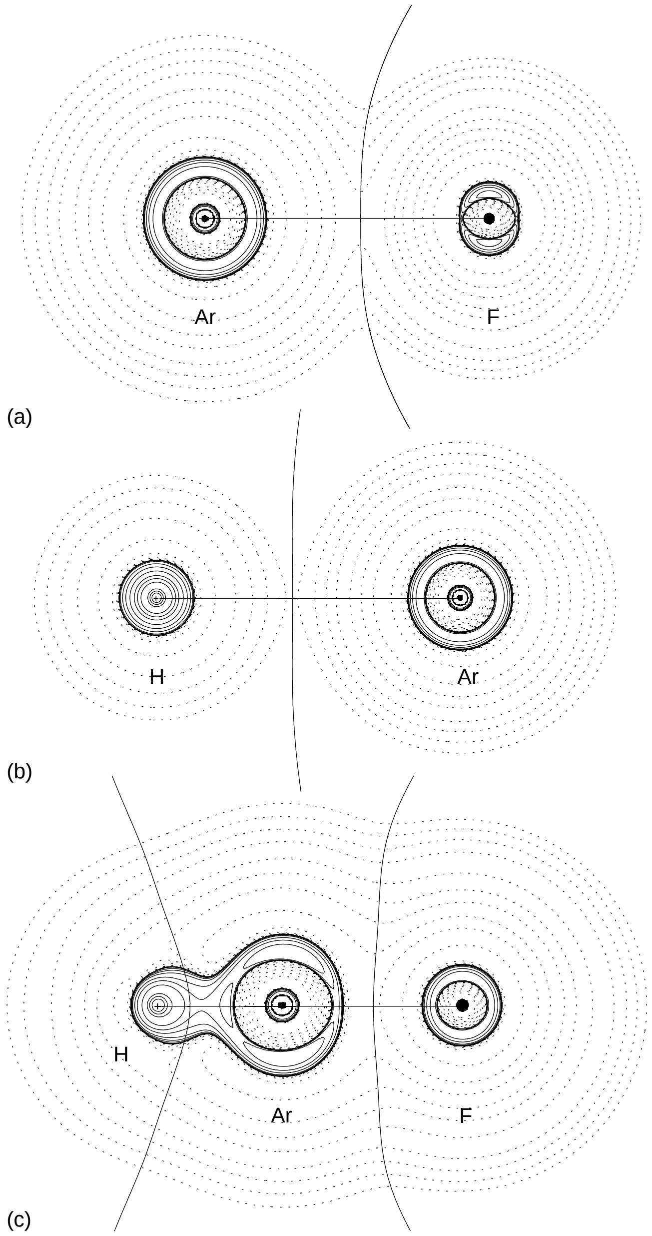

Figure 16 Contour line diagrams of the Laplacian distribution $\nabla^2\rho(\mathbf{r})$ of (a) ArF; (b) ArH; (c) HArF. Solid lines give areas of charge concentration ($\nabla^2\rho(\mathbf{r}) < 0$), while dashed lines give areas of charge depletion ($\nabla^2\rho(\mathbf{r}) > 0$). The solid line connecting the atomic nuclei is the bond path. The solid lines that cross the bond path at the bond critical point show the zero-flux surface crossing the shown plane. (Ref. 37. Reproduced by permission of Springer Verlag)

means that ρ is a minimum at $\mathbf{r}_b$, while the values of the other two second derivatives in the plane that is perpendicular to the internuclear axis are negative, that is, ρ is a maximum. Other critical points where $\nabla\rho(\mathbf{r}) = 0$ that are defined in a similar way are ring critical points (two positive and one negative eigenvalue), cage critical point (three positive eigenvalues), and atomic nuclei position (three negative eigenvalues). The bond path is defined as the line of maximum charge density linking the bond critical point $\mathbf{r}_b$ and the atomic nuclei. Thus, the QTAIM defines chemical bonds in molecules without ad hoc assumptions about the interatomic interactions. However, Figure 16(a) shows that the existence of a bond path does not mean that there is a true chemical bond, because ArF is only a weakly bonded van der Waals complex that is held together by dispersion forces but not by a genuine chemical bond. Additional criteria have to be fulfilled in order to distinguish a chemical bond from weak interatomic interactions. Various properties such as the electron density, the energy density and the value of the Laplacian at the bond critical point can be used for the characterization of a chemical bond.

There is another solid line that crosses the bond path at the bond critical point. This line shows where the zero-flux surface, which separates the atomic basins of Ar and F, is cutting the plane shown in Figure 16(a). Every atom in a molecule is bounded by a zero-flux surface, which is defined by the gradient vector field $\nabla\rho(\mathbf{r})$. The zero-flux surface is spanned by those trajectories $\nabla\rho(\mathbf{r})$ that vanish at the bond critical point $\mathbf{r}_b$. All other trajectories vanish at the atomic nuclei of either Ar or F. There is no gradient vector that crosses the zero-flux surface, which is the reason for its name. The advantage of the definition of an atomic basin using the zero-flux surfaces is that it comes directly from the topological analysis of the electron density distribution, which may be obtained from calculations or from experiment. The definition of an atom by the QTAIM is the physically most meaningful way to divide a molecule into atoms.

Figure 16(b) shows the contour line diagram for ArH, which is very similar to the diagram for ArF shown in Figure 16(a). Both molecules are weakly bonded van der Waals complexes. The strength of the QTAIM method for giving insight into the bonding situation in molecules becomes obvious when the shape of the Laplacian distribution of HArF (Figure 16(c)) is compared with Figures 16(a) and 16(b). The largest difference is found between the H–Ar bonds of HAr and HArF. There is a continuous area of charge concentration ($\nabla^2\rho(\mathbf{r}) < 0$, solid lines) between hydrogen and argon in the latter molecule, which indicates that the valence electron density of the two atoms is strongly distorted by the interatomic interactions. The bond critical point of the H–Ar bond is located in the region where $\nabla^2\rho(\mathbf{r}) < 0$. Table 21 shows that the values of the charge density $\rho(\mathbf{r}_b)$, the Laplacian $\nabla^2\rho(\mathbf{r}_b)$, and the energy density $H(\mathbf{r}_b)$ for the H–Ar bond in HArF are very different from the values in free ArH. In the former compound, the charge density at the bond critical point is much higher and the Laplacian even has an opposite sign than in the latter species. Also the energy density at the bond critical point $H(\mathbf{r}_b)$ for the H–ArF bond is more than three orders of magnitude larger than for Ar–H. The calculated values are typical for covalent bonds, which are called electron-sharing bonds in the QTAIM.[36] The values for the HAr–F and Ar–F bonds are less different because both arise from closed-shell interactions.

Table 21 Calculated electron density $\rho(r_b)$ [e/Bohr^3], Laplacian $\nabla^2\rho(r_b)$ [e/Bohr^5] and energy density $H(r_b)$ [Hartree/Bohr^3] at the bond critical points of the compounds ArH, ArF, and HArF

	Ar–H	Ar–F	H–ArF	HAr–F
$\rho(r_b)$	$2.768\cdot10^{-4}$	$1.614\cdot10^{-3}$	$2.053\cdot10^{-1}$	$8.520\cdot10^{-2}$
$\nabla^2\rho(r_b)$	$9.502\cdot10^{-4}$	$9.173\cdot10^{-3}$	$-5.539\cdot10^{-1}$	$3.608\cdot10^{-1}$
$H(r_b)$	$-7.242\cdot10^{-5}$	$-5.645\cdot10^{-4}$	$-1.769\cdot10^{-1}$	$-2.096\cdot10^{-3}$

The Laplacian distribution in the bonding region of the Ar–F bond of HArF appears not very different from ArF at first sight (Figures 16(b), (c)). Note, however, that the valence shell of the fluorine atom in HArF is spherically symmetric while it shows local areas of charge concentration in the π region in ArF. This is a visual hint that the p orbitals of fluorine are completely filled in HArF, which means that there is a F^- anion in the latter molecule while the fluorine atom in ArF is neutral. Integration of $\rho(\mathbf{r})$ over the atomic basins gives according to the QTAIM the partial charges in the molecule. The calculation for HArF confirms the visual impression of the bonding situation. The fluorine atom has a negative charge of -0.800 electrons while HAr carries a positive charge of $+0.800$ e, which is rather equally distributed over Ar ($+0.445$ e) and H ($+0.355$ e). Thus, the QTAIM suggests that the H–ArF bond has a covalent character while the HAr–F bond is ionic. Table 21 shows that the values of $\rho(\mathbf{r}_b)$, $\nabla^2\rho(\mathbf{r}_b)$, and $H(\mathbf{r}_b)$ for the HAr–F bond are close to the values of free Ar–F. The latter values are typical for closed-shell interactions like in weakly bonded van der Waals complexes but also in strongly ionic compounds. In order to distinguish between the two types of interactions, one has to consider the partial charges and the interatomic distance.

Another example that demonstrates the value of the topological analysis of the electron density distribution is the electronic structure of the donor–acceptor complex Cl_3B–CO. The molecule was already discussed in paragraph 2 in the context of the NBO analysis. The donor and acceptor atoms carbon and boron both carry a positive partial charge (Table 2). The donor atom C is even more positively charged ($+0.43$) than the acceptor atoms B($+0.29$). The atomic partial charges may not be used to estimate the interatomic electrostatic interactions. The atom that carries the largest positive charge (carbon) is actually the center of the negative charge concentration, which yields strong electrostatic attraction with the boron atom. Figure 17 shows the Laplacian distribution of Cl_3B–CO and the donor and acceptor moieties in the frozen geometry of the complex. It becomes obvious that the carbon atom of CO has an area of charge concentration along the bonding axis pointing away from oxygen, which comes mainly from the HOMO, which is a σ lone-pair orbital (Figure 17(b)). The σ charge concentration at carbon becomes deformed by the donor–acceptor interactions. Figure 17(a) shows that the σ charge concentration in Cl_3B–CO points towards the area of charge depletion at the boron atom. The electrostatic attraction (see the results of the EDA analysis below) comes from the interactions between the *local area of negative charge concentration of an overall positively charged atom with another positively charged atom.*

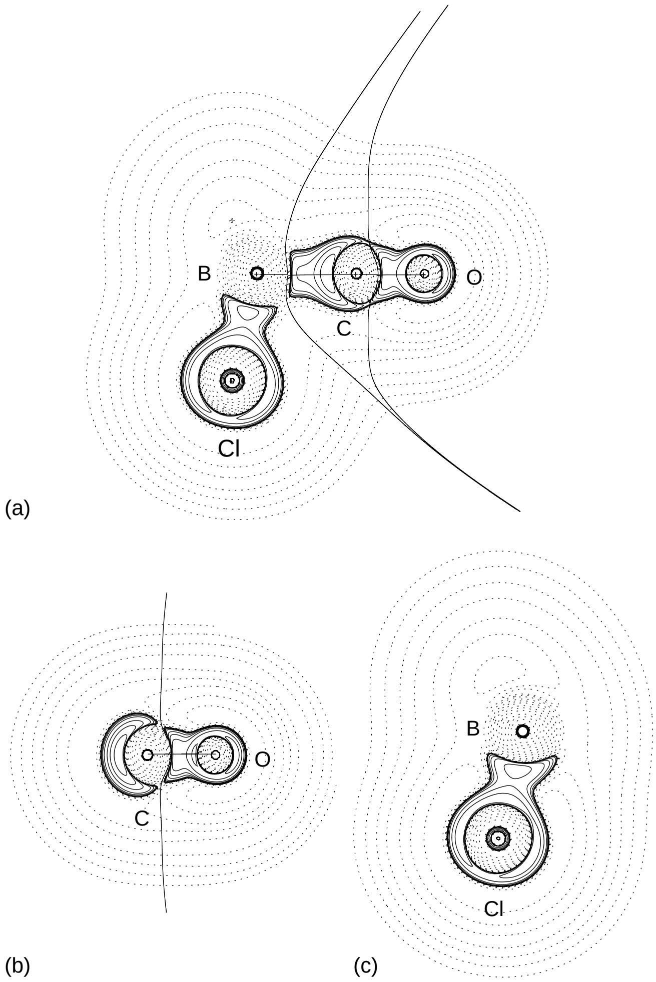

Figure 17 Contour line diagrams of the Laplacian distribution $\nabla^2\rho(\mathbf{r})$ of (a) Cl_3B–CO; (b) CO; (c) Cl_3B. CO and Cl_3B have been calculated in the frozen geometry of Cl_3B–CO. Solid lines give areas of charge concentration ($\nabla^2\rho(\mathbf{r}) < 0$), while dashed lines give areas of charge depletion ($\nabla^2\rho(\mathbf{r}) > 0$). The solid line connecting the atomic nuclei is the bond path. The solid lines that cross the bond path at the bond critical point show the zero-flux surface crossing the shown plane. The bond path and zero-flax surface of the BCl_3 moeity are not shown

7 CHEMICAL BONDING IN DONOR–ACCEPTOR COMPLEXES

A covalent two-electron bond A–B between two atoms or fragments A and B arises in most cases through the coupling of unpaired electrons at A and B. This type of bonding is also called a shared-electron interaction. A covalent bond A–B

may also be formed through donation of the electron pair of a donor B to an acceptor A. This is called a donor–acceptor bond where the bond is sometimes written with an arrow A ← B. The latter bonding type has been the subject of pioneering studies by G. Lewis.[1] The bonding partners of a donor–acceptor complex are therefore called Lewis acids and bases. Donor–acceptor bonds are usually weaker than strong electron-sharing bonds. The strongest bonded main-group complexes have bond energies of $\sim 50\,\text{kcal mol}^{-1}$.[39] The strength of the Lewis acids and Lewis bases for binding each other has been described by several chemical models in the past.

The donor–acceptor bond is usually explained in terms of two types of interactions. One type considers HOMO–LUMO interactions between the donor and acceptor moiety yielding a covalent bond and the other type considers electrostatic attraction between the negative charge of the donor electron pair and the nucleus of the acceptor atom. The dichotomy of bonding models is related to the concept of hard and soft acids and bases (HSAB) proposed by Pearson.[40] The central quantity of the HSAB model is the absolute hardness η. The hardness η was originally derived from the ionization energy I and the electron affinity A as $\eta = (\text{I}-\text{A})/2$. Since according to Koopman's theorem the ionization energy and the electron affinity are approximated by the energy levels of HOMO and LUMO, it follows that a larger HOMO–LUMO gap correlates with greater hardness. The HSAB model suggests that a hard base prefers to bind to a hard acid through electrostatic attraction while a soft base prefers to bind to a soft acid with a covalent bond. The predictions of the HSAB model are in qualitative agreement with experimental observations.[40]

Donor–acceptor complexes have already been discussed in Section 2 and in the previous paragraph, where it was shown that charge partitioning methods give insight into the electronic structure and bonding situation of the molecules. The energy decomposition analysis that was introduced in Section 3 can also be used for analyzing the nature of donor–acceptor interactions in complexes of main-group elements and transition metals.[10] Table 22 shows the EDA results for complexes of the Lewis acids BH_3, BF_3, BCl_3, AlH_3, $AlCl_3$ with the Lewis bases NH_3, NMe_3, PMe_3. The donor–acceptor bond in $H_3B\text{-}NH_3$ may be compared with the electron-sharing bond in isoelectronic H_3C-CH_3 (Table 8). The latter bond is much stronger, but the relative contributions of ΔE_{elstat} and ΔE_{orb} do not exhibit dramatic differences. The covalent contributions in ethane are somewhat larger (58.6%) than in $H_3B\text{–}NH_3$ (49.6%). The interaction energy and the BDE in $H_3B\text{–}NMe_3$ and particularly $H_3B\text{–}PMe_3$ are higher than in $H_3B\text{–}NH_3$. The bonding in $H_3B\text{–}PMe_3$ is also more covalent (57.3%) than in $H_3B\text{–}NH_3$. This is in agreement with the HSAB model, because BH_3 and PMe_3 are considered as soft molecules while NH_3 and NMe_3 are hard.

The HSAB model is also supported by the EDA results for the complexes of the hard Lewis acid BF_3 with NH_3, NMe_3, and PMe_3, which indicate a higher degree of electrostatic attraction than in the respective BH_3 complexes (Table 22). The calculated data show that the bond dissociation energy may not be a reliable probe for the strength of the donor–acceptor interaction. The D_e values of the complexes with BF_3 are significantly smaller than for the BH_3 complexes but the ΔE_{int} data are very similar. This is because the preparation energies of the BF_3 complexes are clearly higher than the preparation energies of the BH_3 complexes. The deformation of the planar structure of BF_3 towards the pyramidal form in the complexes is energetically more demanding than for BH_3. The EDA results for the BCl_3 complexes are very similar to the values that are calculated for the BF_3 complexes. The ΔE_{int} values and the bond dissociation energies of the former compounds are slightly larger than for the latter. The stronger Lewis acidity of BCl_3 compared with BF_3 comes from the larger contribution of the $\Delta\ E_{orb}$ term, which can be explained with the finding that BCl_3 has an energetically lower-lying LUMO than BF_3.[41] BCl_3 and BF_3 are hard acids but BCl_3 is not as hard as BF_3.[40] The data in Table 22 shows also that the HSAB model is not always correct. The hard acids BF_3 and BCl_3 should bind stronger to the hard bases NH_3 and NMe_3 than to the soft base PMe_3. The calculations predict stronger bonding in the phosphane complexes than in the amine complexes.

The calculated interaction energies for the aluminum complexes with AlH_3 and $AlCl_3$ are lower than for the respective BH_3 and BCl_3 complexes (Table 22). However, the bond dissociation energies of the $AlCl_3$ complexes are higher than the D_e values of the BCl_3 adducts because the preparation energies of the former species are much smaller than for the latter. $AlCl_3$ is considered to be a stronger Lewis acid than BCl_3.[39] Table 22 shows that the intrinsic Lewis acidity of BCl_3 is higher than that of $AlCl_3$. The donor–acceptor bonding in the aluminum complexes is clearly more electrostatic than in the boron complexes. Note that the D_e values at BP86/TZ2P, which are given in Table 22, are a bit smaller than the MP2/6–31G(d) data shown in Table 2 but the trends are always the same. This is because DFT underestimates the strength of donor–acceptor interactions.

8 CHEMICAL BONDING OF THE HEAVIER MAIN-GROUP ELEMENTS

Molecules of heavier main-group elements show significant differences to compounds of elements from the first-octal row of the periodic system. The coordination number of the lighter elements is rarely larger than 4 while many stable molecules of the heavier elements with coordination number 5 and 6 are known. Another difference concerns the stability of molecules with multiple bonds. Many stable molecules with double or triple bonds between the lighter elements are well known, particularly compounds that have C=C, C=N, C=O,

[a]Percentage of the total attractive interactions $\Delta E_{elstat} + \Delta E_{orb}$. [b]Percentage of the total orbital interactions ΔE_{orb}. Small contributions (<1 kcal mol^{-1}) by orbitals with a_2 symmetry have been neglected.

N=O, C≡C, and C≡N bonds. Molecules with multiple bonds between heavier elements are much less stable and they can only become isolated when the multiple bonds are stabilized by protective substituents.[42] The geometries of the latter molecules are frequently very different from homologs of the lighter elements. Molecules with double bonds $R_2E{=}ER_2$ are not planar like $R_2C{=}CR_2$ and molecules RE≡ER are not linear like RC≡CR (E = Si–Pb). The electronic structure

and bonding situation in $R_2E{=}ER_2$ and $RE{\equiv}ER$ has been discussed in paragraphs 4.2 and 4.3.

What is the reason for the different structures and reactivities of molecules of the elements Li–F compared with the heavier main-group analogs? For a long time it was assumed that the larger coordination numbers 5 and 6 of the heavier elements come from the nd ($n \geq 3$) AOs, which are available as valence orbitals for the heavier elements. It was thought that the octet rule holds only for the first-octal row elements because they have only 2s and 2p valence AOs while the heavier elements may also use the nd orbitals in compounds that were considered to be hypervalent. Chemical bonding in the latter compounds was then discussed in terms of sp^nd^m orbitals. The heuristic bonding model seems plausible because d orbitals are available only for elements of rows ≥ 3. It is also attractive because it is easy to write a 'hypervalent' compound such as SF_6 with a Lewis structure that has six S–F bonding pairs. Several quantum chemical studies using different partitioning methods have been carried out in the past. All agree that the valence space of the heavy main-group elements in 'hypervalent' compounds rarely exceeds the number eight, that is, the octet role is fulfilled even for compounds like SF_6 and $HClO_4$.[43] A Lewis structure that correctly describes the bonding situation in such molecules is given in Figure 18. Heavy-atom molecules of main-group elements, which bind more than four ligands, are stable because they are larger than elements of the first-octal row. There are no stable hypervalent compounds of the lighter elements because the ligands would repel each other when there were more than four atoms bonded to the central atom, not because it does not have d valence orbitals.

The chemical instability of heavy-atom molecules, which have a multiple bond, has previously been explained with the suspected weakness of the π bond. It was thought that the overlap of the $p(\pi)$ AOs of heavier elements is smaller compared with the atoms of the first-octal row because of the longer bonds of the former atoms. This is not true. The longer interatomic distance is compensated by the more diffuse orbitals of the heavier atoms, which yield similar overlaps to

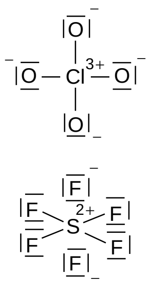

Figure 18 Lewis structures for ClO_4^- and SF_6 that obey the octet rule. Only one of several equivalent resonance forms is shown. The shown Lewis structures are suggested by quantum chemical calculations to be the best resonance forms for the molecules

those of the lighter elements. Table 5 shows that the ratio of σ and π bond strength in the diatomic molecules E_2 (E = N–Sb) does not vary a lot.

The difference in the bonding situation between elements of the first octal row and heavier atoms has been analyzed by Kutzelnigg.[44] There is a significant difference between the ns and np valence orbitals of the first-octal row ($n = 2$) and the heavier atoms ($n \geq 3$). The difference does not come from the *energies* of the valence orbitals. The energy differences between ns and np orbitals for when $n \geq 3$ is smaller than for $n = 2$. Hybridization should therefore take place more easily for the heavier elements, which is not the case because of the *size* of the valence orbitals. Figure 19 shows the calculated values for the mean radius of the ns and np orbitals $\langle r_s \rangle$ and $\langle r_p \rangle$ of main-group elements with $n = 2 - 6$. It becomes obvious that the $\langle r_s \rangle$ and $\langle r_p \rangle$ values for B–F are very similar, that is, $\langle r_p \rangle$ values are only ~10% larger than the $\langle r_s \rangle$ values. This means that the s and p valence orbitals of the second row elements are in the same region of space. The radii $\langle r_p \rangle$ of the heavier elements are significantly larger than the $\langle r_s \rangle$ radii, which means that the valence p orbitals of the latter atoms are clearly more diffuse than the valence s orbitals. The difference is particularly large for elements of the sixth row of the periodic system. Electrons in the valence ns orbitals of the heavier elements tend to behave more like core electrons when n becomes larger. It is known that compounds of elements of the sixth row may be stable when the heavy atom has only six electrons in the valence shell. An example has been presented in Section 4.3 above where the bonding situation of E_2H_2 is discussed. The trans-bent form of Pb_2H_2, which has a Pb–Pb single bond and σ electron lone pairs at Pb, is lower in energy than the trans-bent form that has a Pb=Pb double bond, although the lead atoms in the former species have only an electron sextet while there is an octet in the latter isomer. The octet rule is violated in many compounds of sixth row elements for which numerous stable molecules are known with only six electrons in the valence shell of the heavy atom. This is sometimes termed the 'lone-pair effect'. The important point is that the lower tendency of the heavier atoms toward formation of sp^n hybrid orbitals comes from the size of the ns and np valence orbitals but not from their energies.[44]

A second factor, which becomes important for the heavier elements, is relativistic effects. Many theoretical studies have been devoted to studying the influence of relativity on the structures and chemical properties of molecules in the last 10 years.[46] There are two major relativistic effects concerning the electronic structure of atoms that are important for chemistry. (i) The s and p orbitals are contracted by the influence of relativity while d and f orbitals are expanded. (ii) Coupling of spin and orbit movement of the electrons. The latter effect becomes obvious in Figure 19. The energy level of the p orbitals split into the components $p_{1/2}$ and $p_{3/2}$ because of spin-orbit coupling. The energy differences are very small and negligible for most chemical properties for elements of rows 2 and 3. They become larger in rows 4 and 5 and they are very important for elements of the rows 6 and above.

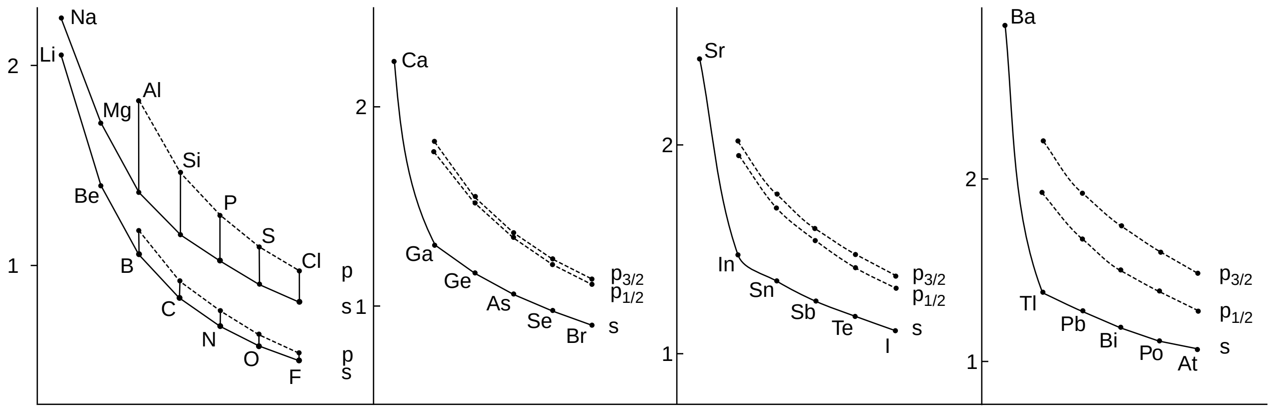

Figure 19 Calculated radii (expectation value) ⟨r_s⟩ and ⟨r_p⟩ for the s and p valence orbitals of main-group atoms. The indices $p_{1/2}$ and $p_{3/2}$ give the components of the p orbitals, which come from spin-orbit interactions. The calculated values have been taken from relativistic calculations of Desclaux.[45] (Ref. 15. Reproduced by permission of Wiley-VCH)

The difference between the structures and properties of the elements Li–F and the heavier homologs is not, however, caused by relativistic effects. The reason for the similar size of the 2s and 2p orbitals comes from the fact that there are no lower-lying filled p orbitals at the first-octal row elements. If the energy level l of an atomic shell n_l (l = s, p, d, etc.) is filled for the first time, the electrons can penetrate rather deeply into the core because there is no l–l repulsion with core electrons possessing the same l. This is the reason that the radii of the 2p orbitals are comparatively small having similar values as the 2s orbitals (Figure 19). This yields effective hybridization of the 2s and 2p orbitals in chemical bonds while the ns and np orbitals with $n \geq 3$ do not hybridize as well. It is important to learn that a correlation between hybridization and bond angle is valid only for elements of the first-octal row. For example, the localized bond orbitals in SiH_4 at silicon are $\sim sp^2$ hybridized and not sp^3 like the carbon atoms in methane although the molecule has tetrahedral (T_d) symmetry. The bond orbitals at P in PH_3 are $sp^{3.8}$ hybridized although the H–P–H bond angle is 95°, which would suggest nearly pure p AOs at phosphorus.[44]

The increasing reluctance of the heavier main-group elements to have more than six electrons in the valence shell and the corresponding stability of low-valent compounds shall be demonstrated using lead compounds in the oxidation state Pb(II) and Pb(IV) as examples.[47] The two systems show also the influence of relativity on the stability of the molecules. Most inorganic lead compounds such as halides and oxides are derived from Pb(II) while inorganic Pb(IV) compounds are either unknown or highly reactive. In contrast to this, organic Pb(IV) compounds are relatively stable while most lead organic species PbR_2 are unstable molecules. The calculated reaction energies of reactions 3–5 show typical differences:[47]

$$PbH_4 + 2PbF_2 \longrightarrow PbF_4 + 2PbH_2 + 104.0\,\text{kcal mol}^{-1}\text{(rel)} + 57.6\,\text{kcal mol}^{-1}\text{(nonrel)} \quad (3)$$

$$PbH_4 + 2PbCl_2 \longrightarrow PbCl_4 + 2PbH_2 + 89.5\,\text{kcal mol}^{-1}\text{(rel)} \quad (4)$$

$$PbMe_4 + 2PbF_2 \longrightarrow PbF_4 + 2PbMe_2 + 103.2\,\text{kcal mol}^{-1}\text{(rel)} \quad (5)$$

The calculated values for reactions 3 and 4 show that Pb(II) compounds become stabilized relative to Pb(IV) by electronegative substituents. Reaction 3 was calculated with and without relativistic effects. Electronegative substituents attract electronic charge from Pb, which becomes more positively charged. The valence s orbitals contract more than the p orbitals when the central atom becomes more positive. Thus, the size difference increases owing to the electron-withdrawing effect of electronegative substituents. This effect is enhanced by relativity. The calculated values for reaction 1 show that the endothermicity increases from +57.6 kcal mol^{-1} to +104.0 kcal mol^{-1} when relativistic effects are included in the calculation. Chlorine stabilizes Pb(II) slightly less than fluorine while hydrogen and methyl exhibit similar behavior.

Glossary

Hybridization: the mixing of two atomic orbitals of differing angular quantum number at one atom
ML_n: a generic transition metal bonding to n ligands (L) where the ligand is considered to be a two-electron donor
Orthogonal: when the overlap between two wavefunctions is zero

Abbreviations

e_i = The orbital energy associated with ϕ_i; SALC = Symmetry adapted linear combination; S_{ij} = The overlap between the wavefunctions ϕ_i and ϕ_j.

1 INTRODUCTION

There is a bewildering array of geometrical patterns offered to organometallic compounds. Consider that the transition metal can commonly be from two to nine coordinate and that there is a vast catalog of ligands that can be coordinated to the metal (*see* ***Coordination Numbers & Geometries***). The synthetic chemist can easily be overwhelmed when trying to determine the electronic structure for a specific molecule or comparing it to others. It is, of course, this diversity in the geometry of organometallic molecules that leads to a very rich set of bonding schemes. However, there are many simplification devices. These in turn can be exploited to see the threads that link the electronic structure of one structural type to another. Perhaps the earliest bonding concept was the 18-electron or EAN rule proposed by Sidgwick in 1927 (*see Effective Atomic Number Rule*). The hypothesis that most catalytic cycles involve alternating 16- and 18-electron intermediates is another concept directed towards the reactivity of organometallic molecules (*see* ***Mechanisms of Reaction of Organometallic Complexes***). Certainly another very important advance was the *Dewar–Chatt–Duncanson Bonding Model* of metal–alkene complexes. We shall see in this article the evolution of the Dewar–Chatt–Duncanson model to many other bonding situations.

This article will not cover the bonding in clusters (*see* ***Electronic Structure of Clusters***), in extended solids (*see* ***Electronic Structure of Solids***), or in main group compounds (*see* ***Electronic Structure of Main-group Compounds***). It will be confined to discrete transition metal compounds from Groups 4–11 in the *Periodic Table*. Detailed coverage of the bonding in organolanthanide/actinide molecules[1] and the electronic requirements of reaction mechanisms[2–4] have been provided elsewhere. With the advent of density functional methods, organometallic structures and reactions can be investigated on a more or less routine level with some confidence that the quantitative details will match experiment. But the insight into where these numbers come from and what they mean does not come from these computer programs. This is the focus of this article. The material discussed here is qualitative in nature and is applicable to evaluating the results from semiempirical, local density, or ab initio molecular orbital calculations (*see* ***Molecular Orbital Theory*** for a description and uses of these techniques in inorganic chemistry). It starts from an LCAO expansion of the wavefunction (*see LCAO Approximation*) and utilizes only symmetry properties and the qualitative application of perturbation theory. The principal rules that govern how orbitals interact with each other within the context of perturbation theory are given in the next section.

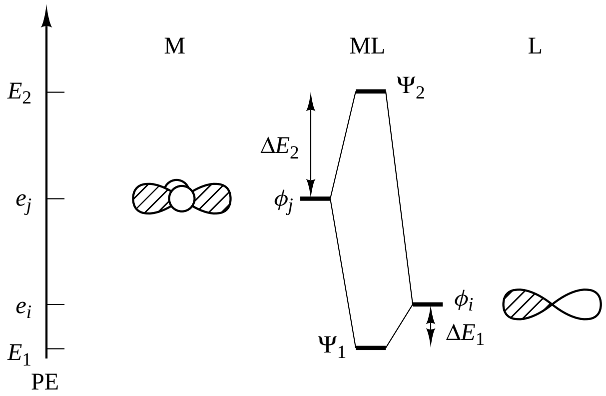
2 THE ELEMENTS OF ORBITAL INTERACTION

The construction of the electronic structure of an organometallic compound can be envisioned as a building block process, wherein the important valence orbitals of the ligands (a subset of the *Valence Orbitals* for the ligand set) interact with the valence AOs of the transition metal. Alternatively, the important valence orbitals of an ML_n fragment can interact with the important valence orbitals of a ligand. In the former approach, the bonding between the metal and all surrounding ligands is highlighted. A practical consequence is that all of the ligands should be electronically similar (but not necessarily identical), although there are techniques to build in π bonding on one or more ligands as a second step in the building block process as

outlined in Section 4. The latter method concentrates on the bonding between the metal (as influenced by auxiliary ligands) and a specific ligand. Both techniques utilize a qualitative application of perturbation theory[5] to estimate the magnitude of orbital interaction and the form of the resulting MOs. Certainly other qualitative or semiquantitative techniques exist (*see* ***Ligand Field Theory & Spectra***). The simplicity here is that any orbital interaction pattern can be constructed from two cases.

2.1 The Two Orbital Problem

Let us consider the formation of an M–L *σ-Bond* as a generic model. In most instances a lone pair on the ligand lies lower in energy than the metal d set of AOs prior to orbital interaction. This is reflected in (**1**) by the relative positioning of ϕ_i, a ligand centered orbital at an energy e_i, and ϕ_j, a metal d orbital at an energy e_j. The vertical scale, explicitly drawn for this case on the left side of (**1**), in this orbital interaction diagram then denotes potential energy with $e_i < e_j$. There are phases (the amplitude of the *Wavefunction*) associated with every AO and MO. The convention followed here is to denote positive phase by shading and negative phase by no shading in the two-dimensional representations of the wavefunctions.



(**1**)

Notice in (**1**) that the relative phases of the starting, unperturbed wavefunctions, ϕ_i and ϕ_j, have been adjusted so that the *Overlap Integral*, S_{ij}, between them is positive. That is, upon going from atoms M to L along the bond vector there is no phase inversion in ϕ_i and ϕ_j. When ϕ_i and ϕ_j interact with each other, two molecular orbitals, Ψ_1 and Ψ_2, are produced. The mixing of ϕ_j into ϕ_i is given by a mixing coefficient, $t_{ji}^{(1)}$, that can be qualitatively assessed by equation (1). The resultant molecular orbital is approximately given by equation (2).

$$t_{ji}^{(1)} \propto \frac{-S_{ij}}{e_i - e_j} \tag{1}$$

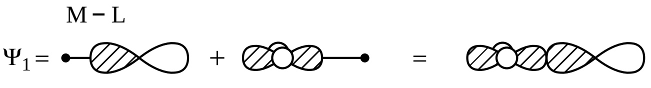
$$\Psi_1 \approx \phi_i + t_{ji}^{(1)}\phi_j \tag{2}$$

Since $e_i < e_j$ and S_{ij} we have taken to be positive in drawing the relative phases in (**1**), then $t_{ji}^{(1)}$ is a positive number. That is, ϕ_j will mix into ϕ_i with the phase present in (**1**). The construction of Ψ_1 is diagrammatically indicated in (**2**). This is a bonding MO; there is no phase inversion on going from M to L. The value of $t_{ji}^{(1)}$ will be less than 1; however, Ψ_1 will be primarily associated with the ligand lone pair, ϕ_i. The magnitudes (or weights) of the orbitals that mix are pictorially represented in a qualitative fashion by the size of the orbitals. For Ψ_2, the mixing of ϕ_i into ϕ_j, $t_{ij}^{(1)}$ is given by equation (3) and the resultant MO, Ψ_2, by equation (4). Here $t_{ij}^{(1)}$ becomes negative, that is, ϕ_i mixes into ϕ_j with the opposite phase given in (**1**).

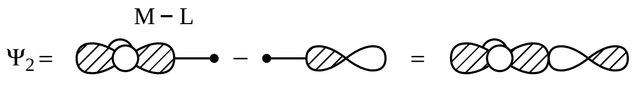
$$t_{ij}^{(1)} \propto \frac{-S_{ij}}{e_j - e_i} \tag{3}$$

$$\Psi_2 \approx \phi_j + t_{ji}^{(1)}\phi_i \tag{4}$$

Consequently, as shown by (**3**), Ψ_2 is primarily associated with the transition metal d AO (the absolute magnitude of $t_{ij}^{(1)}$ is also less than 1) and there is antibonding associated with this MO, that is, there is a phase inversion on going from M to L in Ψ_2.



(**2**)



(**3**)

The bonding between ϕ_i and ϕ_j in Ψ_1 causes e_i to be lowered in energy by an amount ΔE_1 as provided by equation (5).

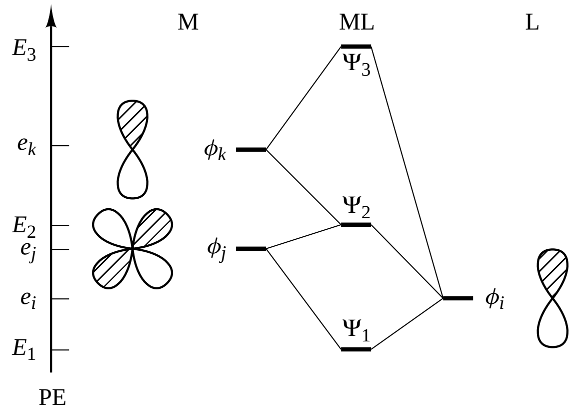
$$\Delta E_1 \propto \frac{S_{ij}^2}{e_i - e_j} \tag{5}$$

Notice that, since $e_i < e_j$, ΔE_1 is negative, that is, Ψ_1 is stabilized. The antibonding orbital Ψ_2 is destabilized by an amount ΔE_2. This is set by an equation analogous to equation (5) except that the ordering of e_i and e_j in the denominator is reversed. An important feature of perturbation theory, and indeed when one does a molecular orbital calculation at any level which that includes overlap, is that the antibonding combination (Ψ_2) is destabilized more than the bonding combination (Ψ_1) is stabilized, that is, $|\Delta E_2| > |\Delta E_1|$. Therefore the addition of two electrons to Ψ_1 in (**1**) is associated with stabilizing the formation of an M–L

bond. However, adding two more electrons fills Ψ_2, and this will then represent a net destabilizing interaction.

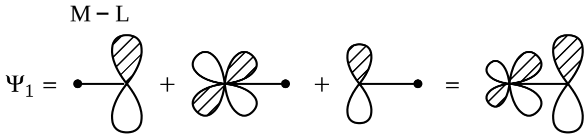
2.2 The Three-orbital Problem

The three-orbital pattern results when two orbitals on one fragment (or atom) strongly interact with an orbital on another fragment. One possible, again generic, situation is illustrated in (**4**). In this instance, both a metal d, ϕ_j, and a metal p, ϕ_k, AO interact with a single p AO, ϕ_i, on a ligand.



(**4**)

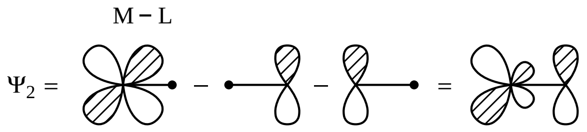
Notice that, again, the phases of the starting orbitals have been adjusted so that the overlap between ϕ_i and ϕ_j along with that between ϕ_i and ϕ_k are positive. Since ϕ_j and ϕ_k are on the same center, they are orthogonal (have no overlap between each other). The form of Ψ_1 is particularly simple. It represents just the sum of mixing ϕ_j into ϕ_i and ϕ_k into ϕ_i. There are then two terms analogous to equation (1). Since $e_i < e_j$ and e_k, both mixing terms are positive, that is, both ϕ_j and ϕ_k mix into ϕ_i in a bonding fashion as indicated by (**5**).



(**5**)

The metal orbital is hybridized in this MO to provide maximal bonding to the ligand. Ψ_2 will be primarily localized on ϕ_j; furthermore, ϕ_i will mix into ϕ_j with a negative mixing coefficient (in an antibonding fashion since ϕ_i lies lower in energy). However, ϕ_k can also mix into ϕ_2 with a mixing coefficient given by equation (6). The relative sign of $t_{kj}^{(2)}$ is negative; thus Ψ_2 is constructed as shown in (**6**).

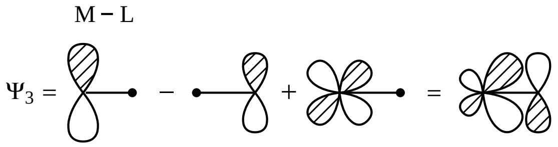
$$t_{kj}^{(2)} \propto \frac{S_{ki}S_{ji}}{(e_j - e_k)(e_j - e_i)} \qquad (6)$$



(**6**)

Notice the hybridization again at the metal; in this case it is in a direction away from the ligand. It is clear from the construction in (**6**) that Ψ_2 is a nonbonding MO. The form of Ψ_3 is determined in an analogous fashion in that it is primarily ϕ_k with ϕ_i mixed in an antibonding way. There is also the mixing of ϕ_j into ϕ_k which is given by equation (7).

$$t_{jk}^{(2)} \propto \frac{S_{ki}S_{ji}}{(e_k - e_j)(e_k - e_i)} \qquad (7)$$



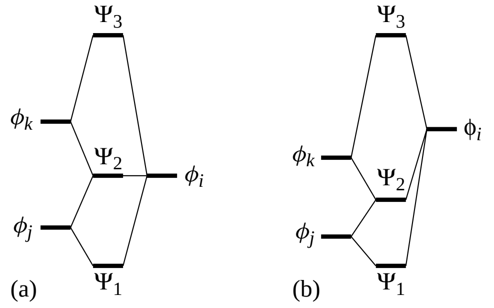
(**7**)

The construction of Ψ_3 is then given in (**7**). As in Ψ_1, it is hybridized towards the ligand now to produce a maximally antibonding MO. The bonding present in Ψ_1 causes e_i to be stabilized and the corresponding antibonding in Ψ_3 translates into a destabilization. We have indicated in (**4**) that Ψ_2 is destabilized. This is a reflection that the bonding between ϕ_k and ϕ_i is less than the amount of antibonding between ϕ_j and ϕ_i. However, Ψ_2 is *not* destabilized as much as Ψ_1 is stabilized (provided that the overlap between ϕ_i and ϕ_k is of reasonable magnitude). Therefore, the addition of four electrons, filling both Ψ_1 and Ψ_2, can lead to a net stabilizing situation.

Besides (**4**) there are two other three-orbital patterns that can be constructed as indicated by (**8**). One can easily work through the orbital mixings that evolve. In each instance, the pattern found in (**4**) is present. Namely, Ψ_1 and Ψ_3 are maximally bonding and antibonding between M and L, respectively, while Ψ_2 is nonbonding. The relative weight of each MO does change on going from (**4**) to (**8**). For example, Ψ_2 in (**4**) is primarily ϕ_j, whereas it is primarily ϕ_i in (**8a**) and ϕ_k in (**8b**). The important point is that the functional form of Ψ_2 always remains the same, that is, nonbonding.

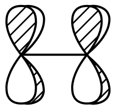
2.3 Generalizations

The orbital interaction patterns that were presented in the previous two sections have a number of features in common. Any MO most strongly resembles the starting, unperturbed orbital closest to it in energy. A higher lying orbital will always mix into a lower lying one in a bonding fashion and a lower lying orbital mixes into a higher lying one in an antibonding



(**8**)

fashion. Notice that this occurs as well in the $t^{(2)}$ mixing terms for the three-orbital problem. In (**6**) the high-lying ϕ_k mixes with ϕ_j in a bonding way with respect to ϕ_i and in (**7**) the lower lying ϕ_j mixes into ϕ_k in a way which is antibonding to ϕ_i. The amount of stabilization or destabilization is dependent upon two factors: it directly depends upon the magnitude of the overlap between the two starting orbitals and inversely upon the energy difference. The overlap which exists between orbitals is sensitive to a number of factors. Firstly, it depends upon the type of overlap. The situation illustrated in (**1**) is that of σ overlap; there are no *nodes* along the internuclear axis (M–L), whereas that in (**4**) is of the π type where one node lies along the internuclear axis for each combination. A final type, shown in (**9**), represents δ overlap. Here two nodes lie along the internuclear axis. Since the amount of overlap in a nodal plane is necessarily zero, it then follows as a general rule that overlap varies in the manner of $\sigma > \pi > \delta$.



(**9**)

The geometry present in the molecule also has a decisive impact on the magnitude of the overlap. Figure 1 shows the angular dependence of the overlap between two d orbitals and an s orbital. The σ overlap in each instance is maximal at very different angles of θ. Furthermore, as shown above each curve, the functional form of the d AO creates a specific angular dependence on S_{ij}. This feature forms the basis for the *Angular Overlap Model*. The positions of the atoms in the periodic table is another variable to be considered. For valence orbitals, a general rule of thumb is that the more diffuse the orbital is, the less it overlaps with another orbital. A valence orbital becomes more diffuse when one goes down a column or proceeds from right to left along a row in the periodic table. Hence the overlap of the 2s/2p AOs on oxygen will create a larger overlap with a metal set of d AOs than for the 3s/3p AOs on sulfur, for example. There is, however, one important exception. The 3d AOs for the first transition metal row are too contracted. There is no inner core of d

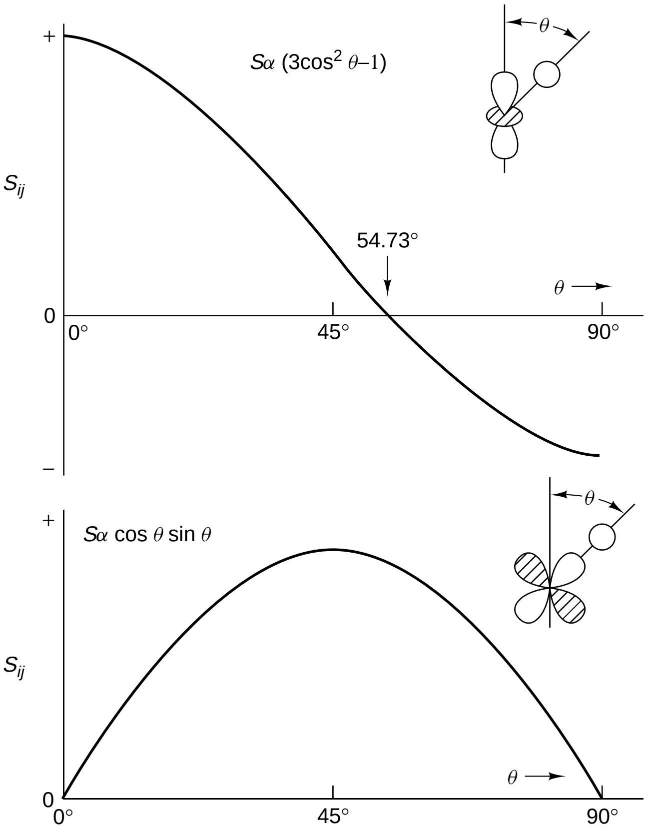


Figure 1 The angular dependence of the overlap, S_{ij}, between a metal d and a ligand s orbital for two different d AOs

electrons. Consequently, they overlap less with ligand orbitals than do the 4d or 5d AOs of the second or third row analogs, respectively.[6]

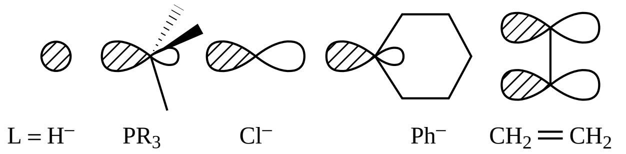
The final variable in determining overlap lies in symmetry. A discussion of group theory and the formation of *Symmetry Adapted Linear Combinations* (SALC) lies beyond the scope of this entry.[7] For our purposes it is sufficient to state that when a collection of orbitals exists which can be interrelated by symmetry elements, then combinations of these orbitals can be constructed. Each SALC is orthogonal to all others and reflects the full symmetry properties present in the molecule. A short-hand way to designate these symmetry properties is by the Mullikan notation[7] for the irreducible representations of the group which are used throughout this contribution. Since irreducible representations are orthogonal to each other, then any orbitals and/or collections of orbitals with different Mullikan symbols have zero overlap with each other. An alternative, very powerful way of stating this is that only orbitals of the same symmetry can interact with each other.

The energy gap between two interacting orbitals also plays a critical role in determining the magnitude of the interaction. As indicated previously the amount of stabilization in the bonding combination is inversely proportional to the energy gap between the two interacting orbitals. The electronegativity

of the atom(s) obviously is directly related to orbital energies. For example, the lone pair of a phosphine lies at a higher energy than that of an amine (*see* ***Photoelectron Spectroscopy of Transition Metal Systems***) and consequently will form a stronger bond to a transition metal. The presence of a charge or inductive effects of substituents will also scale the energies of orbitals. Electron-donating groups or the presence of a negative charge will raise orbital energies while a positive charge will lower orbital energies.

3 BASIC SPLITTING PATTERNS

In this section, we shall cover the electronic structure of the basic coordination types in organometallic compounds. Since σ interactions are stronger than π because of overlap, the strategy is to first build the MO's that are σ bonding. Any π type interactions can be added on in a second, separate step. The details of this are reserved for Section 4. All of the ligands in (**10**) present a high-lying filled orbital to the metal which can be used for σ interaction. In other words, a cylindrical field of electron density is donated to the metal. Of course, they will not all lie at the same energy; that can be treated as a subsequent minor perturbation. We shall then use a stylized representation for that orbital on L, a teardrop shape, and regard L as a neutral, two-electron σ donor ligand. It is recognized that when several specific ligand types coordinate to the transition metal, then the symmetry of the molecule is considerably lower than that of the parent ML_n complex. However, there is an effective pseudosymmetry that the transition metal experiences in the σ system that is the same as that in the ML_n example.



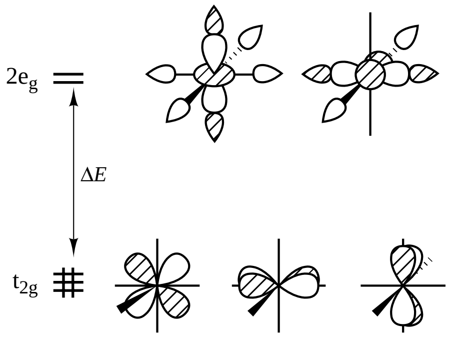
(**10**)

3.1 The Octahedron

Figure 2 presents an orbital interaction diagram for building the valence orbitals of an octahedral ML_6 complex. On the left side are the nine valence AOs of a transition metal. The six SALCs for the L_6 set of lone pairs are drawn on the right side. They have $a_{1g} + t_{1u} + e_g$ symmetry. The relative energies have been set so that the lone pairs lie slightly lower than the metal d set. This will be generally true; however, one can point to exceptional instances where combinations of very electronegative metals and electropositive ligands reverse this ordering. It is clear that metal s interacts only with the a_{1g} SALC and metal p with the t_{1u} set. Two metal d orbitals, $x^2 - y^2$ and z^2, interact with the e_g combination. Six ligand centered bonding MOs, $1a_{1g} + 1t_{1u} + 1e_g$, are produced. This is the delocalized equivalent of six 2-center−2-electron M–L σ bonds where one forms six equivalent sp^3d^2 hybrid orbitals at the metal and interacts each with one ligand σ orbital. The $2e_g + 2a_{1g} + 2t_{1u}$ MOs are the antibonding counterparts and are concentrated more at the metal. Left behind in this interaction are three d AOs; using the coordinate system at the top of Figure 2 they are *xz*, *xy*, and *yz*. Provided that the ligands have only σ donor capabilities (or at this stage of the electronic structure analysis recall that we are only concerned with σ effects), then these three orbitals, the t_{2g} set, are rigorously nonbonding.

A family of molecules exists with 12 valence electrons (e.g. WF_6, $W(NMe_2)_6$, $TiCl_6^{2-}$) and the $1a_{1g}$ through $1e_g$ molecular orbitals are filled. In cases where the ligands are strong σ donors (i.e. the metal d−ligand lone pair overlap is large and the ligand orbitals are close to or even above the metal d orbitals), then the $1e_g$ MOs may lie lower in energy than the $1t_{1u}$ set. The order of the MOs that is displayed in Figure 2 simply reflects the relative ordering of the starting orbitals. For a molecule to be stable at the octahedral geometry the *HOMO−LUMO Gap* between t_{2g} and $1t_{1u}$ or $1e_g$ must be large. In the 12-electron WMe_6 molecule, the $t_{2g}-1t_{1u}$ energy gap at the octahedral geometry is small (this is one instance where $1t_{1u}$ lies higher in energy than $1e_g$). Consequently, the molecule adopts a very unusual and sterically unfavorable distorted trigonal prismatic geometry.[8,9] This is also the case for a number of other d^0 ML_6 molecules.[10]

A more common bonding situation exists when the nonbonding t_{2g} set is filled with six electrons and, of course, there are 12 electrons in the M–L σ bonding orbitals, which yields a total of 18 electrons. The heavy box in Figure 2 highlights those orbitals that are metal d-centered. The HOMO-LUMO energy gap, now between t_{2g} and $2e_g$, is critical and controls the chemistry of these molecules. Recall that $2e_g$ is the antibonding combination of metal $x^2 - y^2$ and z^2 to the ligand σ set. It is explicitly drawn in (**11**).



(**11**)

The magnitude of the $t_{2g} - 2e_g$ energy gap is primarily determined by how much $2e_g$ is destabilized by the ligand σ donor set. When the ligands are strong σ donors (e.g. PR_3, CO, alkyl, alkoxide, alkene), then $2e_g$ lies at a very high energy and

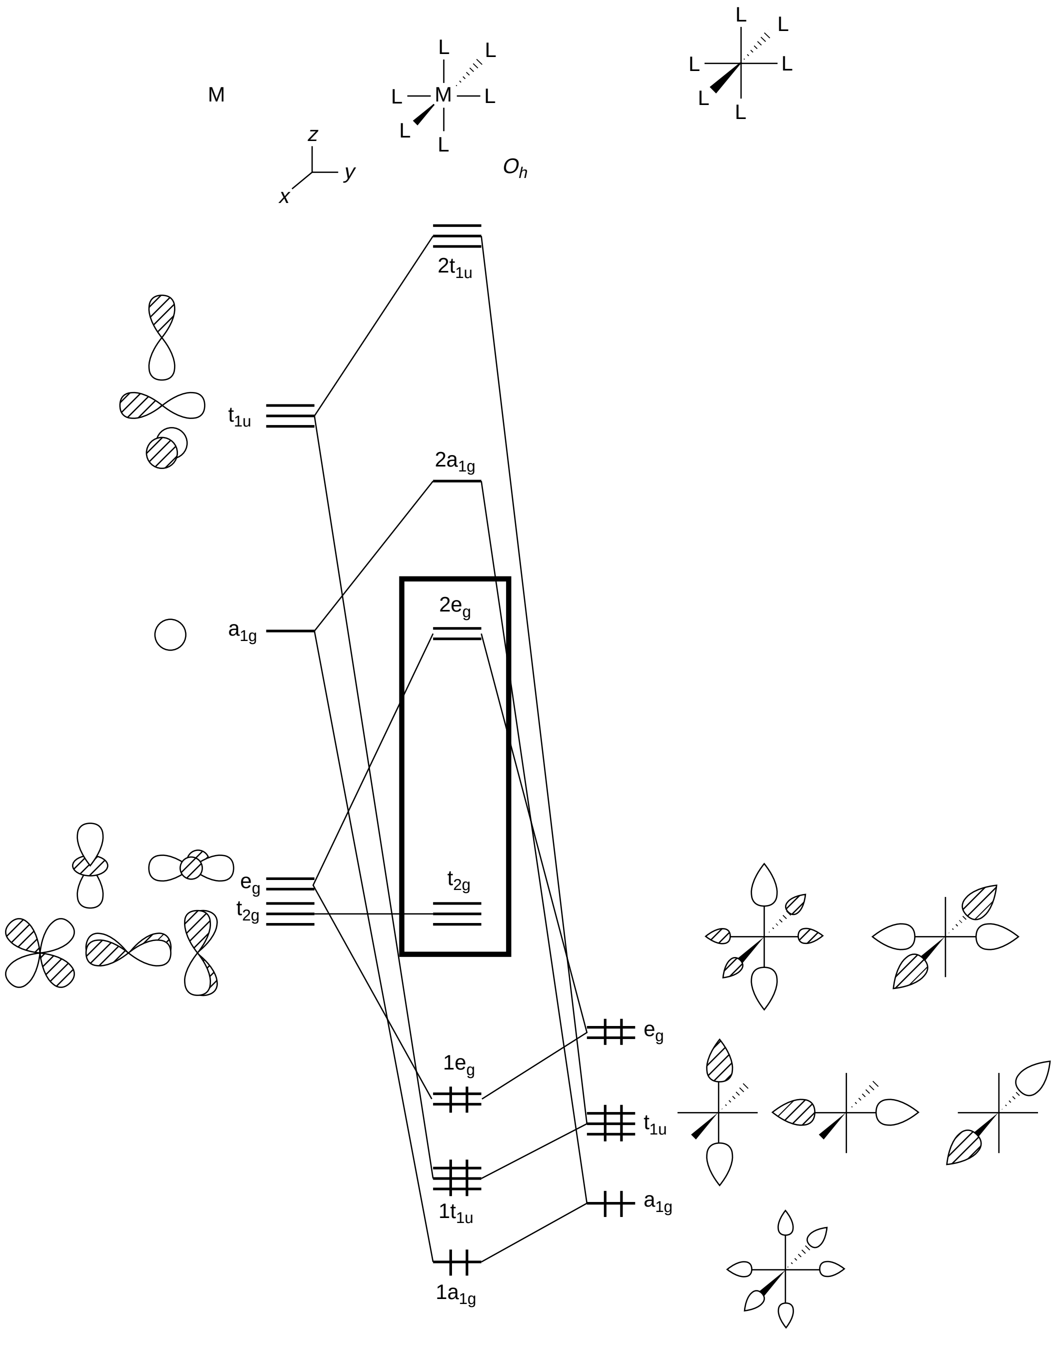


Figure 2 Building the valence orbitals for an octahedral ML_6 complex

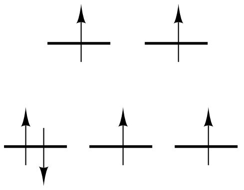
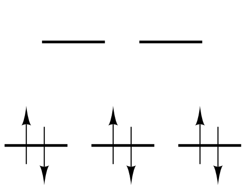
population of it is energetically costly. Thus, addition of an electron to $Cr(CO)_6$ does not give the 19-electron $Cr(CO)_6^-$ molecule; instead, CO is lost to yield $Cr(CO)_5^-$.[11] In general 19- or 20-electron organometallic compounds are quite rare unless there is some symmetry based reason which prohibits one or more symmetry combination of ligand orbitals from overlapping with the metal orbitals. We shall cover a few of these cases in Section 4.3. On the other hand, the classic coordination complexes (*see* ***Coordination & Organometallic Chemistry: Principles***) possess weak σ donor ligands (e.g. NH_3, H_2O) and they are very electronegative. Consequently, the lone pairs lie at a low energy and the overlap between them and the metal d AOs is small. Much of the attractive interaction between the metal and ligand is electrostatic rather than covalent. The $2e_g$ orbitals are destabilized to a lesser extent and the $t_{2g} - 2e_g$ energy gap is small. Consider a hypothetical example where there are two electrons and two orbitals to place them in. When the energy difference between the two orbitals is smaller than the Coulomb repulsion integral generated by putting an electron in each orbital, it is then

energetically favorable to unpair the electrons and put one in each orbital.[5] In the present case for coordination compounds, there is a delicate balance between high-spin (a maximum of unpaired spins in the d orbital splitting block) and low-spin electronic states. An 18-electron example such as $Fe(H_2O)_6{}^{2+}$ is high spin with the electron occupancy in (**12**), whereas $Cr(CO)_6$ and the vast majority of 18-electron organometallic complexes are low-spin with the electronic configuration shown in (**13**).



High spin

(**12**)



Low spin

(**13**)

3.2 The Square Plane

On the left side of Figure 3 are the metal s, p, and d orbitals. On the right side are the four ligand SALCs. The e_u set matches two metal p orbitals and b_{1g} combines with metal $x^2 - y^2$ (the coordinate system is shown at the top of Figure 3). Three bonding and antibonding MOs are formed. Just as in the octahedron, three metal d AOs, *xz*, *yz* (of e_g

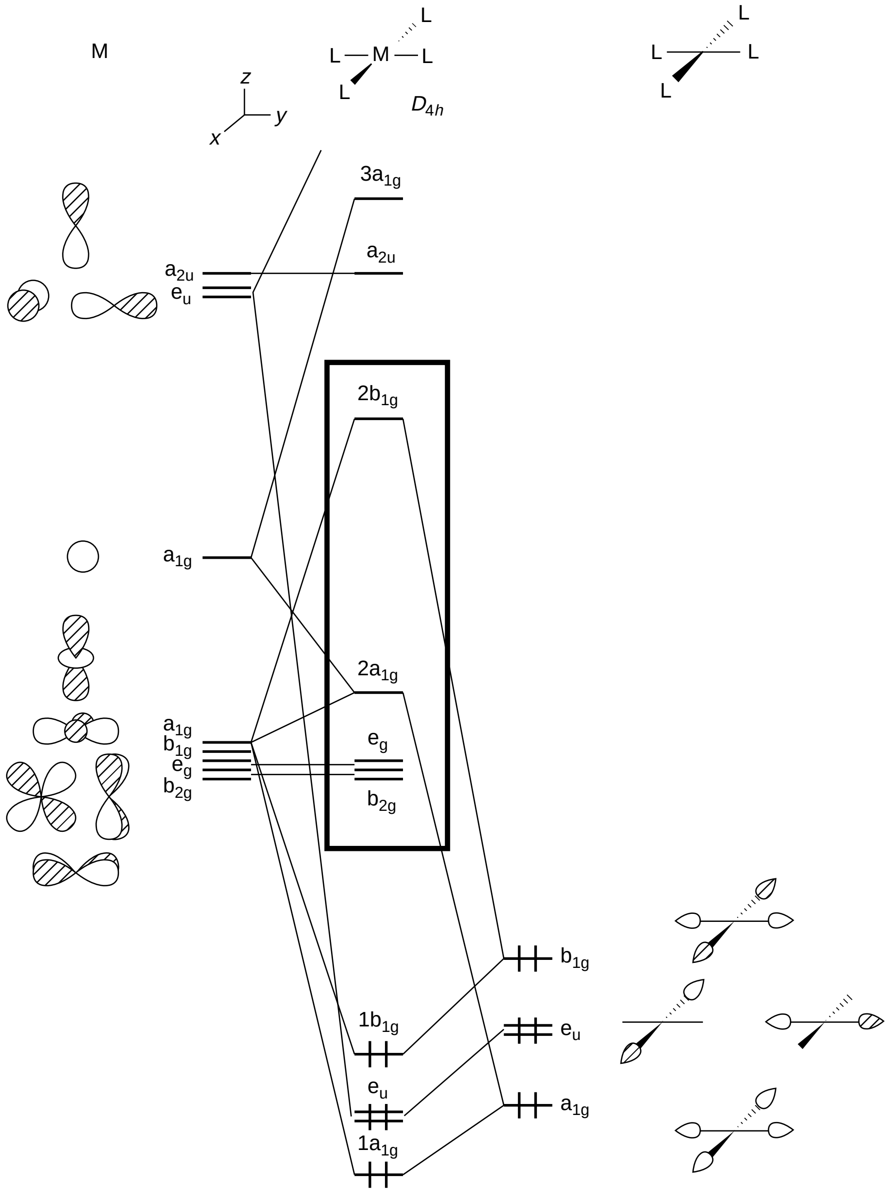


Figure 3 Construction of the valence orbitals of a square-planar ML_4 complex

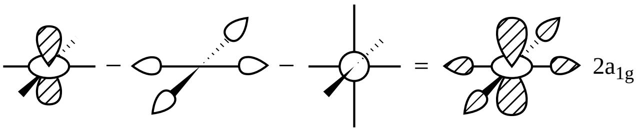
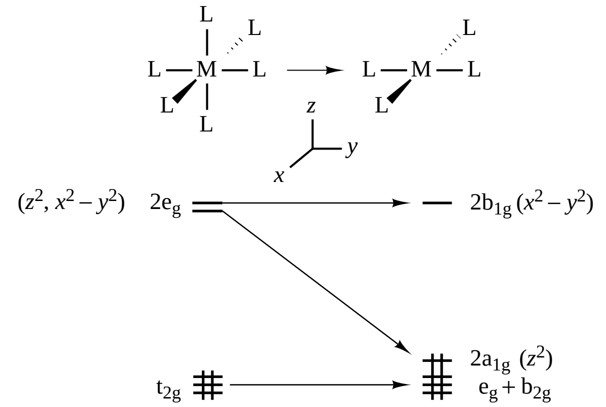
symmetry), and *xy* (b_{2g}) are left nonbonding. The ligand a_{1g}, metal z^2, and metal s all have the same symmetry. Thus, we have a three-orbital pattern, precisely analogous to (**4**) which evolves. The lowest MO, $1a_{1g}$, is primarily ligand based with metal z^2 and s mixing into it in a bonding fashion. The fully antibonding analog is $3a_{1g}$. Here the MO is primarily metal s and the ligand SALC mixes in an antibonding fashion to metal s and z^2. The nonbonding MO, $2a_{1g}$, remains at about the same energy as the starting metal d AOs. Its constitution is given in (**14**). It is primarily metal z^2 antibonding to ligand a_{1g}. Metal s mixes into this orbital also in a bonding way to the lone pairs. The valence metal d region is highlighted with a box in Figure 3. One might think that a molecule with 8 valence electrons ($1a_{1g} + e_u + 1b_{1g}$ filled) might be stable. In fact, this is not the case. As we shall see in the next section, a tetrahedral geometry is preferred. In this context, when L is a strong σ donor, then the $1b_{1g}$ MO may lie lower in energy than the e_u set. We shall also see in Section 4.3 that π donors interact with and destabilize *xz*, *yz*, and *xy*. In $W(OR)_4$ with 10 valence electrons, this does, in fact, occur and the molecule is more stable at the square-planar geometry with the HOMO being $2a_{1g}$ (e_g and b_{2g} are destabilized by the alkoxide lone pairs). Filling all metal d nonbonding orbitals (e_g, b_{2g}, and $2a_{1g}$) leads to a 16 electron complex. This is a very common electron count for organometallic molecules.



(**14**)

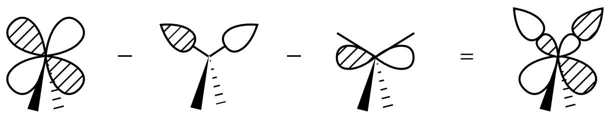


(**15**)

Notice in Figure 3 that the metal *z* AO, a_{2u}, also remains at high energy. It is clear that the addition of two electrons to yield an 18-electron complex will be energetically prohibitive. Yet, there is a strong electronic correlation between an 18-electron octahedral ML_6 complex and a 16-electron square-planar ML_4 one. This correspondence is illustrated in (**15**). When two trans ligands in an octahedral complex are removed, the z^2 component of $2e_g$ is considerably stabilized and joins the block of the other three nonbonding d AOs. The remaining four d-based MOs are identical. Thus, as shown, a d^6 ML_6 complex is electronically analogous to a d^8 square-planar ML_4 one.

3.3 The Tetrahedron

Figure 4 presents the MOs for a tetrahedral ML_4 complex. The a_1 ligand combination interacts with metal s to form the bonding, $1a_1$, and antibonding, $2a_1$, MOs. Using the coordinate system at the top of the figure, metal z^2 and *xy* are rigorously nonbonding and form an e set. The metal $x^2 - y^2$, *xz*, and *yz* along with the p AOs combine with the ligand t_2 set to form a three-orbital pattern. The $1t_2$ and $3t_2$ MOs are the bonding and antibonding components. The middle, nonbonding (or in this case slightly antibonding) member is the $2t_2$ set. The construction of it follows the pattern developed in the previous examples and is explicitly shown for the *yz* member in (**16**). Notice that the orbital is hybridized away from the ligand σ donor functions. Molecules with 8 valence electrons, for example, $ZrMe_4$ and $TiMe_4$, are more stable at this geometry with $1a_1$ and $1t_2$ filled than at the square-planar geometry. The reason behind this rests in the fact that $1t_2$ in Figure 4 lies lower in energy than e_u in Figure 3.



(**16**)

$Ru(Mes)_4$ and $Ir(Mes)_4^+$ have been isolated and found to possess a tetrahedral geometry.[12] These are rare examples of 12-electron count molecules. From Figure 4 the e set should be completely filled. Indeed, the molecules are diamagnetic. However, by far the most common tetrahedral organometallic molecules have an 18-electron count where $2t_2$ is the HOMO. There is a very specific dependence of the electron count on the geometry; recall that 16-electron ML_4 complexes were square planar. The variation of the valence MOs associated with the metal d-block going from the square planar to tetrahedral geometry is given in Figure 5. It is easy to see why d^{10} (18 electron) complexes prefer the tetrahedral geometry over the square-planar one; $2t_2$ lies lower in energy than $2b_{1g}$. For a d^8 (16 electron) complex, $2a_{1g}$ on the square-planar side lies much lower than $2t_2$. What is not so apparent is why $Ru(Mes)_4$ and $Ir(Mes)_4$ are tetrahedral. A high-spin square-planar geometry should lie at about the same or lower energy. The reason partially lies in the steric bulk of the Mes ligands, which is minimized in the tetrahedral structure. In fact, the isoelectronic $MnMe_4^-$ molecule is paramagnetic and square planar.[13] The d^2 system presents an analogous situation:

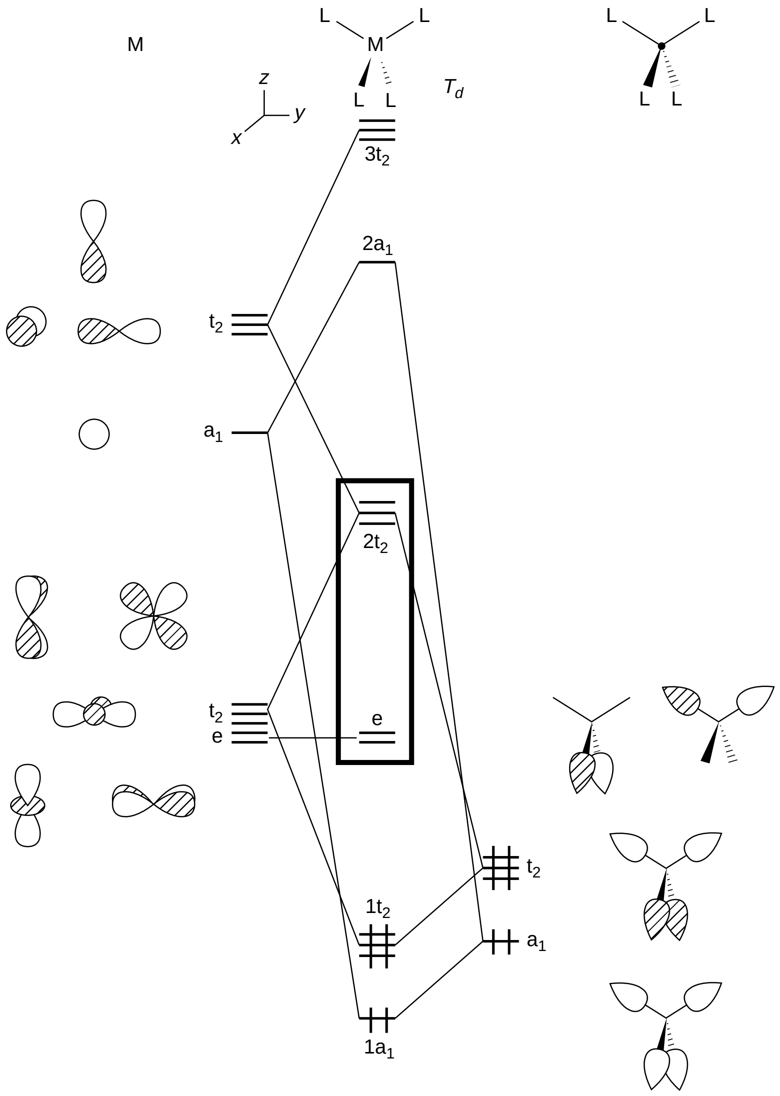


Figure 4 An orbital interaction diagram for the valence orbitals of a tetrahedral ML_4 complex

$Cr(C_6H_{11})_4$ is tetrahedral and a triplet;[14] however, square-planar d^2 systems are also known where π effects provide the discriminating factor. Another factor at work in these molecules is the spin pairing energies. As indicated previously, 3d valence orbitals are considerably more contracted that 4d and 5d; thus the Coulomb repulsion integrals are much larger for first-row transition metal complexes and high-spin states are more favored than is the case for second and third row complexes.

3.4 The Trigonal Bipyramid and Trigonal Plane

The orbital interaction diagram for a trigonal bipyramid is illustrated in Figure 6. Notice that there are two ligand SALCs of a_1' symmetry. The metal z^2 and s AOs also have a_1' symmetry so one might think that all four orbitals will interact with each other. However, this is not the case. The lower ligand SALC possesses no nodal planes; this is also the case for metal s. Therefore those two orbitals combine to produce the $1a_1'$ bonding and $4a_1'$ antibonding MOs. The higher ligand SALC has two nodal planes that match the pattern in z^2. Thus, $2a_1'$ and $3a_1'$ represent their bonding and antibonding interactions, respectively. The a_2'' ligand SALC interacts with metal z also in a two orbital pattern. The metal *xz*/*yz* (e″) set are left totally nonbonding. There is one three-orbital combination which arises from the ligand e′ SALC with the $xy/x^2 - y^2$ and x/y sets at the metal. The middle d-centered MOs (2e′) are determined in the standard fashion and are shown in (**17**). For an 18-electron complex, that is, $Fe(CO)_5$, 2e′ is the HOMO. Populating $3a_1'$ will create an unstable situation. One ligand will be lost to generate an 18-electron, tetrahedral ML_4 complex.

The situation for electron counts less than 18 is slightly more complicated since another ML_5 geometry, that of the square pyramid, must be considered. The evolution of orbital

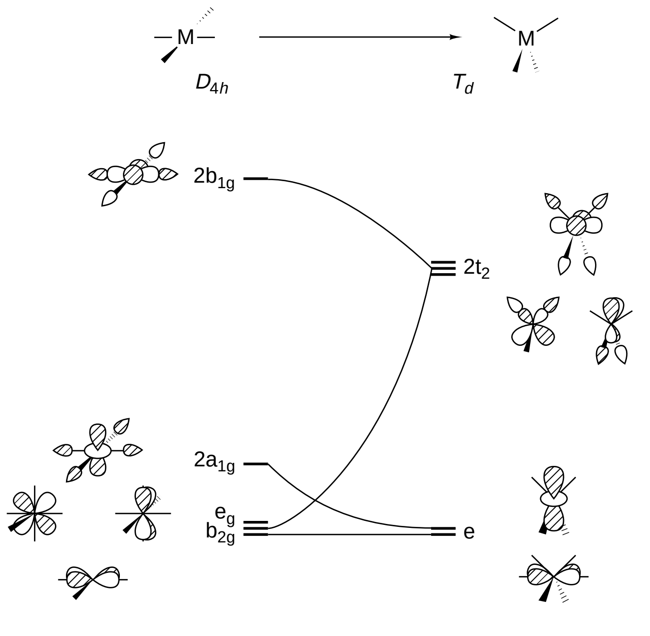

Figure 5 Variation of the orbital energies on going from the square planar to tetrahedral geometry

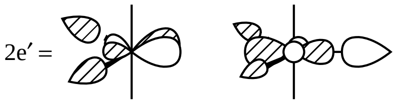
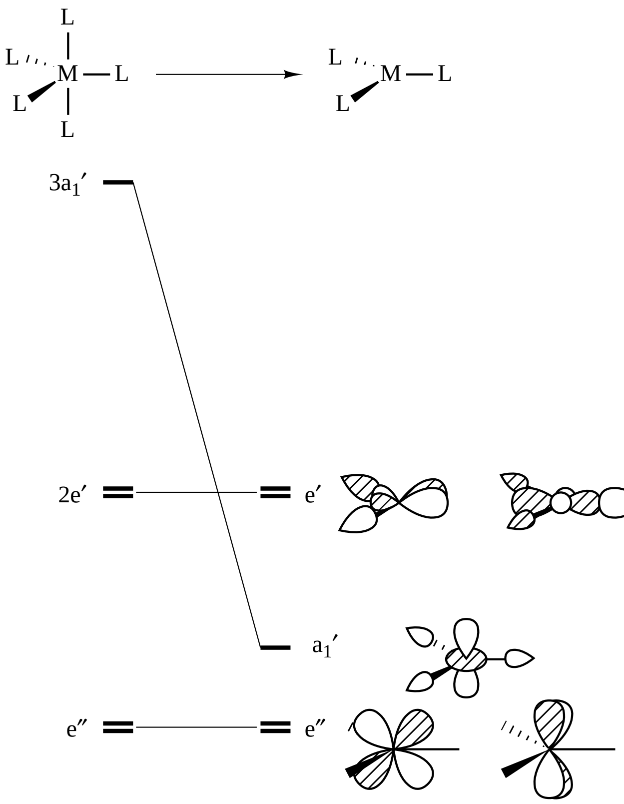


(**17**)

energies on going from a trigonal bipyramid to the square pyramid and the resulting shapes is given for the d-block orbitals in Figure 7. Any variation of energy is simply a reflection of changes in overlap between the metal and ligand orbitals and will not be discussed here.[5] For the d^8 (18 electron) system, there is actually a very small energy difference between the two structures. In fact, there exists a collection of solid-state structures for molecules at this electron count which lie along the *Berry Pseudorotation* path for converting a trigonal bipyramid into a square pyramid.[15] A d^6 system, like $Cr(CO)_5$, strongly prefers the square pyramid for a low-spin complex.[16] At the trigonal bipyramidal geometry the 2e′ set is half-filled and, therefore, a less stable triplet state is found at this geometry. For two electrons less, a d^4 complex, the trigonal bipyramid becomes more stable. The ground state for $RePh_3(PEt_2Ph)_2$ is a low-spin complex[17] with e″ filled; however, analogous manganese complexes are high-spin[18] with e″ and 2e′ occupied.

The valence orbitals of a trigonal planar complex can be easily constructed as we have done for the preceding examples. An alternative way to view the construction of the d-block manifold is shown in (**18**). Just as in the octahedral ML_6 to square-planar ML_4 transformation shown in (**15**), only one metal d-based MO is affected. The majority of the M–L σ antibonding is lost in z^2; furthermore, metal



(**18**)

s mixes into this MO in a bonding way to the remaining ligands. Thus, the a_1' orbital is stabilized considerably on going from ML_5 to ML_3. An 18-electron, d^8 ML_5 complex is, therefore, electronically analogous to a 16-electron, d^{10} ML_3 species. Just as a d^6 trigonal bipyramidal ML_5 complex distorts to a square pyramid, a d^8 trigonal planar ML_3 complex undergoes an analogous transformation to a T-shaped geometry.[8]

3.5 Electron Counting

The orbital interaction patterns that we have derived in the previous sections, along with those for seven- and eight-coordinate molecules,[19,20] can be generalized as indicated in Figure 8. If there are n ligands surrounding the transition metal, then n SALCs of ligand σ donor functions exist. All will be stabilized by metal d, s, and p AOs. Thus, n M–L bonding orbitals, centered on the ligands, are formed. There are of course n M–L σ antibonding orbitals also created. These MOs are pushed to high energies and are more concentrated at the metal. Left behind are $9 - n$ nonbonding orbitals provided that the metal and all of the ligands do not lie in a common plane. These nonbonding MOs are primarily d in character since d AOs have more nodes than the s and p AOs. Filling all bonding and nonbonding orbitals with two electrons then provides a total of $2(n + 9 - n) = 18$ electrons. Figure 8 provides an MO rationalization of the 18-electron rule. Notice that we are

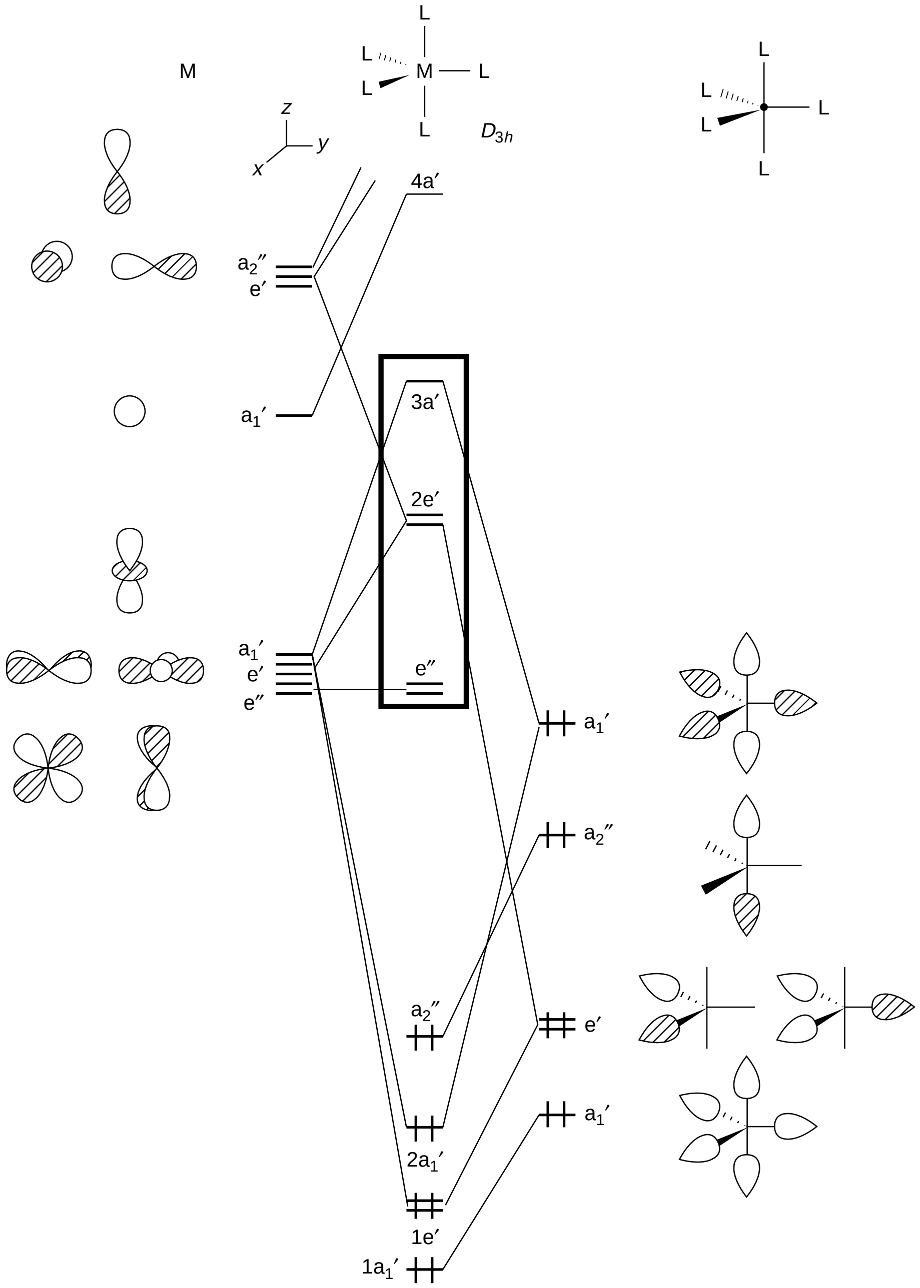


Figure 6 An orbital interaction diagram for the valence orbitals of a trigonal bipyramid

counting the number of electrons engaged in M–L bonding, as well as those localized at the transition metal. Figure 8 can easily be modified to include the two common instances where 16 electrons are preferred, namely, the square plane and trigonal plane. Since in these cases the metal and surrounding ligands lie in a plane, there can be no interaction between the ligand σ donor set and one of the p AOs at the metal. The metal p AO lies at a high energy and it is not energetically advantageous to fill it.

The assignment of formal charge at the metal can be problematic since it depends on a person's bias of how to view the ligands. As long as this is done in a consistent manner, one will always obtain the same total valence electron count. The particular convention described here has the virtue that it will immediately pinpoint how many d electrons are present, that is, the occupation of the metal d-centered MOs that have been described in the previous sections. We shall treat all ligands as Lewis bases. Listed in (**19**) are some ligands. In each case we will treat the ligand as a two-electron σ donor group. The total number of d electrons can be obtained by adding the formal charges assigned to the ligands in (**19**) and subtracting the sum from the charge on the molecule. This will yield the formal

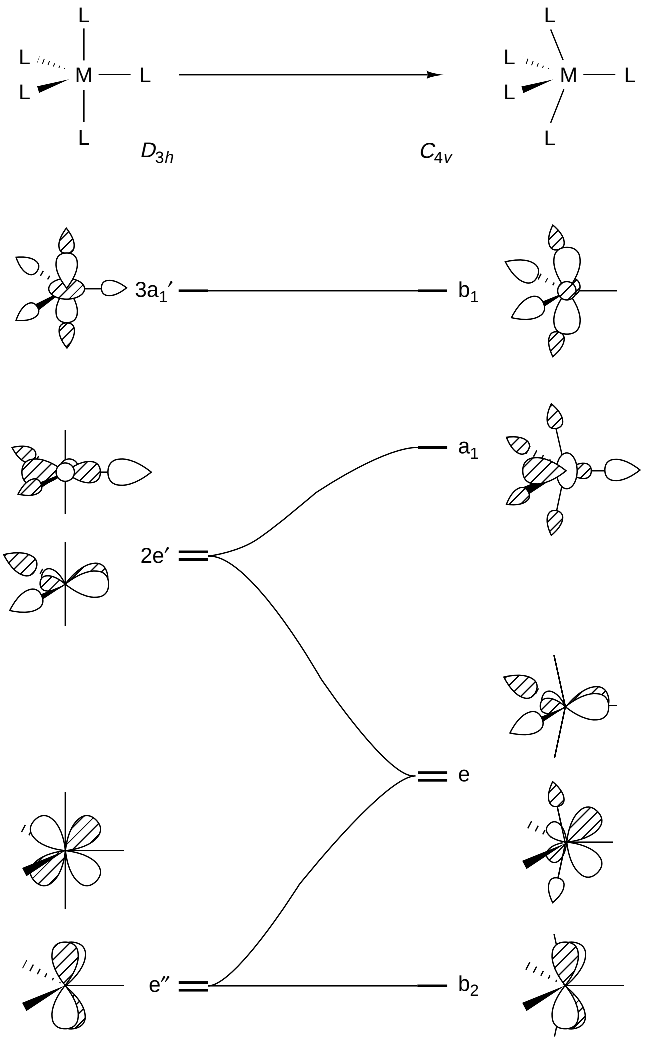

Figure 7 Variation of the orbital energies on going from the trigonal bipyramid to square pyramid

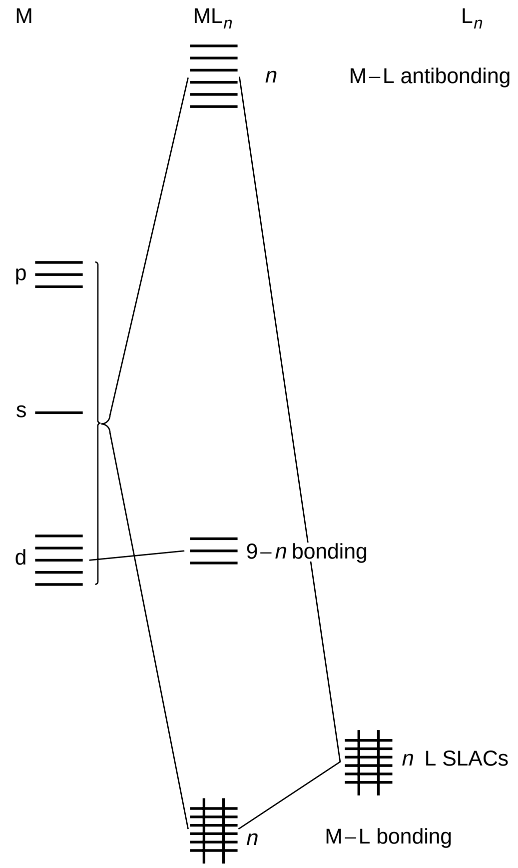

Figure 8 A generalized orbital interaction diagram for a ML_n transition metal complex

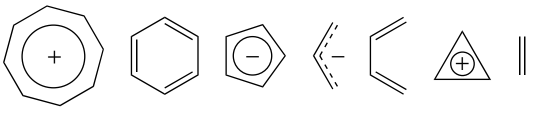


6 6 6 4 4 2 2 π electrons

(**20**)

charge (oxidation state) at the metal and subtracting it from the number of d electrons for the metal in the zero oxidation state gives the number of d electrons formally assigned to the metal d orbitals (those orbitals within the boxes in the previous sections). Summing the number of electrons donated by the ligand set and the number of d electrons then equals the total number of valence electrons. Notice that we have only counted the number of electrons which are M–L σ bonding along with the d electrons localized at the metal. No M–L π interactions have been counted.

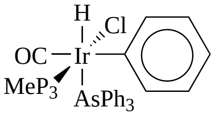
NR_3, PR_3, SR_2, CH_3^-, SiR_3^-, H^-	(σ donors)
CO, NO^+, CNR, SO_2, CR_2, CR^+	(π acceptors)
NR_2^-, Cl^-, OR^-, NR^{2-}, O^{2-}, P^{3-}	(π donors)

(**19**)

Polyenes are counted so that all bonding and nonbonding π orbitals associated with the polyene are occupied. The most commonly encountered examples are illustrated in (**20**). Below each structure is the number of π electrons (which interact with the metal in a σ fashion) used for polyene–M σ bonding provided that the metal is bonded to all carbon atoms in the polyene. Thus Cp donates six electrons only if it is an η^5 ligand. For an η^3-Cp situation, it donates four electrons analogous to a π-allyl ligand, etc.

There are two points that should be remembered. Firstly, the splitting patterns developed previously are not especially sensitive to the exact ligand set. This is especially true for the d-block. For example, in (**21**) there are six different ligands coordinated to the metal. There are three metal d MOs which are filled in this d^6 complex and lie very close together in energy. They correspond in shape to the t_{2g} set in Figure 2.

Two MOs lie at much higher energy and are metal–ligand antibonding, the $2e_g$ set. Secondly, the ligand σ donor set in (**21**) certainly is not contained within a narrow energy region. One might consider that the s orbital for H lies above the Ir d AOs; thus, it should be regarded as an H^+ (rather than H^-) ligand. Indeed, many metal hydrides are acidic (*see* ***Hydride Complexes of the Transition Metals***). One could then view (**21**) as a d^8 complex. The problem with this approach is that an Ir–H σ bond will be formed and lie lower than the t_{2g}-like set. It will be hybridized more at the metal (rather than the hydrogen). However, the t_{2g} set still contains six electrons. Little is gained by regarding (**21**) as a d^8 species.



(**21**)

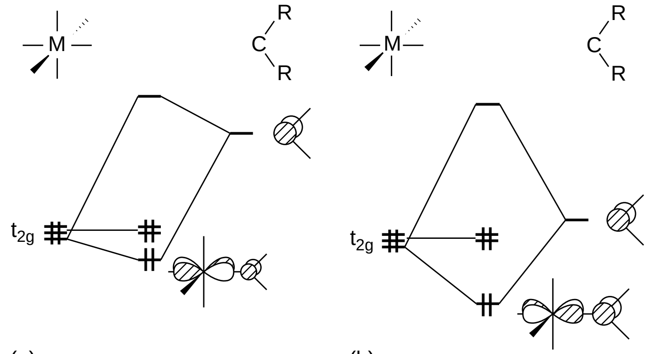


Figure 9 The π interaction between a carbene and metal for an octahedral system. Case (a) refers to a Fisher-type carbene and (b) to a Schrock-type carbene

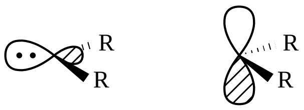
4 OVERLAYING π EFFECTS

The three t_{2g}-like orbitals in (**21**) do not all lie at the same energies. There will be some variation in energy because of the presence of the CO and Cl ligands which possess π-acceptor and π-donor functions, respectively. The t_{2g} set interact in a π-type fashion with the surrounding ligands. For the other splitting patterns this will occur always for the d-block nonbonding orbitals. Since π bonding is intrinsically weaker than σ, the latter can be viewed as a perturbation of the basic electronic structure set by the σ interactions.



(**22**) (**23**)

4.1 Typical π-Acceptor Patterns

A very simple π-acceptor ligand is the carbene. A carbene contains one hybrid orbital (**22**), which is used for σ bonding, and an orthogonal p AO (**23**), which can participate in π interactions with the metal.[21] Using the electron counting formalism in (**19**), (**22**) is regarded as being occupied with two electrons and (**23**) is empty. This is the signature of a π-acceptor ligand; a low-lying empty orbital must be present on the ligand. Figure 9 presents two cases for the π-type interaction between the carbene and metal in an octahedrally based system. In Figure 9(a), the carbene p AO lies well above the octahedral t_{2g} in energy. It mixes into, and stabilizes, one component of the metal t_{2g} set. As shown, the bonding combination is still largely localized on the metal. Electron density which in (**22**) is localized on the carbene is shared in the metal complex. The back donation of electron density from metal t_{2g} to the carbene for the π bond in Figure 9(a) does not entirely compensate that forward donation from the carbene to the metal in the σ system. Therefore, the carbene is electron deficient and the molecule behaves as an electrophile in terms of its reactivity. On the other hand, in Figure 9(b) the carbene p AO lies at the same energy (or perhaps even lower) as the metal t_{2g} set. The bonding combination, as shown, contains much more electron density on the carbene. Therefore, the molecule now reacts as a nucleophile. Of course, the situation also depends upon the metal and auxiliary ligands. The addition of other π acceptor ligands, for example, CO, and high oxidation states at the metal will cause t_{2g} to lie at a low energy and favor the situation in Figure 9(a). These are called Fisher-type carbene complexes. The addition of strong σ and/or π donating ligands, for example, Cp and amido, will favor Figure 9(b) and these complexes are called Schrock-type carbenes.

A slightly more complicated pattern is presented by the carbonyl ligand. On the right side of Figure 10 are the π and π^* orbitals of a carbonyl ligand. The electronegativity difference between C and O serves to localize more electron density on the O atom for the π set, whereas π^* is more concentrated on the C atom. Consequently the overlap between metal t_{2g} and π^* is greater than that between t_{2g} and π (the carbonyl is, of course, bonded to the metal via the carbon end). A three-orbital interaction pattern is formed. Two components of the metal t_{2g} set interact with the π and π^* orbitals. The lowest MO, 1e, is primarily carbonyl π with some metal d mixed in a bonding fashion. This is shown for one component in Figure 10. The highest MO, 3e, is shown to be primarily π^* antibonding to metal d. The middle level, 2e, is derived in (**24**). It is metal d mixed in a bonding fashion to the higher energy π^* and in an antibonding way to the lower π orbital. There is an approximate cancellation of electron density at the carbon atom in 2e. Notice in Figure 10 that one member of t_{2g}

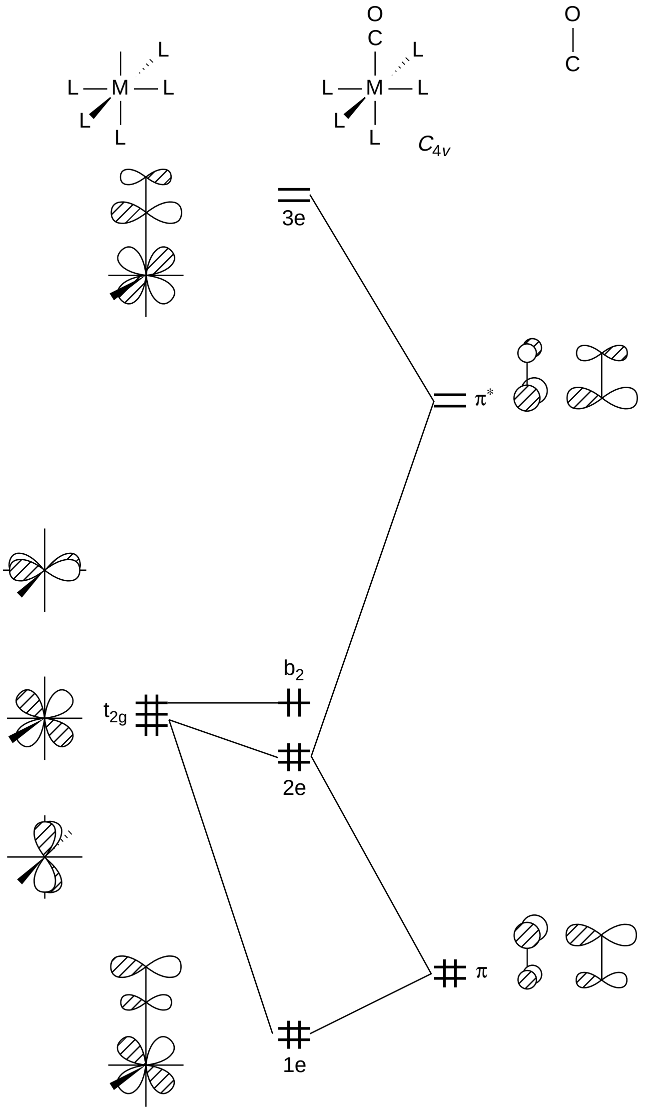


Figure 10 The π interactions for an octahedral complex with one carbonyl ligand

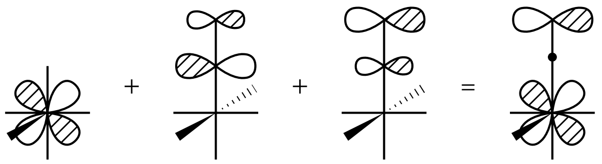

(24)

is unperturbed (b_2). How much the 2e MOs will be stabilized relative to b_2 will depend upon the metal and auxiliary ligands in an obvious manner. When the $t_{2g} - \pi^*$ energy gap increases, there is less stabilization associated with 2e. There is less π^* character in the 2e MOs. Since π^* is strongly C–O antibonding, the C–O stretching frequency increases. An example is provided by the isoelectronic $V(CO)_6^-$, $Cr(CO)_6$, and $Mn(CO)_6^+$ molecules where the C–O stretching frequencies are 1843, 1984, and 2094 cm^{-1}, respectively (*see* ***Transition Metal Carbonyls: Infrared Spectra***). The energy of the metal d AOs will decrease in that order since the electronegativity of the metal increases. Furthermore, there is a charging effect at work. The negative charge in $V(CO)_6^-$ causes the metal d AOs to rise in energy while the positive charge in $Mn(CO)_6^+$ has the opposite effect. These effects are nicely supported by density functional calculations on the isoelectronic series $Hf(CO)_6^{2-}$ to $Ir(CO)_6^{3+}$.[22] But just how much 'forward donation' from the lone pair of the CO ligand to empty $2e_g$ on the metal versus 'back donation' from the filled metal t_{2g} to the empty π^* on CO is there? Table 1 lists some calculated[23] values for a few representative $L{-}W(CO)_5$ complexes, where L is a π-acceptor ligand. Here 'forward' represents the electron density (in electrons) from the filled ligand σ orbital transferred to the metal and 'back' is the electron density transferred to the empty π-acceptor orbital on L. CO is a strong σ-donor and π-acceptor. On going to NO^+ one expects, on the grounds of electronegativity, that the σ and π levels will be lowered and so it should be a weaker σ-donor and a stronger π-acceptor than CO. The computations bear this out. Conversely, also for electronegativity reasons, CN^- is a very strong σ-donor and a weak π-acceptor and N_2 is neither a good σ-donor nor π-acceptor. The numbers here do not directly reflect the magnitude of the L–W bond energy. Other factors such as electrostatic and Pauli repulsion play and important role; however, it is easy to see why the N_2–W bond is extraordinarily weak. The CH_2 ligand, as indicated by Figure 9, is similar to CO. The last two entries in Table 1 will be discussed later.

4.2 π-Donor Effects

A π-donor ligand possesses a high-lying filled orbital that can serve to interact with and destabilize a member of the nonbonding metal d set. As an illustrative example we present the trans and cis dioxo problem. Figure 11(a) constructs the π orbitals for a trans dioxo–ML_4 complex. Two of the three members of the t_{2g} set can interact with two of the four SALCs of oxygen p AOs. Thus, one metal d and two oxo orbitals are left nonbonding. The orientation

Table 1 Charge decomposition for 'forward' and 'back' donation (in electrons) for a series of $L{-}W(CO)_5$ complexes[23]

L	Forward	Back (electrons)
CO	0.315	0.233
NO^+	0.119	0.378
CN^-	0.488	0.024
N_2	0.027	0.107
CH_2	0.314	0.282
C_2H_4	0.500	0.175
H_2	0.349	0.129

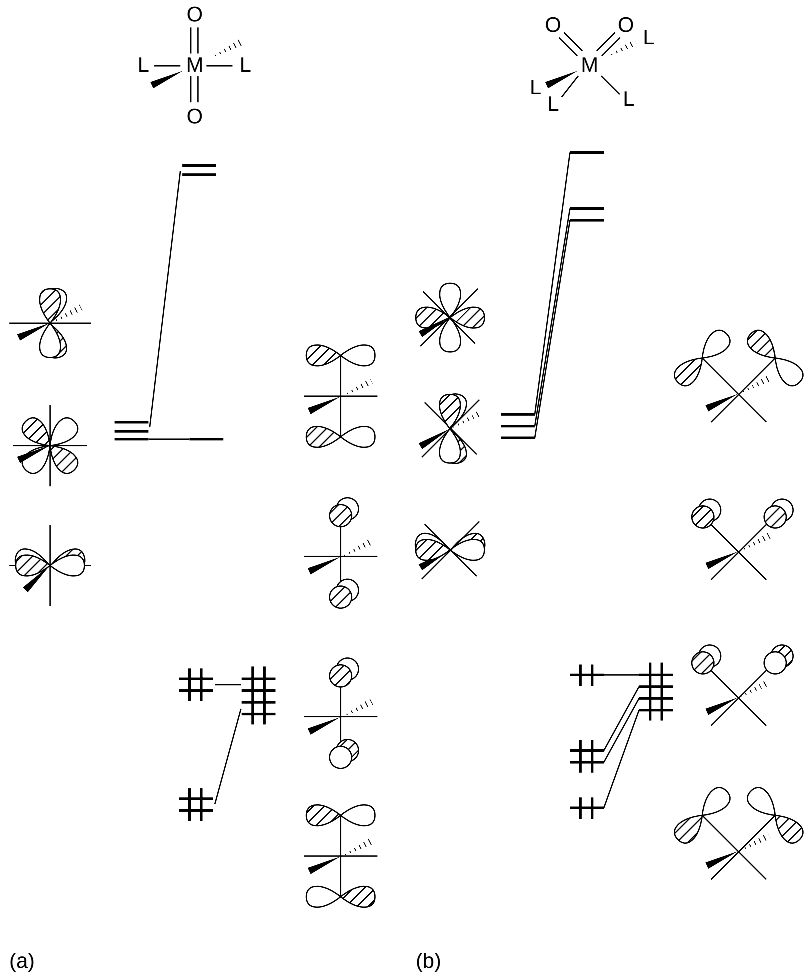

Figure 11 Building the π orbitals in a (a) *trans* and (b) *cis* dioxo–ML_4 complex

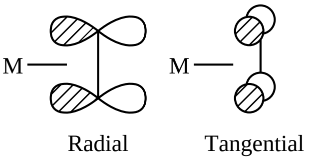
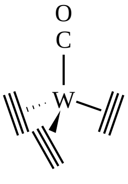
of the octahedron has been redrawn in Figure 11(b) for the cis dioxo–ML_4 case to facilitate comparison. Now all three members of t_{2g} are utilized for π bonding. One SALC of the dioxo set remains nonbonding. It is then clear that a d^0 complex prefers the cis geometry since maximal π bonding occurs at this geometry. But a d^2 complex prefers the trans structure since in it the HOMO is metal nonbonding. A cis d^2 complex has two electrons in a strongly M–O antibonding orbital. This is a general solution that can be applied to many different situations.[5] Given two geometries or conformations associated with a molecule, the most stable one maximizes all two electron–two orbital bonding patterns and minimize the four electron–two orbital ones. Thus, for a d^0 cis dioxo–ML_4 complex there are three two electron–two orbital interactions as opposed to the two in the trans dioxo–ML_4 case. In the d^2 system, there are no four electron–two orbital combinations for the trans geometry; however, there is one in the cis structure. Also notice that the oxo ligand has two perpendicular filled p AOs which can be used to form π bonds to the metal. Thus, in a dioxo complex one might naively be lead to the belief that there ought to be four π M–O bonds. Figure 11(a) and 11(b) demonstrate that this can never be the case. The trans complex (Figure 11(a)) can form two, and only two, π bonds for the d^0 and d^2 cases when symmetry has been properly taken into account. The cis structure can possess a maximum of three π bonds in a d^0 complex. A symmetry based approach in this instance lends itself to a clear and particularly simple solution. Some further effects of symmetry on the electronic structure of organometallic compounds are contained within the next section of material.

4.3 Extraordinary Symmetry Effects

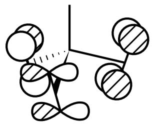
Acetylenes are adaptable ligands in that there are two orthogonal π orbitals which can be used for bonding to the metal. These are indicated by (**25**) as radial and tangential π orbitals. The radial orbital has a σ type overlap with the metal; however, that for the tangential one is of the π sort. Thus the acetylene ligand can be viewed as a two or four electron donor. Consider then the case of tris(acetylene)W(CO), shown



(**25**)



(**26**)



(**27**)

in (**26**). Counting the acetylene ligands as four electron donors yields a 20-electron complex. Given the discussion in Section 3, this would certainly seem to be unprecedented. When one forms the SALCs for the two types of acetylene π orbitals, then one radial combination, illustrated in (**27**), has unique symmetry features. This SALC cannot overlap with a d, s, or p AO on tungsten; it is left nonbonding and does not contribute to the electron count. Thus (**26**) is an 18-electron complex.

An even more spectacular example of the tricks that symmetry can play is provided by Ni(P-*t*-Bu)$_6$. Here the

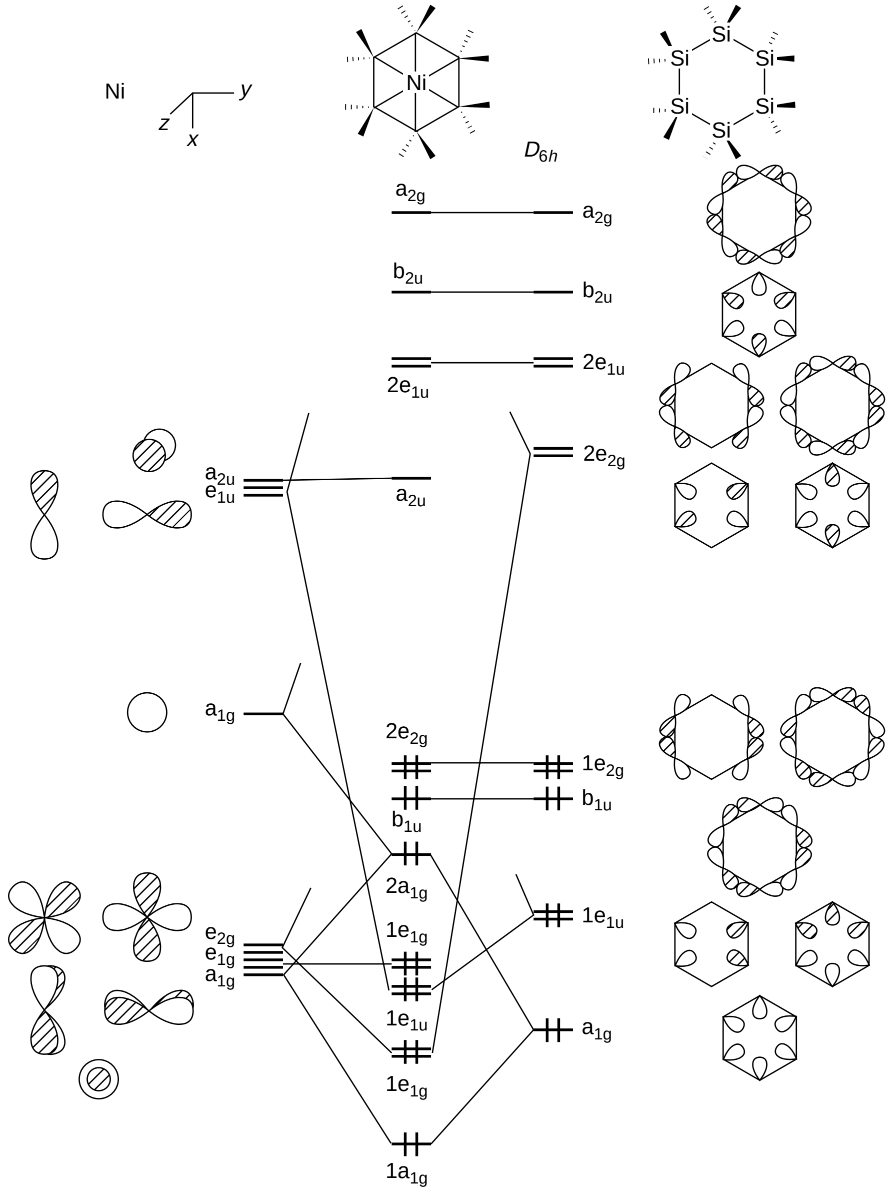


Figure 12 An orbital interaction diagram for Ni(SiR$_2$)$_6$

Ni and six phosphorus atoms lie in a common plane.[24] But rather than developing the electronic structure in this molecule, an isoelectronic example will be used to highlight the symmetry features more clearly. A SiR_2 ligand is electronically analogous to PR since in this instance the extra lone pair on PR is not involved in bonding to the metal. Of course, SiR_2 is isoelectronic with a carbene. Thus $Ni(SiR_2)_6$ along with $Ni(PR)_6$ might be considered to be a d^{10}, 22-electron complex! The Si atoms lie in a common plane so that, given a Ni−Si distance of 2.41 Å, the Si–Si distance between adjacent ligands is also 2.41 Å. This is somewhat longer than the Si–Si distances in silanes ($\approx$ 2.35 Å; *see* ***Silicon: Inorganic Chemistry***). The same feature is present in Ni(P-*t*-Bu)$_6$. One might then consider $Ni(SiR_2)_6$ to be a Ni complex of cyclohexasilane. The important point is that there will also be Si–Si interactions present in the compound. There will be six SALCs derived from the radial orbitals on SiR_2 groups that are directly pointed at the Ni atom and analogous to (**22**). As indicated on the right side of Figure 12, three SALCs, $a_{1g} + 1e_{1u}$, are Si–Si bonding and stay at low energy while three, $2e_{2g} + b_{2u}$, are strongly Si–Si antibonding and are at a much higher energy for the radial set. The six SALCs of tangential Si p AOs analogous to (**23**) form the same pattern. Three, $b_{1u} + 1e_{2g}$, are Si–Si bonding and the other three, $2e_{1u} + a_{2g}$, are Si–Si antibonding. The formal electron count associated with the Si_6R_{12} fragment is put at 12 electrons, identical to that in a cyclohexasilane. The Ni x and y AOs interact with and stabilize the $1e_{1u}$ SALC. The $2e_{2g}$ SALC stabilizes Ni $x^2 - y^2$ and *xy*. The Ni z^2 and s AOs along with the a_{1g} SALC combine to form a three-orbital pattern where the bonding and nonbonding MOs are occupied. The Ni *xz* and *yz* d AOs remain rigorously nonbonding. A key feature in this analysis is that the $1e_{2g}$ SALC does not have an appreciable overlap with $x^2 - y^2$ and *xy*. Since $1e_{2g}$ is composed of tangential combinations, most of the electron density lies around and to the outside of the periphery of the Si ring. The b_{1u} SALC does not have a symmetry match with the metal set of AOs. Therefore three MOs, $b_{1u} + 2e_{2g}$, with six electrons remain Si–Si bonding in the molecule. There are eight MOs, $1a_{1g} + 1e_{2g} + 1e_{1u} + 2e_{1g} + 2a_{1g}$, with 16 electrons that are either metal centered or metal−ligand bonding, that is, this is a 16-electron, not 22-electron, complex. Electron density from the filled $1e_{1u}$ Si–Si bonding orbital is transferred to the Ni x and y AOs. There is also back donation from the filled $x^2 - y^2$, *xy* set to the empty Si–Si antibonding $2e_{2g}$ orbital. Thus the Si–Si bonding present in the cyclohexasilane is reduced upon forming the complex. Exactly the same electronic structure is present in $Ni(PR)_6$. Theoretical work[25] in this laboratory on $Ni(SiH_2)_6$ shows that it is a minimum at the geometry shown in Figure 12. Furthermore, the binding energy for it, calculated relative to ground-state Ni (d^8s^2) and the optimized geometry for Si_6H_{12} in the chair geometry, is over 280 kJ mol^{-1} at a highly correlated level.[25] This is similar to what has been found by theory for $Ni(PMe)_6$.[24]

5 FRAGMENT ORBITALS

The methods used in the two previous sections can be easily applied to any mononuclear transition metal complex where the ligand presents one σ donor function to the metal. For a polyene−ML_n complex or a transition metal dimer, it is frequently more useful to construct the electronic details by dividing the molecule into two fragments and then allowing the fragment orbitals to interact with each other. The virtue of this method is that one can concentrate exclusively on the bonding in one region of a molecule. The effects of the auxiliary ligands are present in that they will tailor the shapes and determine the relative energies of the fragment orbitals. Rather than assembling the orbitals of an ML_n fragment by interacting the n SALCs with the AOs of the metal, we shall take a reductive approach. Using the splitting patterns already established in Section 3, we will consider what occurs when one or more ligands are removed from the transition metal complex. The ligand L will again be viewed as a generic two-electron σ donor. Our starting point will be the octahedron and square plane in each instance.

5.1 The ML_5 and ML_3 Fragments

The metal d-centered orbitals for an octahedral ML_6 complex are shown on the left side of Figure 13. These are just the MOs developed in Section 3.1. When one ligand is removed, only one perturbation occurs. The z^2 component of $2e_g$ loses much of its antibonding. Therefore, that orbital, a_1 on the right side of Figure 13, is stabilized considerably. It also becomes hybridized by mixing metal s and p so that it has radial extent in the direction of the missing ligand. The other orbitals are unperturbed; there are three metal nonbonding orbitals, $e + b_2$, and one strongly M–L antibonding orbital, b_1. The five orbitals here are identical to those for a square pyramid on the right side of Figure 7 except for one minor detail. In Figure 7, the basal−M−apical angle is greater than 90°; therefore the e set is destabilized by the basal ligand σ donors relative to the b_2 orbital. In Figure 13 the basal−metal−apical angle is 90°; and e is at the same energy as b_2.

Figure 14 shows the evolution of the metal d oribtals in a square-planar complex when one ligand is removed to form an ML_3 fragment. Here again there is only one significant perturbation. One-fourth of the antibonding to metal $x^2 - y^2$ is removed and so the $2a_1$ fragment orbital of ML_3 is stabilized. It is also hybridized towards the missing ligand. The other four orbitals remain nonbonding. It was demonstrated in (**15**) that there is an electronic relationship between the metal d-centered orbitals for an octahedron and square plane. This extends to the fragment orbitals derived from them, as well. Each has a set of nonbonding orbitals (three for a ML_5 fragment and four for ML_3) and one hybridized orbital at moderate energy. Thus, a d^n ML_5 fragment is electronically analogous to a d^{n+2} ML_3 one. We shall defer an illustration of the use of these fragment orbitals to Section 5.3.

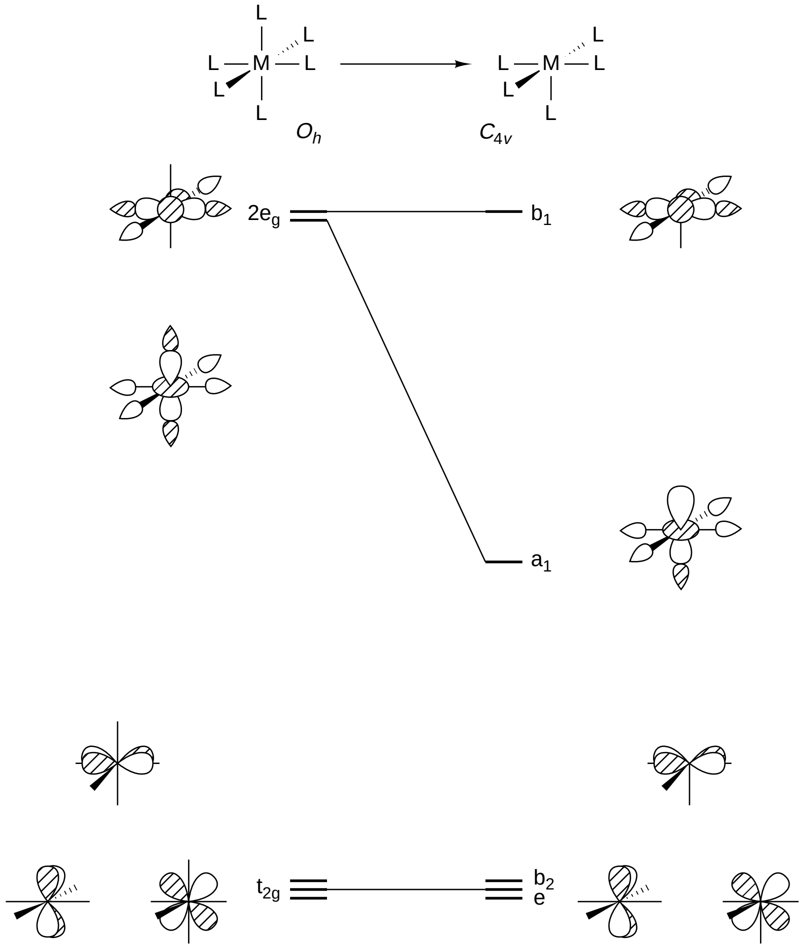

Figure 13 Construction of the important valence orbitals for a ML_5 fragment

5.2 The ML_4, ML_3, and ML_2 Fragments

The orbitals of an ML_4 and ML_2 fragment are constructed by removing two cis ligands. The resultant fragment orbitals are displayed in Figure 15 and 16. In each case, two M–L antibonding orbitals are stabilized. One is descended from a metal d and the other from a metal s-based orbital. For both orbitals in each example, metal p character also mixes in such a way to hybridize them towards the missing ligands. There is again a correspondence between the electronic structure of a d^n ML_4 and d^{n+2} ML_2 fragment.

The orbitals of a pyramidal ML_3 fragment can be obtained by removing three fac ligands from an octahedron. This is done in Figure 17. The orbitals of an octahedron on the left side have been modified in form to correspond to the removal of the three fac ligands. The t_{2g} set is still rigorously M–L nonbonding and e_g is M–L antibonding. Removing the three fac ligands stabilizes three antibonding orbitals. In each case, metal p mixes to hybridize the orbitals towards the missing ligands. The other three fragment orbitals do not change in their composition or energy.

The common theme which runs through this and the previous section is that when one removes one, two, or three ligands from an octahedron then one, two, or three fragment orbitals are formed at moderate energies. These orbitals originate from metal d or s orbitals which are antibonding to the surrounding ligands and are hybridized towards the missing ligand sites by mixing metal p character into them. All other orbitals in the metal d-block are essentially unaffected and remain at the same relative energies as their octahedral or square-planar counterparts.

5.3 The Electronic Structure of Polyene–ML_nComplexes

The utility of fragment orbitals can be documented in many different situations.[8] Here only two examples, alkene−ML_n and $CpML_3$ complexes, are covered. We start with Zeise's salt, ethylene−$PtCl_3^-$. A $PtCl_3^-$ fragment is d^8; the electron occupancy for the five fragment orbitals is shown on the left side of Figure 18(a). The empty $2a_1$ $PtCl_3^-$ hybrid interacts with and stabilizes the π orbital of the ethylene ligand while filled b_2 is stabilized by ethylene π^*. The same basic pattern

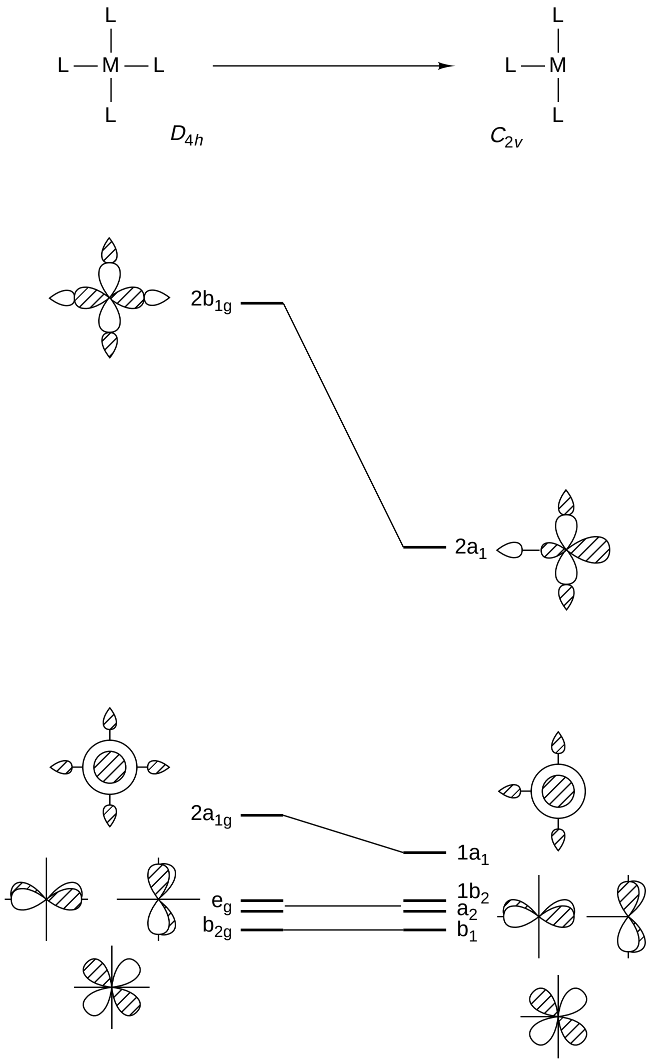

Figure 14 Correlation of the metal d orbitals from a square-planar complex to a ML_3 fragment

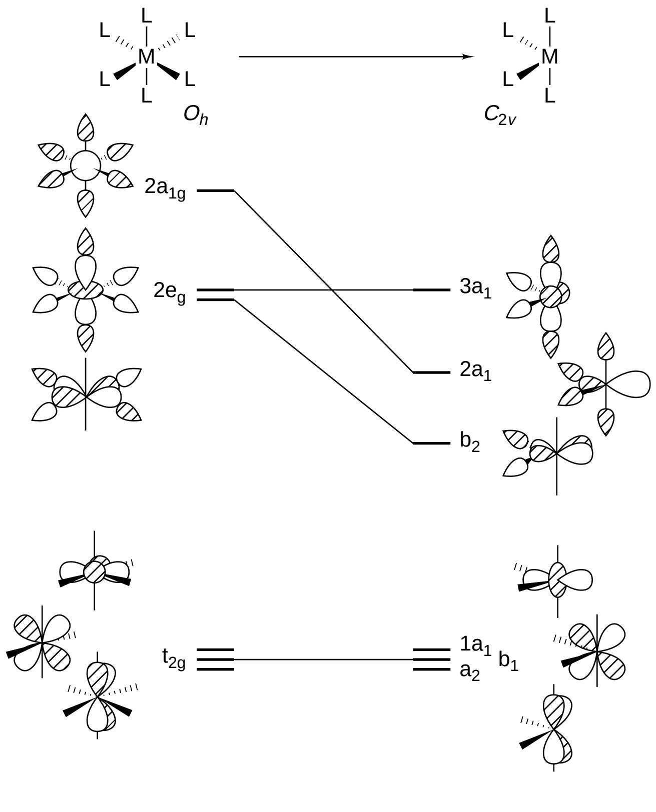

Figure 15 Derivation of the important valence orbitals in a ML_4 fragment

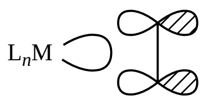
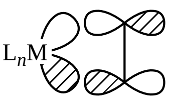
unfolds for ethylene–$Fe(CO)_4$ in Figure 18(b). One slight complication exists in that there are now two fragment orbitals, $1a_1$ and $2a_1$, on the $Fe(CO)_4$ fragment which interact with ethylene π. The bonding and nonbonding combination in this three-orbital interaction are filled. Notice that the splitting pattern for a trigonal bipyramid has been reestablished. The nonbonding a_1 combination along with the b_2–π^* MO are analogous to the 2e′ set in the trigonal bipyramid (see (**17**) and Figure 7). The lower two MOs, b_1 and a_2, correspond to the e″ set. It is also clear in Figure 18(a) that the square-planar splitting pattern has been recreated.



(**28**)



(**29**)

One can easily work through other examples of alkene–transition metal complexes. In each instance an empty orbital on the ML_n fragment will stabilize ethylene π as shown in (**28**). Electron density flows from the ethylene to the ML_n unit and is called forward donation. There will also always be one filled metal d orbital that will be stabilized by ethylene π^* (**29**), which is back donation. Electron density then is transmitted from the metal to the alkene. This is the essence of the Dewar–Chatt–Duncanson model. Referring back to Figure 13, a d^6 ML_5 fragment, for example, $W(CO)_5$, will use the a_1 orbital to interact with ethylene π and one member of the e set to participate in backbonding with ethylene π^*. Table 1 shows that for $(C_2H_4)W(CO)_5$ forward donation is more important than back donation. But there certainly is a spectrum of examples where the relative importance of each interaction varies and this, in turn, depends upon energy gap and overlap factors. The essence of the Dewar–Chatt–Duncanson bonding model is also present in the metal-carbene and metal-carbonyl bonding models that were presented in Section 4.1. A very related situation occurs in metal-dihydrogen complexes (**30**). Stylized representations of forward and back donation are given in (**31**). Table 1 shows that the relative magnitude of these interactions in $H_2W(CO)_5$ is similar to the ethylene example. A unique feature, however, in $H_2W(CO)_5$ is that forward donation of electron density from H_2 σ to the metal weakens the H–H bond. Likewise back donation from the

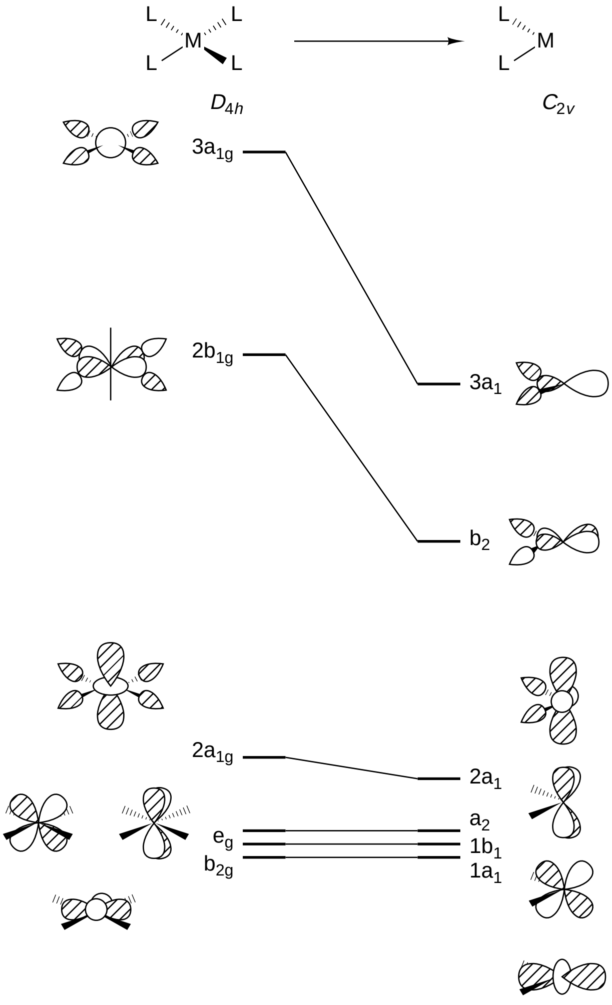


Figure 16 The orbitals for a ML_2 fragment

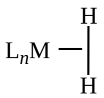
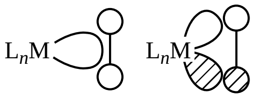
metal to H_2 σ^* also weakens the H–H bond. If the two interactions in (**31**) become strong enough, then the H–H bond will elongate to the extent that it becomes broken – oxidative addition occurs.



(**30**)



(**31**)

The cyclopentadienyl ligand is pervasive in organometallic chemistry. An orbital interaction diagram for $CpMn(CO)_3$ is presented in Figure 19. The lowest Cp π orbital, a_2'', interacts primarily with $2a_1$ to form a filled bonding and empty antibonding combination. The overlap between a_2'' and $1a_1$ is quite small. The p AOs in a_2'' lie approximately in the nodal cone of the z^2 orbital (see the top of Figure 1). The 2e orbitals on $Mn(CO)_3{}^+$ interact with e_1'' on Cp to form a filled bonding and empty antibonding MO. The 1e set on $Mn(CO)_3{}^+$ do not overlap much with the π^* Cp orbitals (e_2'') and there is a large energy gap between these fragment orbitals. Therefore 1e is stabilized only a small amount and these orbitals are more localized on the metal. The situation which unfolds in Figure 19 should look familiar. Three Cp based orbitals bonding to the metal are at low energy. Another three CO σ donor orbitals will also lie in this energy region and are not shown. There are three predominantly nonbonding metal d orbitals grouped together in a narrow energy range which are also filled and lie at a moderate energy. Finally, there are two primarily metal d orbitals which are strongly Cp–Mn antibonding. They are at high energy and empty. We have restored the octahedral splitting pattern. Another way of putting this is that a Cp^- ligand is electronically equivalent to a fac L_3 set of σ donors. The $a_2'' + e_1''$ set of π orbitals in Cp^- are topologically analogous to the SALCs in L_3. This is also true for the three occupied π levels in benzene. Thus the

orbital interaction diagram for benzene–$Cr(CO)_3$, ferrocene, or bis(benzene)Cr all strongly resemble an octahedron.

6 THE ISOLOBAL ANALOGY

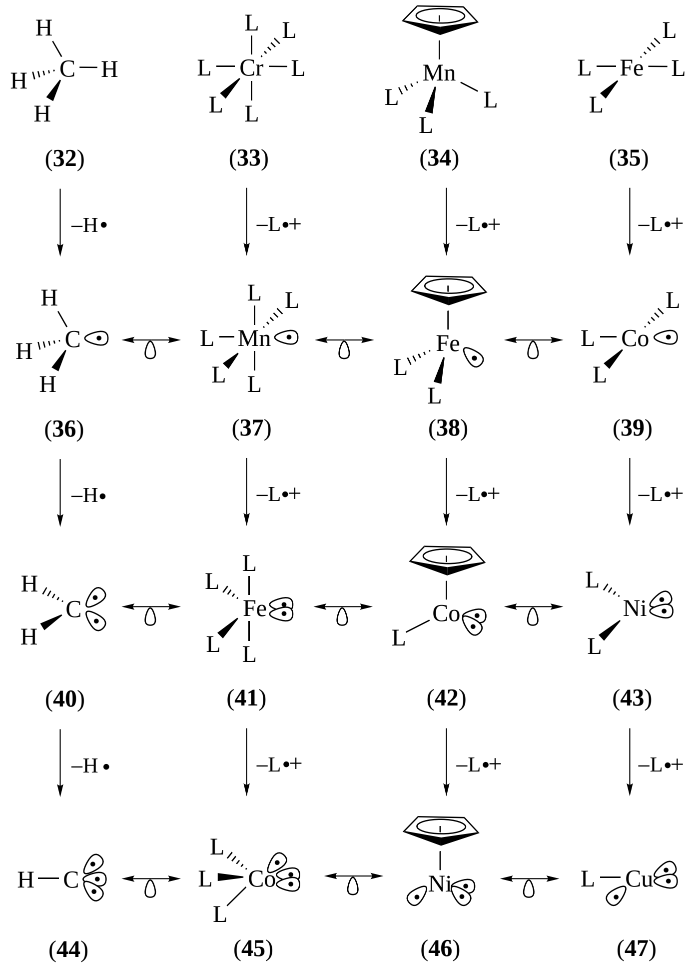
In the preceding sections, relationships between the electronic structure of different molecules and fragments have been stressed. We shall now formalize this relationship and extend it greatly via the isolobal analogy.[5,26] Two molecules or fragments are determined to be isolobal if their frontier orbitals:

- are equal in number
- are identical in symmetry properties
- have the same number of electrons
- have approximately the same relative energies in comparison to the other orbitals
- have approximately the same radial extent

The first three criteria are absolute; however, the last two standards are only approximated. Thus the isolobal analogy is relatively crude, but it is very useful since it relates the important orbitals in organic, organometallic, main group, and inorganic molecules to each other in a particularly simple fashion. The isolobal analogy can then be used as a short-cut to understand the basic electronic structure in a molecule. It can also be used to classify molecules that would appear to be quite different upon quick inspection and provide a mechanism for predicting the existence of unknown molecules. Finally, it offers clues about reactivity and possibly about reaction mechanisms.

6.1 Building Isolobal Fragments

Scheme 1 illustrates how isolobal fragments can be generated and specifies what the frontier orbitals are that were



Scheme 1

discussed in the previous paragraph. Methane (**32**) is taken as the archetypical example of an 8-electron molecule. CrL_6 (**33**) and $CpMnL_3$ (**34**) are two particular starting points in the inorganic/organometallic world. In both cases, L is taken to be a neutral, two-electron donor ligand. So in (**33**) and (**34**) the metal has an 18-electron count associated with it. The square-planar FeL_4 complex (**35**) represents a 16-electron starting point. Molecules (**32**)–(**35**) then all represent electronically saturated molecules. All bonding and nonbonding orbitals are occupied and all antibonding MOs are empty. When a C–H bond in methane is broken in a homolytic fashion, one orbital (to use loose terms, an sp^3 hybrid) at moderate energy is formed and there is one electron associated with it. This is what shall be termed a frontier orbital; it is hybridized so that it points towards the missing ligand as in (**36**). Breaking one Cr–L bond in a homolytic fashion in CrL_6 generates a CrL_5^- fragment that is isoelectronic with MnL_5 (**37**). This fragment has also one frontier orbital at moderate energy with one electron in it. The specific orbital that we are referring to is a_1 in Figure 13. It too is hybridized out towards the missing ligand. Therefore (**36**) and (**37**) are said to be isolobal. This relationship is symbolized by the double-headed arrow with the teardrop shape below it as shown in Scheme 1.

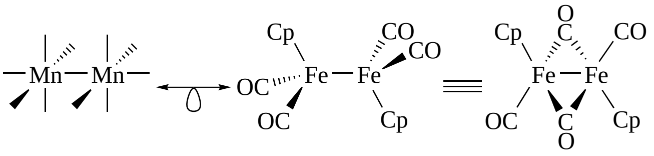
Removing one ligand in a homolytic manner from $CpMnL_3$ and FeL_4 generate the $CpFeL_2$ (**38**) and CoL_3 (**39**) fragments, respectively. The frontier orbital for (**39**) is $2a_1$ in Figure 14. Recall that, in Section 5.1, it was shown that a d^n ML_5 fragment is electronically analogous to a d^{n+2} ML_3 one. Here we extend this to show that (**36**)–(**39**) are all isolobal to each other. Removing two hydrogen atoms in methane generates the methylene fragment (**40**). There are now two frontier orbitals with two electrons partitioned in them. Removing two cis ligands in CrL_6 forms the FeL_4 fragment (**41**), which is isolobal to CH_2. The frontier orbitals in (**40**) and (**41**) are localized constructions. Their delocalized, symmetry correct counterparts are shown in (**22**) and (**23**) for CH_2 and the $2a_1$ along with b_2 orbitals in Figure 15 for FeL_4. Both (**22**) and $2a_1$ are cylindrically symmetrical, whereas both (**23**) and b_2 contain one nodal plane. One can also generate the CpCoL (**42**) and NiL_2 (**43**) fragments by removing two ligands from the parent molecules and they are isolobal to CH_2 and FeL_4. Finally, breaking three C–H and M–L bonds in a homolytic

manner generates the isolobal series (**44**)–(**47**). In each case there are three frontier orbitals with symmetry properties analogous to $2a_1$ and 2e in Figure 17 and three electrons are housed in them. The fragments shown in Scheme 1 are but a small subset. One can, of course, use isoelectronic replacements so that SiH_2, OsL_4, and $CpOsL^+$ are isolobal to the (**40**)–(**43**) series. There is almost a limitless diversity in the ligands that can be used for the transition metal complexes and the organic partners can have substituents other than hydrogen. Thus $Fe(CO)_4$, $Ni(PPh_3)_2$, CpPdCl, and Ph_2Pb are all isolobal and identical to the (**40**)–(**43**) generic examples. One can adjust the electron count in the frontier orbitals; an isolobal series where there is one frontier orbital and no electrons in it is CH_3^+, $Cr(CO)_5$, and $CpRu(CH_3)(PMe_3)$. Likewise, BH, $Fe(CO)_3$, and CpCo represent an isolobal set where there are three frontier orbitals with two electrons in them. Finally, one can also use many other starting points other than those listed in Scheme 1. For example, the 18-electron trigonal bipyramidal FeL_5, benzene–CrL_3, and tetrahedral NiL_4 could be used to generate fragments. For 16-electron species, trigonal planar NiL_3 or Cp_2ZrMe_2 are equally valid starting points. In this respect, it is important to establish the coordination geometry in the molecule that is formed. In other words, a $Ni(CO)_2$ fragment may have been derived from a 16-electron trigonal plane, a 16-electron square plane, an 18-electron trigonal bipyramid, an 18-electron tetrahedron, or even an 18-electron octahedron! All have different numbers of frontier orbitals and/or different numbers of electrons in them.

The species generated in Scheme 1 can be viewed as molecules in their own right. Thus, for example, CH_3, $Mn(CO)_5$, and $CpFe(CO)_2$ all are very reactive molecules that according to (**36**)–(**38**) have one electron in an orbital at moderate energy, so all undergo similar free radical abstraction reactions. The series of CH_2, $Fe(CO)_4$, and $CpIr(PMe_3)$ each have two electrons in two orbitals (see **40**–**42**); therefore each will have singlet and triplet electronic states associated with them. Singlet CH_2 undergoes a C–H insertion reaction with alkanes, as does $CpIr(PMe_3)$. The major use for the species in Scheme 1, however, is to use them as interchangeable fragments, thus generating alternative molecules. Some typical examples are demonstrated in the next section.

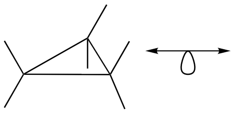
6.2 Uses of the Isolobal Analogy

Consider the first row of fragments given by (**36**)–(**39**) in Scheme 1. The methyl fragment is then isolobal to $Mn(CO)_5$, $CpFe(CO)_2$, and $Pt(PPh_3)_2Cl$ in terms of specific examples. Thus one methyl group in ethane can be replaced by an isolobal partner to generate $CH_3Mn(CO)_5$, $CpFe(CO)_2(CH_3)$, and $CH_3Pt(PPh_3)_2Cl$. All are known molecules. Replacing two methyl groups will generate $Mn_2(CO)_{10}$ (**48**) and $Cp_2Fe_2(CO)_4$ (**49**). However, $Cp_2Fe_2(CO)_4$ does not have this structure. Instead, two carbonyl groups migrate from terminal to bridging positions, as shown in (**50**). What occurs here is a common, low-energy phenomenon in metal-carbonyl chemistry (*see* ***Carbonyl Complexes of the Transition Metals***). What is perturbed most in the terminal to bridging structural distortion is the interaction between carbonyl π^* orbitals with the members of the nonbonding, t_{2g}-like orbitals. The frontier orbitals used by the isolobal analogy are not greatly affected. Thus (**49**) is regarded as being electronically analogous to (**50**).

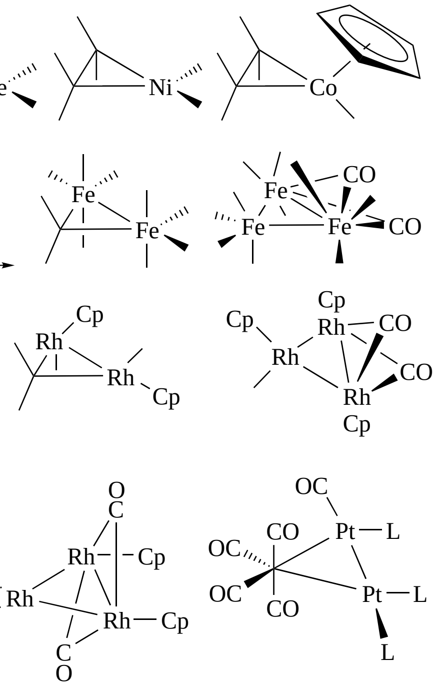


(**48**) (**49**) (**50**)

Using the second row of isolobal fragments (**40**)–(**43**), one can replace one, two, or all three CH_2 units in cyclopropane (**51**) by isolobal partners to form the molecules listed in (**52**). Notice that the top row of structures have been drawn as metallacyclopropanes and that these are equivalent (see Section 5.3) to metal–alkene complexes. The essential details of the bonding and their conformational preferences[5] are identical in each molecule.

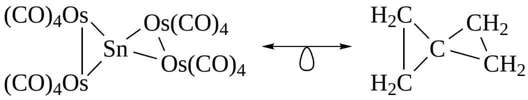


(**51**)

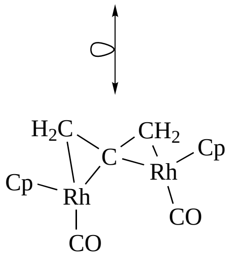


(**52**)

An interesting series is provided by (**53**)–(**55**). In (**53**), replacement of the $Os(CO)_4$ fragments with isolobal CH_2 and Sn with isoelectronic carbon yields spiropentane (**54**). Replacement of two CH_2 units in spiropentane with isolobal



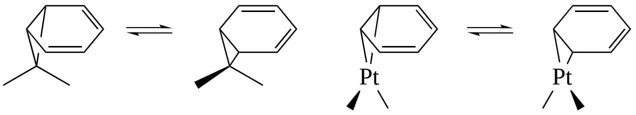
(53) (54)



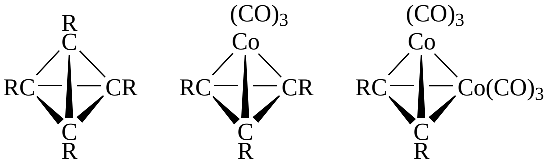
(55)

CpRh(CO) gives the allene complex (**55**). All three molecules, with very different architectures, are isolobal!

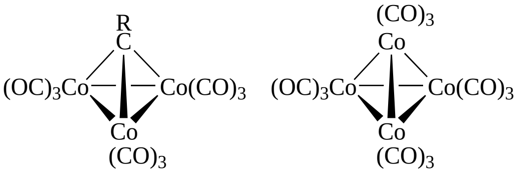
A special kind of sigmatropic rearrangement is shown in (**56**). The isolobal analog is shown in (**57**) where CH_2 has been replaced by $Pt(PR_3)_2$. What is interesting here is that there is a very specific stereochemistry predicted for the rearrangement in each case which is determined by orbital symmetry. However, an alternative route has been shown to occur for both molecules.[27] Thus the reaction mechanisms for (**56**) and (**57**) are thought to be identical. The stereochemical details have been experimentally determined for (**56**) but, thus far, only computationally for (**57**).[27] The reader should again note that the isolobal analogy has been constructed on a very elementary level. Of course, the activation energies for (**56**) and (**57**) are quite different.



(**56**) (**57**)



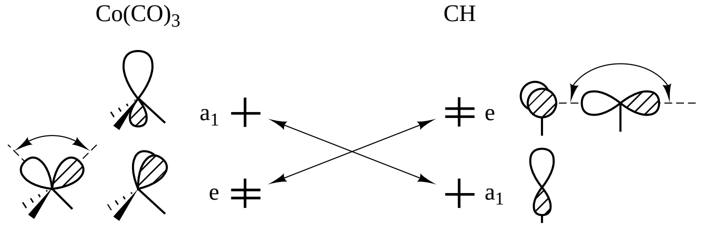
(**58**) (**59**) (**60**)



(**61**) (**62**)

As a final example of the isolobal analogy consider the bottom row of isolobal fragments in Scheme 1. In particular, a CR and $Co(CO)_3$ fragment each have three frontier orbitals with three electrons partitioned in some fashion among them. All of the molecules given by (**58**)–(**62**) have been isolated. In the order that the compounds have been presented, one CR unit has been sequentially replaced by an isolobal $Co(CO)_3$ fragment. Molecule (**59**) is commonly represented as a cyclopropenium–$Co(CO)_3$ polyene type of complex and (**60**) as an acetylene π complex of $Co_2(CO)_6$. However, this is really more of a question of artistic taste than scientific merit. It is analogous to the metal–alkene versus metallacyclopropane controversy which was commented on in Section 5.3. The important point, and nicely illustrated by the frontier orbitals of (**44**) and (**45**), is that there will be three filled C–C σ bonds in (**59**). One frontier orbital with one electron then remains on each C–R unit. These will then form an additional three filled Co–C σ bonds with the $Co(CO)_3$ fragment. From a cyclopropenium–$Co(CO)_3$ perspective, the cyclopropenium cation ligand has three π orbitals (see **20**). The lowest, totally symmetrical π orbital is filled and the other two are empty. A $Co(CO)_3{}^-$ fragment is d^{10} and, therefore, there are four electrons in the 2e set in Figure 17 and $2a_1$ is empty. The $2a_1$ and 2e fragment orbitals combine with the three π orbitals of cyclopropenium to form three two orbital–two electron interactions. This is identical to what the isolobal analogy presents to us.

There is also an important caveat that the (**58**)–(**62**) series highlights. Tetrakis-*t*-butyltetrahedrane (**58**) has only recently been prepared. The parent (R = H) molecule certainly is predicted to be extremely reactive because of the ring strain present in (**58**). Ring strain, if at all present, is much less in (**61**) and (**62**). A comparison of the frontier orbitals for $Co(CO)_3$ and CH is given in (**63**) and (**64**), respectively. The e and a_1 set in (**63**) are stylized representations of 2e and $2a_1$ for an ML_3 fragment in Figure 17. The a_1 frontier orbital contains Co s and p character. Its form *and* radial extension precisely match the a_1 frontier orbital for the CH fragment in (**64**). The e set of $Co(CO)_3$ is primarily metal d with some p character, whereas that for the CH unit is exclusively comprised of carbon p AOs. Consequently, the angle formed between the lobes in the e set of $Co(CO)_3$, as shown in (**63**), is $\approx 90°$; whereas the lobes for the e set in CH are positioned 180° with respect to each other. The form (symmetry) of the e set in each isolobal fragment is identical. However, the radial extent is only similar; in both instances the e set is directed away from the carbonyls and hydrogen atom. In constructing the MOs of tetrahedrane the a_1 hybrids form one bonding and three antibonding MOs. The e sets produce five bonding/nonbonding and three antibonding MOs. Precisely the same combinations occur in (**59**)–(**62**). An important difference lies in the fact that the overlap of the e sets in the bonding MOs of tetrahedrane does occur in a σ-type fashion; however, the electron density does not reside along the C–C vectors. Because p AOs are used, the electron density maxima will occur on the outside of the tetrahedrane skeleton and this is the electronic origin of ring strain. Using d functions in the $Co(CO)_3$ e set for $Co_4(CO)_{12}$ creates σ



(**63**) (**64**)

overlap in a direction much closer to the Co–Co vectors. Notice that there is also an inversion of the level ordering for the a_1 and e frontier orbitals on going from $Co(CO)_3$ to CH. This is simply a reflection of the fact that a metal s AO in (**63**) lies higher in energy than the metal d AOs. On the other hand, in (**64**) the s AO for carbon or another main group atom lies lower in energy than the p AOs. This is a minor difference, since what is important is the number of MOs that are filled upon interacting the frontier orbitals in the molecule. That is identical in both number and form for the series given by (**58**)−(**62**). A molecule whose existence is predicted on the basis of the isolobal analogy may be too reactive to isolate. However, its utility allows one to cross many boundaries in chemistry and offers a very different vantage point for viewing the electronic structure in molecules.

1 INTRODUCTION

Solids are just infinite molecules. Thus, at least in principle, there is no reason why their electronic structures could not be studied using the same techniques and concepts currently used for molecules. However, there is an obvious technical problem because the size of the matrices to be handled is, in fact, infinite. In the case of periodic solids this problem can be easily circumvented by fully exploiting their translational symmetry. Once this is done, the size of the matrices is reduced to that of the unit cell and the problem disappears. A specially simple and useful technique developed by solid-state physicists is the so-called tight-binding method (*see Tight-binding Approximation*), in which the wavefunctions describing the motion of an electron in the solid (i.e. the *Crystal Orbitals*) (CO) are expressed as a linear combination of atomic orbitals (LCAO) or similar local functions. There is an obvious parallelism with the traditional Molecular Orbital Theory (*see* ***Molecular Orbital Theory***) developed by chemists, in which the wavefunctions describing the motion of an electron in the molecule (i.e. the *Molecular Orbitals*) (MO) are also expressed as a LCAOs. As a matter of fact, the first orbital describing the motion of an electron in a polyatomic system was written by Bloch in 1928 and it was a CO. Hence, MO theory finds its roots in solid-state physics.

Being able to calculate (remarkable advances in that direction have been accomplished during the last decade) does not mean being able to understand. Despite the common roots of the MO and tight-binding ideas, physicists and chemists have developed very different ways to rationalize the results of their calculations. A specially fruitful approach used by chemists in order to understand molecular structure and reactivity problems is that of the orbital interaction analysis[1] of the wavefunction. This method provides a simple yet very powerful way to relate the electronic and geometric structures of molecules. It was then a natural choice for chemists trying to understand why a certain solid has the physical properties or the crystal structure it has, to use the conceptual framework provided by the orbital interaction analysis. This approach has been indeed extremely fruitful in providing a real understanding of the chemistry and physics of solid-state materials.[2–5]

In the present contribution, we will examine the fundamentals of such an approach. We first describe some basic notions of the tight-binding method to build the COs of an infinite periodic solid. Then we consider how to analyze the nature of these COs from the viewpoint of orbital interaction by using some one-dimensional (1D) examples. We then introduce the notion of density of states (DOS) and its chemical analysis, which is especially valuable in understanding the structure of complex 3D solids or in studying surface related phenomena. Later, we introduce the concept of Fermi surface needed to examine the transport properties of metallic systems and consider the different electronic instabilities of metals. Finally, a brief consideration of the more frequently used computational approaches to the electronic structure of solids is presented.

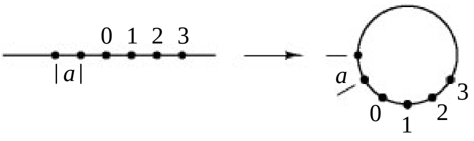
2 CRYSTAL ORBITALS AND BAND STRUCTURE[6]

Let us consider the 1D lattice (**1**) with repeat distance a, where each unit cell contains just one atomic orbital (AO) χ. The simplest way to describe the energy levels of this system is to impose Born–von Karman boundary conditions. Essentially, this means that we are bending our system as shown in (**2**), that is, we are transforming the chain into a loop. However, since the number (N) of sites is very

large, this bending of the chain is imperceptible as far as the atoms of the chain are concerned. The different orbitals of the system can now be easily found by using the symmetry properties of cyclic groups and they are given by equation (1)

$$\phi(k) = N^{-1/2} \sum_n \exp(ikna)\chi(r - na) \quad (1)$$

(**1**)



(**2**)

where N is the number of unit cells in (**1**), $\chi(r - na)$ is the AO χ located at the nth unit cell and $k = 2\pi j/Na$, with $j = 0, \pm1, \pm2, \ldots, \pm N/2$. The symmetry adapted orbitals $\phi(k)$ are the Bloch orbitals (BO) associated with the χ AO and are dependent on the wave vector k. The coefficient $\exp(ikna)$ is a periodic function of k so only the values of k

$$-\frac{\pi}{a} \leq k \leq \frac{\pi}{a} \quad (2)$$

may be used in constructing the BOs of χ. Every one of the N different $\phi(k)$ BOs belong to a different irreducible representation of the C_N cyclic group. The set of k values of equation (2) are known as the first *Brillouin Zone* (BZ) of the system. Because the infinite cyclic group C_N and the infinite translation group T_N are isomorphous, the $\phi(k)$ BOs are also the symmetry adapted solutions appropriate for the infinite translation group and every one of the BOs belongs to a different irreducible representation of the T_N group.

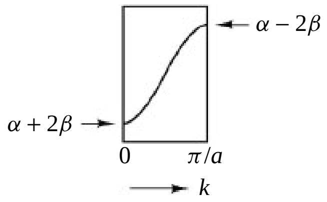
It is now possible to calculate the energy values associated with the $\phi(k)$ BOs according to equation (3)

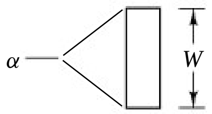
$$e(k) = \frac{H(k)}{S(k)} = \frac{\alpha + 2\beta \cos ka + \cdots}{1 + 2S \cos ka + \cdots} \quad (3)$$

where α is the Coulomb integral, $\alpha = \langle \chi(r)|H^{\text{eff}}|\chi(r)\rangle$, β is the nearest-neighbor resonance integral, $\beta = \langle \chi(r)|H^{\text{eff}}|\chi(r - a)\rangle$, and S is the nearest-neighbor overlap integral, $S = \langle \chi(r)|\chi(r - a)\rangle$. When the overlap integrals are neglected within the first nearest-neighbor approximation, equation (3) is simplified as

$$e(k) = \alpha + 2\beta \cos ka \quad (4)$$

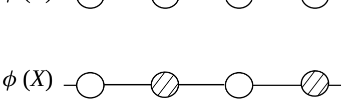
Since N is very large, the difference between two successive energy values is very small and thus the different energy values given by equation (4) lead to a continuous set of energy levels called a band, as schematically shown in (**3**). Within the approximations introduced above, the bandwidth W is given by $W = 4|\beta|$ (*see Band Theory*). In other words, the energy level of the AO χ (i.e. α) is spread into a band of width $4|\beta|$, as depicted in (**4**). An important property of the BOs is that $e(k) = e(-k)$, which is the reason why only half of the band energy levels are represented in (**3**).





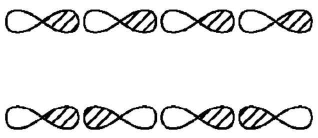
(**3**) (**4**)

It is interesting to examine the nature of the BOs for some specific values of k. For instance, for $k = 0$ the coefficients $\exp(ikna)$ are $(1)^n$ and for $k = \pi/a$ they are $(-1)^n$. In other words, the BO at Γ ($k = 0$) is obtained by repeating the AO χ with the same sign whereas the BO at X ($k = \pi/a$) is obtained by repeating the AO χ with alternating signs. If χ is an s orbital, the two COs are as shown in (**5**). The CO at Γ represents the more bonding combination whereas the CO at X represents the more antibonding combination. The band dispersion should then be as shown in (**3**). However, this is only the case when $\beta < 0$. If $\beta > 0$, as is the case for a 1D chain of p orbitals making σ-type interactions, the CO at Γ is the more antibonding combination whereas that at X is the more bonding combination (see **6**). The band dispersion should then be as in (**7**). However, for a 1D chain of p orbitals making π-type interactions, $\beta < 0$ and, as shown in (**8**), the situation is similar to the 1D chain of s orbitals. Thus, careful examination of the shape and dispersion of a band can give important insight concerning the topology and strength of the interactions along the chain.

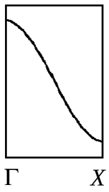


(**5**)

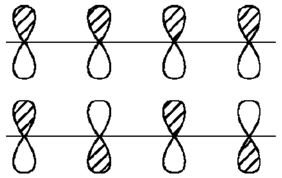
Extension to the case where there are many AOs χ_μ ($\mu = 1, 2, \ldots, M$) per unit cell is straightforward. First, the



(6)



(7)



(8)

symmetry adapted BOs $\phi_\mu(k)$ associated with every AO χ_μ

$$\phi_\mu(k) = N^{-1/2} \sum_n \exp(ikna)\chi_\mu(r - na) \tag{5}$$

are built. Then, the COs ψ_i $(i = 1, 2, \ldots, M)$ describing the motion of electrons in (**1**) are built as a linear combination of these BOs. Since BOs associated with different k values belong to different irreducible representations of the infinite translational group, only those BOs with the same k can be linearly combined

$$\psi_i(k) = \sum_{\mu=1}^{M} C_{\mu i}(k)\phi_\mu(k) \tag{6}$$

The energies $e_i(k)$ of the COs $\psi_i(k)$ are the eigenvalues of the effective Hamiltonian H^{eff}

$$H^{\text{eff}}\psi_i(k) = e_i(k)\psi_i(k) \tag{7}$$

and the requirement that $\partial e_i(k)/\partial C_{\mu i}(k) = 0$ for $\mu = 1, 2, \ldots, M$ leads to the $M \times M$ secular determinant

$$|H_{\mu\nu}(k) - e_i(k)S_{\mu\nu}(k)| = 0 \tag{8}$$

where the matrix elements $H_{\mu\nu}(k)$ and $S_{\mu\nu}(k)$ are defined as

$$H_{\mu\nu}(k) = \langle\phi_\mu(k)|H^{\text{eff}}|\phi_\nu(k)\rangle \tag{9}$$

and

$$S_{\mu\nu}(k) = \langle\phi_\mu(k)|\phi_\nu(k)\rangle \tag{10}$$

Using equation (6) this matrix elements can be expressed as

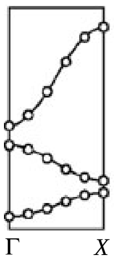
$$\begin{aligned} H_{\mu\nu}(k) = {} & \langle\chi_\mu(r)|H^{\text{eff}}|\chi_\nu(r)\rangle \\ & + \sum_{n=1}^{\infty}[\exp(ikna)\langle\chi_\mu(r)|H^{\text{eff}}|\chi_\nu(r - na)\rangle \\ & + \exp(-ikna)\langle\chi_\mu(r - na)|H^{\text{eff}}|\chi_\nu(r)\rangle] \end{aligned} \tag{11}$$

and

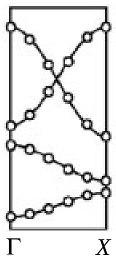
$$\begin{aligned} S_{\mu\nu}(k) = {} & \langle\chi_\mu(r)|\chi_\nu(r)\rangle + \sum_{n=1}^{\infty}[\exp(ikna)\langle\chi_\mu(r)|\chi_\nu(r - na)\rangle \\ & + \exp(-ikna)\langle\chi_\mu(r - na)|\chi_\nu(r)\rangle] \end{aligned} \tag{12}$$

In practice, the summations over n in these expressions are truncated to a reasonable value for which the integrals $\langle\chi_\mu(r)|H^{\text{eff}}|\chi_\nu(r - na)\rangle$ and $\langle\chi_\mu(r)|\chi_\nu(r - na)\rangle$ are negligible. This is the so-called nth nearest-neighbor approximation.

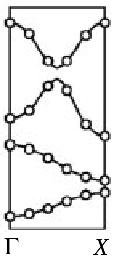
As is obvious from the preceding discussion, calculation of the electronic energy levels for a periodic solid is no more complex than calculation of the electronic energy levels of a molecule. The only difference is that in the case of a periodic solid the calculations have to be carried out for a large number of k values, sampling the first BZ of the solid, that is, from $-\pi/a$ to π/a for a 1D system. However, in this case, because of the general relationship $e_i(k) = e_i(-k)$, calculations can be restricted to the k values $0 \leq k \leq \pi/a$. This region of the BZ is called the irreducible Brillouin zone (IBZ) of the system.



(9)



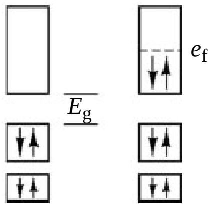
(10)



(11)

In general, the study of the electronic structure of a periodic solid requires the solution of the secular determinant (8) for a set of k values covering the IBZ of the system. This leads to a series of $e_i(k)$ values for the different k points chosen (see **9**, where the empty circles refer to the calculated energies). The band structure of the system is then obtained by connecting those calculated energy values. This is straightforward if the different bands do not overlap (see **9**). If two bands overlap in energy as shown in (**10**), the situation is a little bit more complex. If the symmetries of the two band levels are different for all k points along the $\Gamma \rightarrow X$ line, the two bands can cross as indicated in (**10**). However, if the two band levels have

the same symmetry along this line, crossing of the two bands is not possible and narrower bands result, as shown in (**11**). To determine if the crossing is real or avoided, one has to consider carefully the symmetry properties of the COs (see Section 3), or alternatively one may calculate the $e_i(k)$ values for a fine mesh of k points in the vicinity of the crossing (or avoided crossing) point.



(**12**) (**13**)

Since a band contains N different energy levels, there is room for $2N$ electrons. Usually the occupancy of the energy levels of a band is discussed in terms of the number of electrons per unit cell. Thus, a band is full when there are two electrons per unit cell to fill this band. For instance, if there are four electrons per unit cell to fill the energy levels of (**9**), the two lower bands will be completely filled. This situation can be represented as in (**12**). There is a *Band Gap* (E_g) between the highest occupied level (top of the second band) and the lowest unoccupied level (bottom of the third band from bottom). Such a system having only completely filled or completely empty bands is a semiconductor (*see* ***Semiconductors***) or an *Insulator*, depending on the magnitude of the band gap E_g. If there are five electrons per unit cell, there is only one electron left to fill the top band which is thus half filled and the situation can be represented as in (**13**). In one-electron band theory, where electron–electron repulsions are neglected, a system with one or more partially filled bands such as that represented in (**13**) is a metal (how the electron–electron repulsions can change this situation is discussed in Section 7.2). In a metallic system, there is no band gap between the highest occupied and lowest unoccupied energy levels and the highest occupied energy level is known as the *Fermi Level* (e_f). The corresponding k wave vector is the Fermi wave vector (k_f). For a 1D system it is very easy to know the value of k_f for a partially filled band. The N different k points of the first BZ (equation 2) is a mesh of equally spaced sets of k points. For a given band, when all the energy levels of the first BZ (i.e. $2\pi/a$) are filled, the band is full. When this band is ($1/n$)th filled, only a ($1/n$)th fraction of the $2\pi/a$ levels of the first BZ (i.e. $2\pi/na$) will correspond to occupied states. Consequently, k_f will be given by $1/2(2\pi/na) = \pi/na$ if the bottom of the band is at Γ (**3**), and at $\pi/a - 1/2(2\pi/na) = \pi/a(1 - 1/n)$ if the bottom of the band is at X (**7**). A similar reasoning can be used for more complex situations. For instance, when the Fermi level cuts two bands, as would be the case when there are six electrons per unit cell to be placed in the bands of (**10**), it is easy to see that the Fermi level would lie exactly at the crossing point of the two bands. As will be shown later, the magnitude of k_f plays a crucial role in understanding the structure and physical properties of many 1D systems.

The basic concepts of the electronic band structure theory introduced so far can be easily extended to 2D and 3D systems. As an example of a 2D system, let us consider the rectangular lattice (**14**) with one AO χ per site. The BOs associated with this AO are given by equation (13)

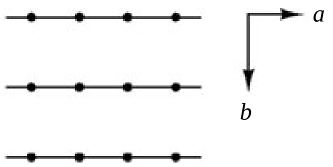
$$\phi(k_a, k_b) = \frac{1}{\sqrt{N}} \sum_m \sum_n \exp(ik_a ma) \exp(ik_b nb) \chi(r - ma - nb) \quad (13)$$

where $\chi(r - ma - nb)$ denotes the AO χ located at the (ma, nb) site of the lattice. In this case, two independent wave vectors, k_a and k_b, are needed to allow all possible phase relationships between the AOs χ along the a- and b-directions, respectively. The coefficients $\exp(ik_a ma)$ and $\exp(ik_b nb)$ are periodic functions of k_a and k_b, respectively, so that only the wave vectors (k_a, k_b) falling in the following region

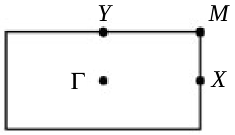
$$-\frac{\pi}{a} \le k_a \le \frac{\pi}{a}$$
$$-\frac{\pi}{b} \le k_b \le \frac{\pi}{b} \quad (14)$$

may be used in constructing the BOs. These wave vectors define the first BZ of the lattice (**15**). In (**15**), $\Gamma = (0, 0)$, $X = (\pi/a, 0)$, $Y = (0, \pi/b)$, and $M = (\pi/a, \pi/b)$. Within the first nearest-neighbor approximation and under neglect of overlap, the energy associated with the BO $\phi(k_a, k_b)$ is given by

$$e(k_a, k_b) = \langle \phi(k_a, k_b) | H^{\text{eff}} | \phi(k_a, k_b) \rangle$$
$$= \alpha + 2\beta_a \cos k_a a + 2\beta_b \cos k_b b \quad (15)$$

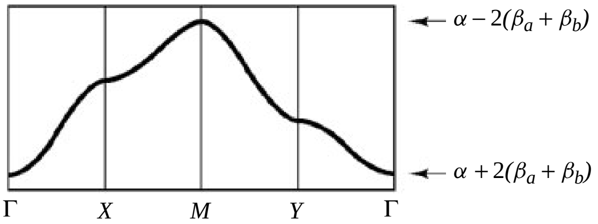


(**14**)

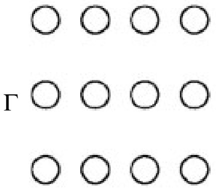


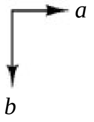
(**15**)

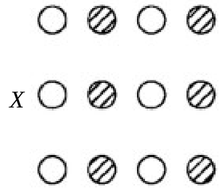
where β_a and β_b are the nearest-neighbor resonance integrals along the a- and b-directions, respectively: $\beta_a = \langle \chi(\mathbf{r}) | H^{\text{eff}} | \chi(\mathbf{r} - \mathbf{a}) \rangle$ and $\beta_b = \langle \chi(\mathbf{r}) | H^{\text{eff}} | \chi(\mathbf{r} - \mathbf{b}) \rangle$. Since the BZ is 2D, some representative lines are usually chosen in order to show the band structure of the system. For instance, the band structure along the $\Gamma \to X \to M \to Y \to \Gamma$ lines (see **15**) assuming that $\beta_a < \beta_b < 0$ is shown in (**16**). The main features of this band structure can be easily understood by looking at the COs of the endpoints of the lines. The values of the coefficients $\exp(ik_a ma) \exp(ik_b nb)$ at Γ, X, Y and M are $(1)^m(1)^n$, $(-1)^m(1)^n$, $(1)^m(-1)^n$ and $(-1)^m(-1)^n$,



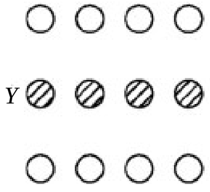
(**16**)

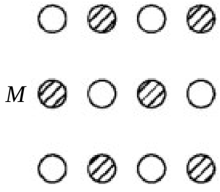






(**17**) (**18**)

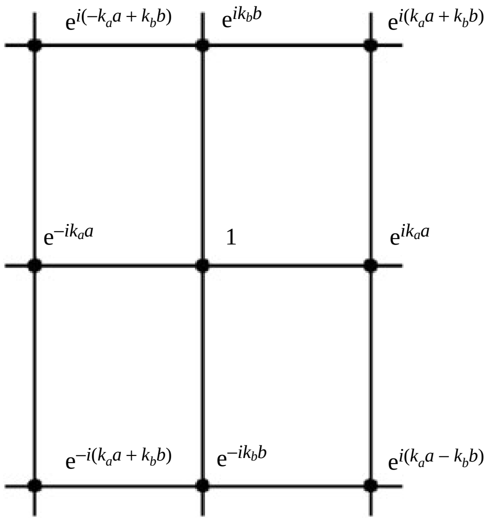




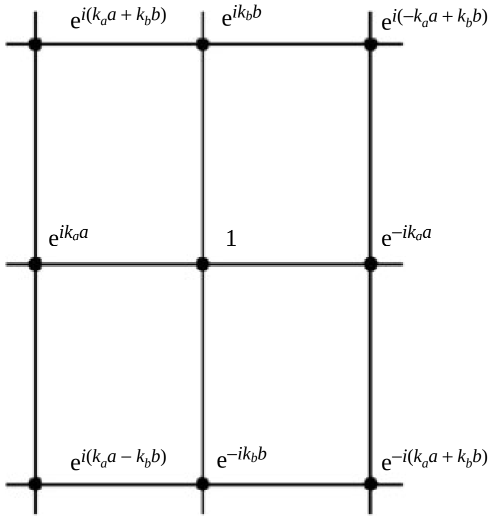
(**19**) (**20**)

respectively. If χ is an s orbital, the phase relationships between the AOs at those k points are illustrated in (**17**–**20**). At Γ, the AOs repeat with the same sign along the a- and b-directions (**17**). At X, the AOs repeat with alternating signs along the a-direction but with the same sign along the b-direction (**18**). At Y, the AOs repeat with the same sign along the a-direction but with alternating signs along the b-direction (**19**). At M, the AOs repeat with alternating signs along the a- and b-directions (**20**). It is easy to explain the band dispersion relations of (**16**) on the basis of (**17**–**20**). For example, the energy is lowest at Γ because this point allows bonding arrangements of the AOs for every nearest-neighbor along the a- and b-directions. Along Γ → X, the energy increases because the nearest-neighbor interaction along the a-direction changes gradually from bonding to antibonding.

The IBZ of (**15**) is the rectangle defined by the points Γ, X, M, and Y. Thus, the area of the IBZ is one-fourth that of the BZ. As mentioned before, the mesh of k points to be considered in actual computational work can be reduced to a mesh covering the IBZ. Thus, it is important to understand how the IBZ for 2D and 3D lattices can be determined. The shape of the IBZ is related to the symmetry properties of the system. For instance, in the rectangular lattice (**14**) there are symmetry planes perpendicular to the a (σ_a) and b (σ_b) directions. Let us see how a general point (k_a, k_b) of the BZ is changed under the effect of these symmetry operations. The BO $\phi(k_a, k_b)$ is given by equation (13) and can be graphically represented as in (**21**), where on top of each lattice point the $\exp(ik_a ma)\exp(ik_b nb)$ coefficient of the χ AO at this site is shown. A symmetry plane perpendicular to a will move the (k_a, k_b) point into $(-k_a, k_b)$. The BO ϕ $(-k_a, k_b)$ is represented in (**22**). The BOs (**21**) and (**22**) are different but completely equivalent. In fact, (**22**) can be obtained from (**21**) after application of the σ_a symmetry operation. In a similar way it can be seen that the BOs corresponding to the $(k_a, -k_b)$ and $(-k_a, -k_b)$ points, that is, those points of the BZ obtained from the previous ones by the effect of a symmetry plane perpendicular to b, can be obtained from (**21**) and (**22**) by application of the σ_b symmetry operation. The BOs $\phi(k_a, -k_b)$ and $\phi(-k_a, -k_b)$ are different but completely equivalent to $\phi(k_a, k_b)$ (**21**) and $\phi(-k_a, k_b)$ (**22**). In general, when a set of points of the BZ can be generated from each other by application of the symmetry operations of the lattice, the BOs for all these points can be obtained from just one of them by using the appropriate symmetry operations. Thus, the BOs for these points are equivalent and, of course, degenerate in energy. Consequently, to determine the IBZ of a lattice (i.e. the minimum number of points needed to generate the BOs and energies for all the points of the BZ), one just needs to consider how a general point of the BZ is transformed under all the symmetry operations of this lattice. In addition, because of the relation $e_i(k) = e_i(-k)$, which by construction is a general property of BOs, the inversion symmetry should always be used even if it is not present in the lattice under consideration. In the case of the lattice (**14**), application of all the symmetry operations to a general (k_a, k_b) point leads to a set of four equivalent points and, consequently, the area of the IBZ is one-fourth the area of the BZ (see **15**). It should be remarked that in general the unit cell of a lattice contains several atoms. Hence the symmetry properties of the actual system can be lower than the symmetry of the general lattice.



(**21**)



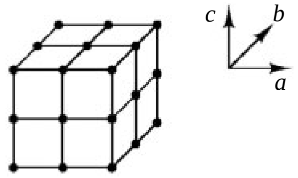
(22)

Extension to a 3D system is straightforward. As an example, consider the 3D orthorhombic lattice (**23**). Now an AO χ located at a lattice site (*ma*, *nb*, *pc*) ($m, n, p =$ integers) is given by $\chi(\mathbf{r} - m\mathbf{a} - n\mathbf{b} - p\mathbf{c})$, and the corresponding BO by

$$\phi(k_a, k_b, k_c) = \frac{1}{\sqrt{N}} \sum_m \sum_n \sum_p [\exp(ik_a ma) \exp(ik_b nb) \times \exp(ik_c pc) \chi(\mathbf{r} - m\mathbf{a} - n\mathbf{b} - p\mathbf{c})] \quad (16)$$

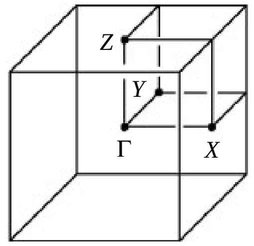
where the three independent wave vectors k_a, k_b, and k_c are needed to describe all possible phase relationships between the AOs along the *a*-, *b*-, and *c*-directions, respectively. Owing to the periodic nature of the coefficients $\exp(ik_a ma)$, $\exp(ik_b nb)$, and $\exp(ik_c pc)$, only the wave vectors (k_a, k_b, k_c) in the following region

$$-\frac{\pi}{a} \le k_a \le \frac{\pi}{a}$$
$$-\frac{\pi}{b} \le k_b \le \frac{\pi}{b}$$
$$-\frac{\pi}{c} \le k_c \le \frac{\pi}{c} \quad (17)$$



(23)

may be used in constructing the BOs. These wave vectors define the first BZ (**24**) of the 3D lattice (**23**). In (**24**), $\Gamma = (0, 0, 0)$, $X = (\pi/a, 0, 0)$, $Y = (0, \pi/b, 0)$ and $Z = (0, 0, \pi/c)$.



(24)

When the overlap integrals are neglected within the first nearest-neighbor approximation, the energy $e(k_a, k_b, k_c)$ of the BO $\phi(k_a, k_b, k_c)$ is given by

$$e(k_a, k_b, k_c) = \langle \phi(k_a, k_b, k_c) | H^{\text{eff}} | \phi(k_a, k_b, k_c) \rangle$$
$$= \alpha + 2\beta_a \cos k_a a + 2\beta_b \cos k_b b + 2\beta_c \cos k_c c \quad (18)$$

where β_c is the nearest-neighbor resonance integral along the *c*-direction: $\beta_c = \langle \chi(\mathbf{r}) | H^{\text{eff}} | \chi(\mathbf{r} - \mathbf{c}) \rangle$. The width of the band given by equation (18) is $4(|\beta_a| + |\beta_b| + |\beta_c|)$. As in the cases of 1D and 2D systems, dispersion relations for 3D systems can be easily explained by knowing the coefficients $\exp(ik_a ma)$, $\exp(ik_b nb)$, and $\exp(ik_c pc)$ at a limited number of specific *k* points such as Γ, X, Y, and Z.

In order to extend the description of electronic band structures to general 2D and 3D systems, it is convenient to introduce the concepts of the direct and reciprocal lattices.[7] For a general 3D lattice with repeat vectors ***a***, ***b***, and ***c***, the positions of lattice sites (*ma*, *nb*, *pc*) can be represented as vectors ***R***

$$\boldsymbol{R} = m\boldsymbol{a} + n\boldsymbol{b} + p\boldsymbol{c} \quad (19)$$

A set of these vectors is usually called the direct lattice. For a given lattice, its reciprocal lattice is defined as a set of vectors ***K*** satisfying the relationship

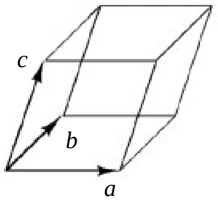
$$\exp(\boldsymbol{K} \cdot \boldsymbol{R}) = 1 \quad (20)$$

Then, any vector ***K*** of the reciprocal lattice can be expressed as

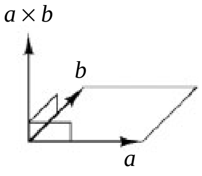
$$\boldsymbol{K} = m\boldsymbol{a}^* + n\boldsymbol{b}^* + p\boldsymbol{c}^* \quad (21)$$

where $\boldsymbol{a}^*$, $\boldsymbol{b}^*$, and $\boldsymbol{c}^*$ are the reciprocal vectors. For the orthorhombic lattice (**23**) the lengths of $\boldsymbol{a}^*$, $\boldsymbol{b}^*$, and $\boldsymbol{c}^*$ are given by $2\pi/a$, $2\pi/b$, and $2\pi/c$, respectively, and their directions are along ***a***, ***b***, and ***c***, respectively.

Let us consider a direct lattice generated by three repeat vectors ***a***, ***b***, and ***c*** which are not necessarily orthogonal to each other, as shown in (**25**), where the volume V of the parallelepiped defined by the three vectors ***a***, ***b***, and ***c*** is given



(**25**)



(**26**)

by $V = \boldsymbol{a} \cdot \boldsymbol{b} \times \boldsymbol{c}$. Then the reciprocal lattice vectors $\boldsymbol{a}^*$, $\boldsymbol{b}^*$, and $\boldsymbol{c}^*$ are given by

$$\boldsymbol{a}^* = \left(\frac{2\pi}{V}\right)\boldsymbol{b} \times \boldsymbol{c}$$
$$\boldsymbol{b}^* = \left(\frac{2\pi}{V}\right)\boldsymbol{c} \times \boldsymbol{a} \tag{22}$$
$$\boldsymbol{c}^* = \left(\frac{2\pi}{V}\right)\boldsymbol{a} \times \boldsymbol{b}$$

The lengths and directions of the vectors $\boldsymbol{b} \times \boldsymbol{c}$, $\boldsymbol{c} \times \boldsymbol{a}$, and $\boldsymbol{a} \times \boldsymbol{b}$ of equation (22) are easily determined. For example, the vector $\boldsymbol{a} \times \boldsymbol{b}$ has the length equal to the area of the parallelogram defined by the vectors $\boldsymbol{a}$ and $\boldsymbol{b}$, and has the direction perpendicular to both $\boldsymbol{a}$ and $\boldsymbol{b}$, as shown in (**26**). The positive direction of $\boldsymbol{a} \times \boldsymbol{b}$ is obtained according to the right-handed screw convention: rotate $\boldsymbol{a}$ around the axis of $\boldsymbol{a} \times \boldsymbol{b}$ toward $\boldsymbol{b}$ as if to advance a right-handed screw. Then the screw-advancing direction is the positive direction of $\boldsymbol{a} \times \boldsymbol{b}$.

It is convenient to express a general position, $\boldsymbol{k}$, of the reciprocal space in units of the reciprocal vectors

$$\boldsymbol{k} = x\boldsymbol{a}^* + y\boldsymbol{b}^* + z\boldsymbol{c}^* \tag{23}$$

where x, y, and z are dimensionless numbers. Then, for any general 3D lattice, the term $\exp(i\boldsymbol{k} \cdot \boldsymbol{R})$ can be written as

$$\exp(i\boldsymbol{k} \cdot \boldsymbol{R}) = \exp(ik_a ma)\exp(ik_b nb)\exp(ik_c pc) \tag{24}$$

where $k_a = x(2\pi/a)$, $k_b = y(2\pi/b)$, and $k_c = z(2\pi/c)$. Therefore, the 3D wave vectors (k_a, k_b, k_c) introduced to construct the BOs of a 3D orthorhombic lattice are also valid for any other nonorthorhombic lattice. The wave vector $\boldsymbol{k}$ is often represented by (x, y, z). Thus for the first BZ (**24**), $\Gamma = (0, 0, 0)$, $X = (1/2, 0, 0)$, $Y = (0, 1/2, 0)$, and $Z = (0, 0, 1/2)$. The primitive unit cell of reciprocal space defined by

$$-\tfrac{1}{2} \le x \le \tfrac{1}{2}$$
$$-\tfrac{1}{2} \le y \le \tfrac{1}{2}$$
$$-\tfrac{1}{2} \le z \le \tfrac{1}{2} \tag{25}$$

contains all wave vectors needed for constructing the BOs. This primitive cell of the reciprocal space may now be referred to as the first primitive zone (PZ). For orthorhombic lattices, the first PZ is identical with the first BZ. This is not the case for other lattices.

The notations for BOs and their related expressions are considerably simplified by the use of $\boldsymbol{k}$ and $\boldsymbol{R}$. An AO χ_μ located at $\boldsymbol{R}$ is given by $\chi_\mu(\mathbf{r} - \mathbf{R})$. Therefore, the BO ϕ_μ is written as

$$\phi_\mu(k) = \frac{1}{\sqrt{N}}\sum_{\boldsymbol{R}} \exp(i\boldsymbol{k} \cdot \boldsymbol{R})\chi_\mu(\boldsymbol{r} - \boldsymbol{R}) \tag{26}$$

and the COs ψ_i are given as linear combinations of the BOs ϕ_μ

$$\psi_i(\boldsymbol{k}) = \sum_\mu C_{\mu i}(\boldsymbol{k})\phi_\mu(\boldsymbol{k}) \tag{27}$$

The energies $e_i(\boldsymbol{k})$ of the COs $\psi_i(\boldsymbol{k})$ are eigenvalues associated with H^{eff}

$$H^{\text{eff}}\psi_i(\boldsymbol{k}) = e_i(\boldsymbol{k})\psi_i(\boldsymbol{k}) \tag{28}$$

which leads to the secular determinant

$$|H_{\mu\nu}(\boldsymbol{k}) - e_i(\boldsymbol{k})S_{\mu\nu}(\boldsymbol{k})| = 0 \tag{29}$$

The matrix elements $H_{\mu\nu}$ $(\boldsymbol{k})$ and $S_{\mu\nu}$ $(\boldsymbol{k})$ are then expressed as

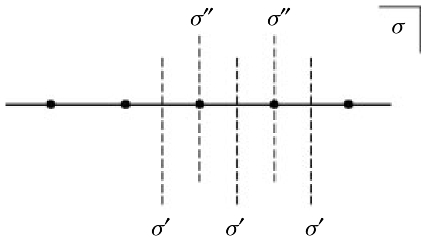
$$\begin{aligned} H_{\mu\nu}(\boldsymbol{k}) &= \langle\phi_\mu(\boldsymbol{k})|H^{\text{eff}}|\phi_\nu(\boldsymbol{k})\rangle = \langle\chi_\mu(\boldsymbol{r})|H^{\text{eff}}|\chi_\nu(\boldsymbol{r})\rangle \\ &+ \sum_{\boldsymbol{R}}[\exp(-i\boldsymbol{k} \cdot \boldsymbol{R})\langle\chi_\mu(\boldsymbol{r} - \boldsymbol{R})|H^{\text{eff}}|\chi_\nu(\boldsymbol{r})\rangle \\ &+ \exp(i\boldsymbol{k} \cdot \boldsymbol{R})\langle\chi_\mu(\boldsymbol{r})|H^{\text{eff}}|\chi_\nu(\boldsymbol{r} - \boldsymbol{R})\rangle] \end{aligned} \tag{30}$$

and

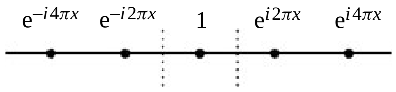
$$\begin{aligned} S_{\mu\nu}(\boldsymbol{k}) &= \langle\phi_\mu(\boldsymbol{k})|\phi_\nu(\boldsymbol{k})\rangle \\ &= \langle\chi_\mu(\boldsymbol{r})|\chi_\nu(\boldsymbol{r})\rangle + \sum_{\boldsymbol{R}}[\exp(-i\boldsymbol{k} \cdot \boldsymbol{R})\langle\chi_\mu(\boldsymbol{r} - \boldsymbol{R})|\chi_\nu(\boldsymbol{r})\rangle \\ &+ \exp(i\boldsymbol{k} \cdot \boldsymbol{R})\langle\chi_\mu(\boldsymbol{r})|\chi_\nu(\boldsymbol{r} - \boldsymbol{R})\rangle] \end{aligned} \tag{31}$$

3 CRYSTAL ORBITALS AND SYMMETRY[8]

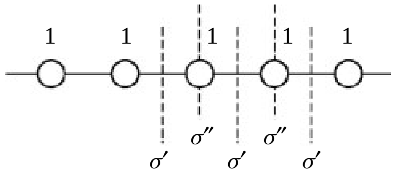
As mentioned before, when two bands overlap in energy they can show a real or an avoided crossing depending on the symmetry of the band levels. These real or avoided crossings have a special importance when they occur at the Fermi level. The existence or absence of an energy gap at the Fermi level dictates if the system is a semiconductor (or insulator) or a



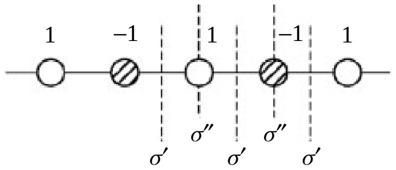
(**27**)



(**28**)



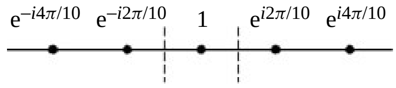
(**29**)



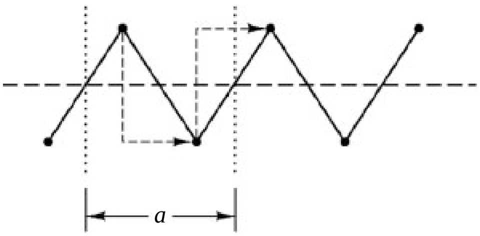
(**30**)

metal. Thus it is very important to know how the symmetry properties of the lattice determine the nature of the COs.

Let us first consider the 1D lattice (**1**) with one s orbital per site. Shown in (**27**) are three different types of symmetry planes. According to equations (23) and (26), a general $\phi_s(\boldsymbol{k})$ BO can be represented as in (**28**), where on top of each lattice point the $\exp(i\boldsymbol{k}\cdot\boldsymbol{R})$ coefficient is given and the dotted lines denote the reference cell. When $k = 0$, that is, $x = 0$, all coefficients are one (**29**) and the BO is symmetric with respect to the symmetry planes σ', σ'', and σ. When $k = \pi/a$, that is, $x = 1/2$, the coefficients are alternately one and minus one (**30**), so that the BO is symmetric with respect to the σ and σ'' planes but antisymmetric with respect to the σ' plane. Thus the BOs $\phi_s(0)$ and $\phi_s(\pi/a)$ are either symmetric or antisymmetric with respect to the σ, σ', and σ'' planes. This is not the case for an arbitrary value of the wave vector, as shown in (**31**) for $k = \pi/5a$, that is, $x = 1/10$. This BO is symmetric with respect to σ but is neither symmetric nor antisymmetric with respect to the σ' and σ'' planes. The reason for this observation is very simple. A BO is an eigenfunction of a symmetry operator if under application of this operator the same BO multiplied by a constant is generated. Because of the presence of the k wave vector in the exponential term, a BO can only be an eigenfunction of symmetry operators leaving the k wave vector unaltered or transforming it into a translationally equivalent one. The σ plane leaves the k vector unaltered whatever the value of k. However, the σ' and σ'' planes transform k into $-k$, so that only for the values 0 and π/a of the wave vector will the BO be an eigenfunction of the corresponding symmetry operators.



(**31**)



(**32**)

Some care is needed when among the symmetry operations of the lattice there are glide reflections or screw rotations. A glide reflection is a reflection followed by a fractional translation parallel to the reflection plane. A screw rotation is a rotation followed by a fractional translation parallel to the rotation axis. The lattice (**32**) with one s orbital per site is an example of a 1D system having both a glide reflection and a screw rotation along the propagation direction. The effect of the glide reflection is indicated in (**32**), where the dotted lines indicate the reference cell. Of course, application of the glide reflection operation twice is the equivalent of a translation by a. If $\boldsymbol{G}$ and $\boldsymbol{T}$ are the symmetry operators for the glide reflection and translation by a, respectively, equation (32) will hold for any ϕ_μ ($\boldsymbol{k}$) BO being an eigenfunction of $\boldsymbol{G}$, where λ is one of the eigenvalues.

$$\boldsymbol{GG}\phi_u(\boldsymbol{k}) = \lambda^2\phi_\mu(\boldsymbol{k}) = \boldsymbol{T}\phi_\mu(\boldsymbol{k}) = \exp(ik_a)\phi_\mu(\boldsymbol{k}) \qquad (32)$$

It follows that

$$\lambda^2 = \exp(ik_a) = \exp(i2\pi x) \qquad (33)$$

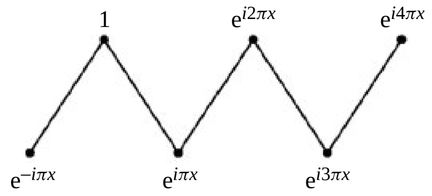
and consequently, the possible values of λ are

$$\lambda = \exp[i(\pi x + 0)] \qquad (34)$$

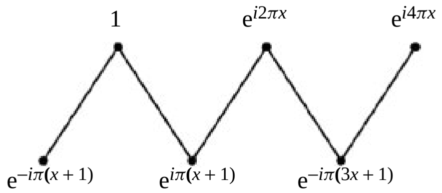
$$\lambda = \exp[i(\pi x + \pi)] \qquad (35)$$

In general, when there are screw rotations or glide planes parallel to a certain direction, the BO for wave vectors along

the same direction are eigenvectors of the corresponding symmetry operators. Since the glide reflection and the screw rotation in (**32**) are along the propagation axis, the BO for any value of k will be an eigenvector of these symmetry operators. Consequently the BO $\phi_s(\boldsymbol{k})$ for any value of the wave vector will be such that the ratio between the coefficients of two successive s AOs will be given by equation (34) or equation (35). The two types of BOs can be represented as in (**33**) or (**34**). An obvious consequence is that the two types of BOs for the wave vector $k = \pi/a$ are completely equivalent and, thus, degenerate. Since only BOs of the same symmetry can mix to generate COs (equation 27) the analysis developed in this section applies also to CO. Of course the same considerations can be used for 2D or 3D systems although some care is needed when the repeat vectors of the direct lattice are not orthogonal.



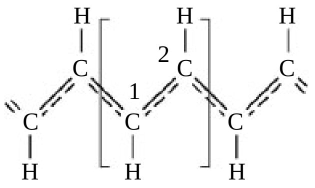
(**33**)



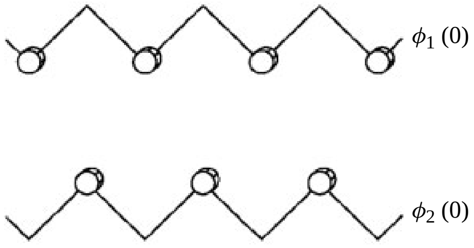
(**34**)

4 CRYSTAL ORBITALS AND ORBITAL INTERACTIONS;[2–6] PEIERLS DISTORTIONS[9]

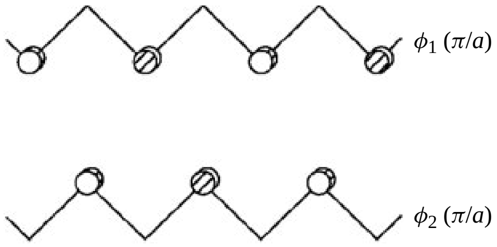
In order to illustrate the workings of the orbital interaction analysis of the COs let us now consider the π-system of ideal polyacetylene (**35**). In (**35**) all the carbon–carbon distances are identical and the repeat unit contains two CH groups. If we are only interested in the π-system, the AO basis contains just two AOs which will be denoted as χ_1 and χ_2. The first step in the calculation of the COs of the system is the building up of the BOs for these two AOs according to equation (5). The BOs corresponding to $k = 0$ and $k = \pi/a$ are shown in (**36**) and (**37**), respectively. Now, the two BOs for a given k value should be linearly combined to generate the corresponding COs. Solving equation (29) for different values of k will lead to the band structure of the system, which is schematically shown in (**38**). For instance, the COs for $k = 0$ and $k = \pi/a$ are those shown in (**39**) and (**40**) respectively.



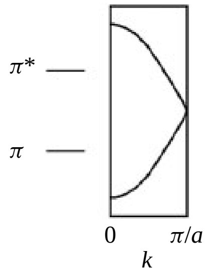
(**35**)



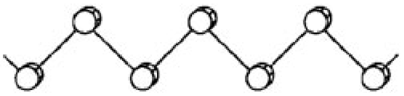
(**36**)



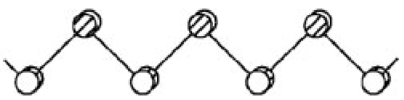
(**37**)



(**38**)

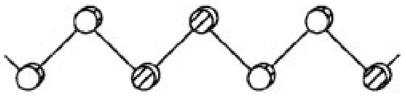


(**39a**)



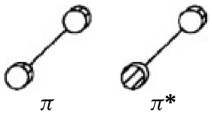
(**39b**)

The previous operations can be done automatically using a computer program. The object of this section is, however,



(**40a**)

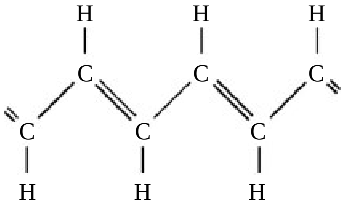
(**40b**)



(**41**)

to try to understand the results of these calculations. It should be remarked that the BOs (**39a**) and (**39b**) are just the combinations always in phase of the π and π^* orbitals of the repeat unit (**41**), respectively. In addition, the BOs (**40a**) and (**40b**) are the combinations always out of phase of the same orbitals. In general, the easiest way to analyze or predict the band structure of a certain material is to build first the fragment orbitals of the repeat unit (or chemically significant fragments of the repeat unit in more complex cases), and later the corresponding BOs for selected points of the BZ. Once this is done the major aspects of the band structure can be discussed. In the present case, the two fragment orbitals would be the π and π^* orbitals of the repeat unit. Applying the known rules to build the COs for $k = 0$ and $k = \pi/a$, the BOs (**39**) and (**40**) would be generated. The main aspects of the band structure (**38**) can now be understood. The COs (**39a**) and (**39b**) are the more bonding and antibonding combinations of the system. When overlap integrals are neglected, and within the first nearest-neighbor approximation, the energies for (**39a**) and (**39b**) would be $\alpha + 2\beta$ and $\alpha - 2\beta$, respectively. It is easy to see that the two COs at $k = \pi/a$, (**40a**) and (**40b**), are completely equivalent and consequently, degenerate. These COs are essentially nonbonding because, as shown in (**40**), half of the carbon–carbon interactions are bonding and half are antibonding. Of course, when overlap integrals are neglected, and within the first nearest-neighbor approximation, the energy of these COs is α. The degeneracy of these two COs is a direct consequence of the existence of a screw rotation axis along the chain, as discussed at the end of Section 3. Essentially, the π and π^* levels of the repeat unit have been broadened into two bands which meet at the border of the BZ (see **38**). Consequently, polyacetylene with this structure would be metallic.

Since we know the origin of the degeneracy at the border of the BZ, we can try to design some way to create a band gap. The two COs (**40**) are alternatively bonding and antibonding in such a way that when one of them is bonding the other is antibonding. Consequently, a distortion towards a structure like (**42**), with alternating single and double bonds, will stabilize one of the orbitals but destabilize the other,

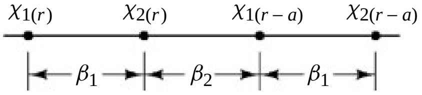


(**42**)

creating a band gap. For a half-filled band, this distortion will lower the electronic energy and the distorted system will be a semiconductor (or insulator). Let us note that the distortion from (**35**) to (**42**) lowers the symmetry of the lattice. Essentially, this type of distortion is the solid state equivalent of the first-order Jahn–Teller distortion (*see Jahn–Teller Effect*) for molecules and is known as a *Peierls Distortion*.[9] Since the two COs (**40**) are degenerate, they can be linearly combined so that the COs (**37**) are an equally valid representation. The COs (**37**) suggest a different way to open a band gap in ideal polyacetylene by creating a difference in the electronegativity of the two centers of the repeat unit. For instance, this could be done by using substituents of different electronegativity for the two carbon atoms.

The Peierls distortion is not a peculiarity of metallic half-filled systems. In general, any partially filled 1D system will be susceptible towards a distortion that opens a band gap at the Fermi level, destroying its metallic properties. In order to show this, let us consider the 1D chain (**43**) in which the unit cell contains two atoms with an AO each. Given the Coulomb integrals of the AOs χ_1 and χ_2 as α_1 and α_2, respectively, and the first nearest-neighbors resonance integrals as defined in (**43**), solution of equation (8) leads to the following expression for the CO energy

$$e_i(k) = \frac{(\alpha_1 + \alpha_2)}{2 \pm [(\alpha_1 - \alpha_2)^2/4 + (\beta_1{}^2 + \beta_2{}^2 + 2\beta_1\beta_2 \cos ka)]^{1/2}} \tag{36}$$

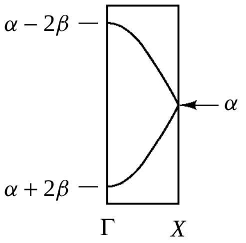


(**43**)

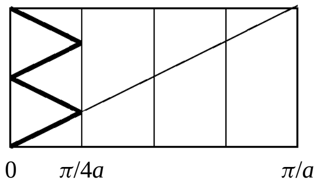
If $\alpha_1 = \alpha_2 = \alpha$ and $\beta_1 = \beta_2 = \beta$, equation (36) reduces to

$$e_i(k) = \alpha \pm 2\beta \cos\left(\frac{ka}{2}\right) \tag{37}$$

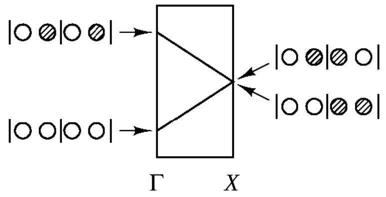
This expression leads to the band structure (**44**), which can be obtained by folding the band structure (**3**) at the midpoint along the $k = 0$ to $k = \pi/a$ line. This is not surprising because (**43**) with $\alpha_1 = \alpha_2 = \alpha$ and $\beta_1 = \beta_2 = \beta$ (case I) is identical to (**1**) except that the repeat distance has been doubled.



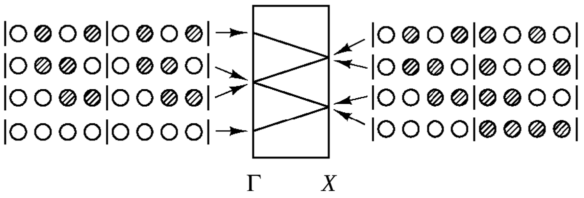
(**44**)



(**45**)



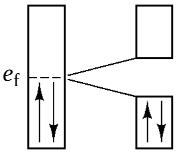
(**46**)

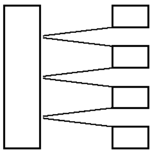


(**47**)

Consequently, the BZ associated with (**43**) must be one-half that appropriate for (**1**). Since the two systems are identical, the information contained in the larger BZ must be translated into the smaller BZ. In practice, for 1D systems this comes back to folding the band structure of the smaller unit cell system at the midpoint along the $k = 0$ to $k = \pi/a$ line. This is why the band structure (**44**) is just a folded version of the band structure (**3**). In general, when a unit cell size increases n times without lowering the symmetry of the system, the resulting band dispersion is folded n times. This is illustrated in (**45**) for $n = 4$. The nature of the degeneracies in (**44**) or (**45**) can be easily explained by building the COs from the dimeric or tetrameric levels of the unit cell as shown schematically in (**46**) and (**47**), respectively.

It should be noted that the two previous strategies to open a band gap for a half-filled band can be obtained from equation (36) when $\beta_1 < \beta < \beta_2 < 0$ and $\alpha_1 = \alpha_2 = \alpha < 0$ (case II, bond length alternation) or $\alpha_1 < \alpha < \alpha_2 < 0$ and $\beta_1 = \beta_2 = \beta < 0$ (case III, electronegativity perturbation). Either case II or case III results from case I by an appropriate perturbation. The essential outcome of such a perturbation, which lowers the symmetry of the lattice, is to open an energy gap in the middle of the band as depicted in (**48**). This band splitting becomes important when the band is half filled, because the band gap opening at the Fermi level lowers the electronic energy of the half-filled system. In general, when a unit cell size is increased n times by a distortion or an external potential (which introduces nonequivalent lattice sites), the band is split into n subbands. This is illustrated for $n = 4$ in (**49**), which can be easily explained on the basis of the folded band dispersion shown in (**47**), because symmetry lowering (as illustrated in (**50a**) and (**50b**)) will split the degeneracies at Γ ($k = 0$) and X ($k = \pi/4a$), thereby introducing band gaps. Consequently, a 1D system having a partially filled band of occupancy $1/n$ or $(n - 1)/n$ is likely to undergo a distortion which increases the unit cell size n times (see (**51a**) and (**51b**)). This general phenomenon is known as a Peierls distortion or a $2k_f$ distortion (see Section 7.1).

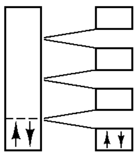


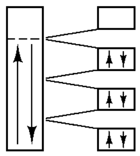


(**48**) (**49**)

(**50a**)

(**50b**)

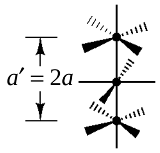




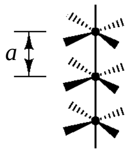
(**51a**) (**51b**)

As a second example of orbital interaction analysis of the COs, let us now consider the tetracyanoplatinate $Pt(CN)_4^{2-}$ chains.[10] Although $K_2[Pt(CN)_4]$ is an insulator, the salt can be cocrystallized with elemental bromine to produce partially oxidized salts, $K_2[Pt(CN)_4]Br_\delta \cdot 3H_2O$. These salts are metallic and have attracted a great deal of attention. The crystal structures of these partially oxidized salts exhibit linear chains with a staggered arrangement of $Pt(CN)_4^{2-}$ units as shown in (**52**). All Pt atoms are equivalent and the Pt–Pt distance becomes shorter when the partial oxidation of Pt increases.

In order to study the band structure of (**52**),[11] it is easiest to consider the eclipsed chain (**53**) first. The band structure

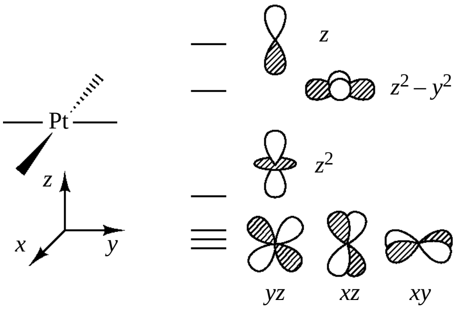


(**52**)

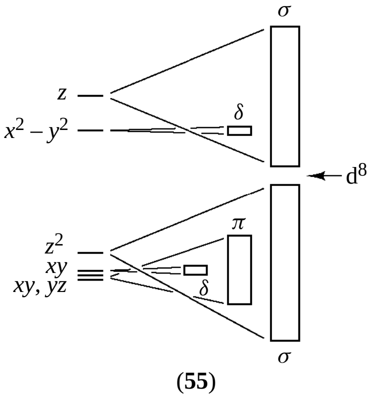


(**53**)

of (**52**) can be obtained from that of (**53**) by folding the bands. Every $Pt(CN)_4{}^{2-}$ unit contains a d^8 Pt. The orbitals of this group are as described schematically in (**54**), where the contributions of the ligands have been omitted for clarity. Using these orbitals and bearing in mind the relative strength of the σ-, π-, or δ-type interactions between the metal orbitals along the chain, the approximate block band diagram shown in (**55**) can be generated. On the basis of this qualitative band diagram it would be predicted that the nonoxidized system should be a semiconductor or insulator. In principle, partial oxidation empties the top of the z^2 band. Since this region contains antibonding Pt–Pt interactions, the Pt–Pt distance in the partially oxidized salts will be considerably shortened. This shortening will lead to a broadening of all the bands but especially those resulting from σ-type interactions. Hence, when trying to derive the band structure of the partially oxidized (**52**) chains one needs to consider the possibility of an overlap of the z^2 and z bands.

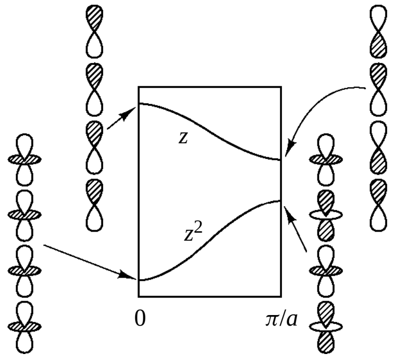


(**54**)

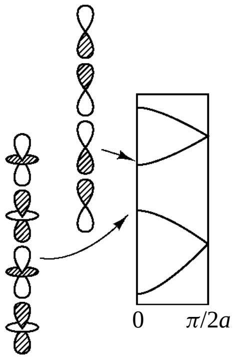


(**55**)

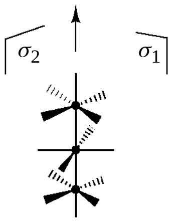
(**56**) is the schematic band structure for (**53**) where only the σ-type bands have been shown. The corresponding band



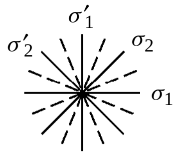
(**56**)



(**57**)



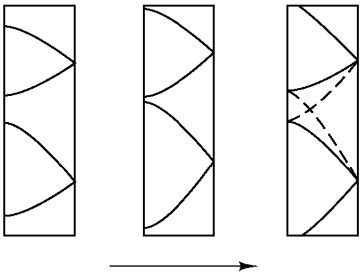
(**58a**)



(**58b**)

structure for (**52**) is obtained by folding (**56**) around the $\pi/2a$ point as shown in (**57**). To understand if the z^2 and z bands can overlap we should consider carefully the symmetry of the chains (**52**). Applying the ideas discussed in Section 3, it is easy to see that the symmetry elements which can be used to classify the band levels for a general value of the wave vector k are the four symmetry planes σ_1, σ_1', σ_2, and σ_2' shown in (**58a**) and the projection view (**58b**), the rotation and screw rotation axes along the chain and the four glide reflection planes shown with dotted lines in (**58b**). As can be seen from the COs at $k = 0$ shown in (**57**), the two bands are of the same symmetry with respect to all the above-mentioned symmetry elements. Thus the z and z^2 bands cannot cross. Consequently, the evolution of the band structure as the Pt–Pt distance shortens will be such that there will always be a band gap between the two bands (see (**59**)) even if the orbital character of the two bands at Γ can be interchanged. A practical consequence

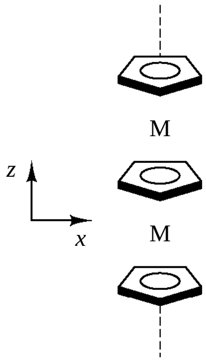
of this analysis is that the only way to have metallic-type conductivity in the $Pt(CN)_4^{2-}$ chains is by partial oxidation. Even if very short Pt–Pt distances could be created by other means, like applying pressure, for instance, a semimetallic overlap of the z^2 and z bands would not be produced.



Pt–Pt shortening

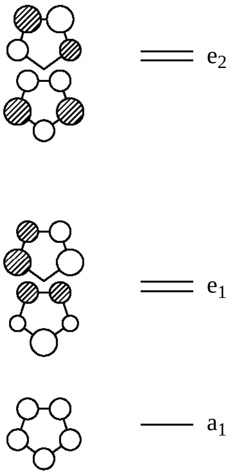
(**59**)

The main result of the previous analysis is that, as long as the oxidation is not too strong, the partially oxidized $Pt(CN)_4^{2-}$ chains have a partially filled single band. Hence, these chains should exhibit metallic properties. However, as any 1D metallic system, they should also be susceptible to a Peierls type distortion which would destroy these metallic properties and increase the periodicity of the lattice. These predictions are in agreement with the experimental results on the $K_2[Pt(CN)_4]Br_\delta \cdot 3H_2O$ salts. Usually, they are metallic at room temperature but the conductivity declines sharply at lower temperatures, becoming semiconducting. It has been shown that the change in the conductivity regime is associated with a periodic lattice distortion (i.e. a Peierls distortion).[10,12]

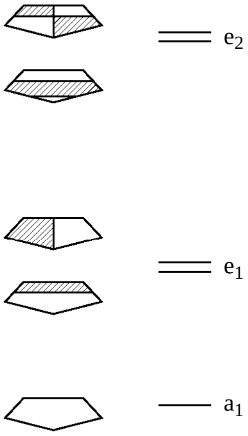


(**60**)

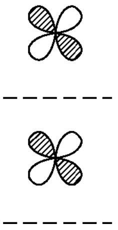
As a final example, let us consider the band structure for the infinite chain $[M(C_5H_5)]$ (**60**).[13] The important orbital interactions to consider are those between the d orbitals of the metal atom and the π-type orbitals of C_5H_5 (**61a**). For simplicity, the shorthand notation (**61b**) will be used for these π-type orbitals. The symmetry labels in (**61**) are those of the C_{5v} group which is the appropriate one for a general k wave vector inside the BZ, although at Γ and X the symmetry is higher (D_{5h}). The BOs for one of the e_1 metal orbitals (xz, yz) at Γ and X are shown in (**62**) and (**63**) respectively. The BOs at Γ and X for one of the $\pi(e_1)$ orbitals of C_5H_5 are shown in (**64**) and (**65**), respectively. By symmetry these BOs can mix at Γ but not at X. Thus (**62**) will be destabilized by mixing (**64**) in an antibonding way and vice versa. Therefore the metal



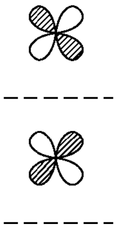
(**61a**)



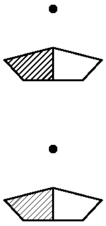
(**61b**)



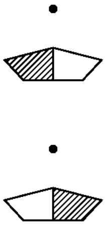
(**62**)



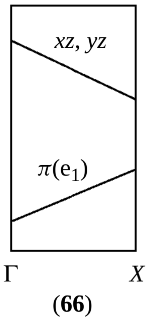
(**63**)



(**64**)

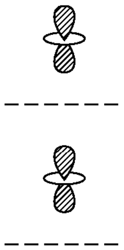


(**65**)

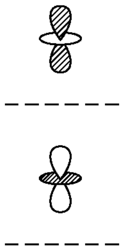


(**66**)

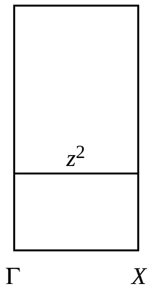
$e_1(xz, yz)$ and $\pi(e_1)$ bands will run as schematically shown in (**66**). The z^2 BOs at Γ and X are shown in (**67**) and (**68**), respectively. Because of its conical nodal surface the z^2 orbital practically does not interact with the $\pi(a_1)$ orbital of C_5H_5. In addition, the metal atoms are too far apart to have any sizeable direct interaction. Consequently, the z^2 band will be quite flat (**69**). The BOs for one of the e_2 metal orbitals (xy, $x^2 - y^2$) at Γ and X are those shown in (**70**) and (**71**), respectively. The BOs at Γ and X for one of the $\pi(e_2)$ orbitals of C_5H_5 are shown in (**72**) and (**73**), respectively. By symmetry these BOs can mix at X but not at Γ. Thus (**71**) will be stabilized by mixing (**73**) in an bonding way and vice versa. However, the e_2 metal orbitals are not well directed towards the $\pi(e_2)$ orbitals and the interaction will be weaker than it was for the e_1 orbitals. The metal $e_2(xy, x^2 - y^2)$ and $\pi(e_2)$ bands will run as schematically shown in (**74**). Finally, as show in (**75–78**), the $\pi(a_1)$ orbital can mix with the metal s orbital at X but not at Γ. The opposite is true for the mixing with the metal z orbital, but this mixing is weaker because of the larger energy difference. The $\pi(a_1)$ band will run as schematically shown in (**79**). Thus the schematic band structure for the $[M(C_5H_5)]$ chain (**60**) will be as shown in (**80**), which compares very well with the calculated one shown in (**81**).[13]



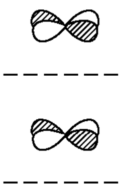
(**67**)



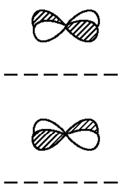
(**68**)



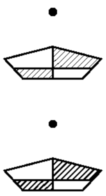
(**69**)



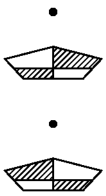
(**70**)



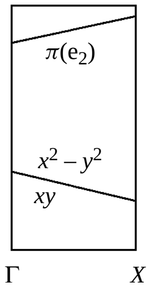
(**71**)



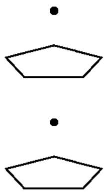
(**72**)



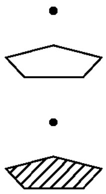
(**73**)



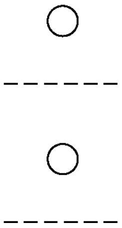
(**74**)



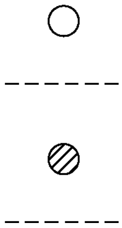
(**75**)



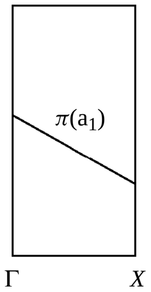
(**76**)



(**77**)

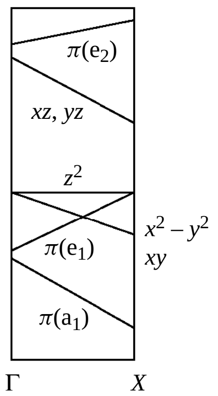


(**78**)

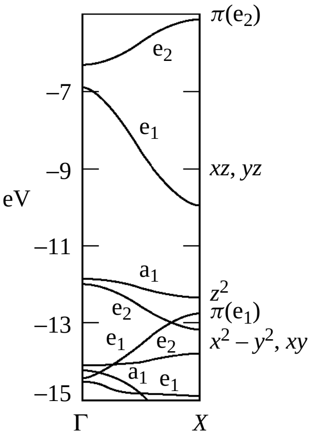


(**79**)

The examples discussed in this section are quite simple and have been chosen in order to illustrate some basic aspects of the orbital interaction analysis of the structure of solids. This type



(**80**)



(**81**)

of approach is very useful in establishing structure–property correlations for solid-state materials, and has been used to understand the calculated band structures for structurally very complex systems.[5]

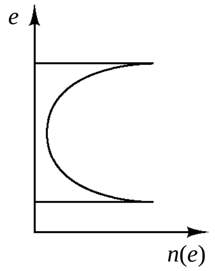
5 DENSITY OF STATES

Real solid-state materials are often structurally complex and there can be a large number of bands to be considered. In addition, for 2D or 3D materials it is practically impossible to examine $e_i(k)$ for all the regions of the BZ. Furthermore, inside the BZ the symmetry is usually quite low and there can be many avoided crossings between bands. Hence, although in principle one can always perform an orbital interaction analysis of several COs, a particular orbital of the repeat unit can be spread out between several bands. Under such conditions, it can be very difficult to single out an orbital or group of orbitals responsible for the structure or properties of the solid. However, since after all, solids are very big molecules, we should be able to develop qualitative arguments similar to those successfully used in molecular chemistry to explain the structure, properties, or reactivity of solids.

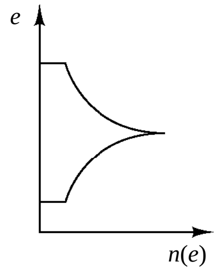
As the problem is that in general there are too many levels (or states) to consider, the more obvious way to circumvent it is to work with a DOS instead of the states themselves. The DOS, $n(e)$, of a solid is defined as the number of states in an energy interval between e and $e + \mathrm{d}e$.[7] Thus $n(e)$ is nonzero within the allowed energy region of a band and vanishes in the forbidden energy region. The $n_i(e)$ values of a given band i satisfy the normalization condition

$$\int_{-\infty}^{\infty} n_i(e)\mathrm{d}e = 1 \tag{38}$$

so that, since a band can accommodate two electrons per unit cell, integration of twice the DOS up to the Fermi level gives the total number of electrons of the system. The electronic structure of solids may be discussed solely on the basis of their DOS values. In such an approach the band orbital information is completely absent. Typical patterns of the DOS for 1D or 2D lattices are shown in (**82**) and (**83**), respectively. As shown in (**82**), the DOS values of a 1D band peak at the bottom and the top of the band. For a 2D square lattice with equal magnitudes of interaction along the a- and b-directions the DOS values peak in the middle of the band, as shown in (**83**). The DOS shape for a 3D lattice depends upon the nature of the lattice, but high DOS values generally occur in the middle of the band. An important DOS value in describing the physical properties of metals is the DOS value at the Fermi level, that is, $n(e_\mathrm{f})$.



(**82**)



(**83**)

Since the COs have been written as a linear combination of BOs associated with the different AOs of the unit cell, the DOS curves can be analyzed in terms of contributions per AO of the unit cell. In other words, once the DOS plot has been calculated, we can project the contribution of certain AOs or fragment orbitals of interest for the analysis.[14] In order to illustrate the process let us consider the two-center MO

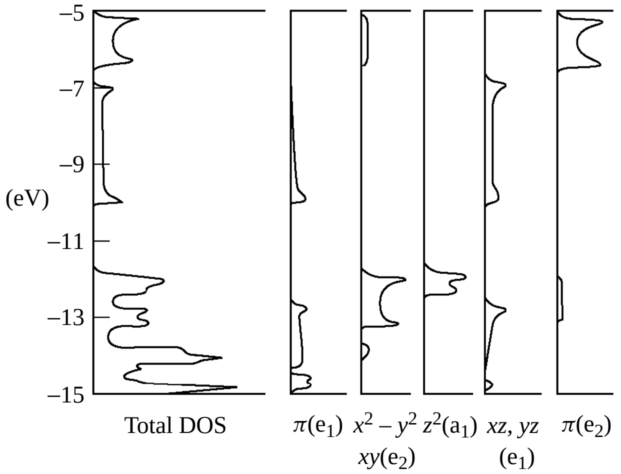
$$\Psi = c_1\chi_1 + c_2\chi_2 \tag{39}$$

The electron distribution in this MO is given by the normalization condition

$$1 = c_1{}^2 + c_2{}^2 + 2c_1c_2S_{12} \tag{40}$$

where S_{12} is the overlap integral between χ_1 and χ_2. Although it is clear that c_1^2 and c_2^2 should be assigned to χ_1 and χ_2, it is not clear how to assign the term $2c_1c_2S_{12}$ which is an overlap density. The simplest solution was suggested by Mulliken. In the Mulliken population analysis,[15] this term is equally shared between centers 1 and 2. Thus the center 1 is assigned a total of $c_1^2 + c_1c_2S_{12}$ and center 2 a total of $c_2^2 + c_1c_2S_{12}$. These contributions should now be multiplied by the occupation number of this MO. This type of analysis can be performed for the different states of a solid and, consequently, a local DOS can be projected out from the total DOS. These local DOS can be those of an AO, a fragment orbital,[14,16] an atom or group of atoms.

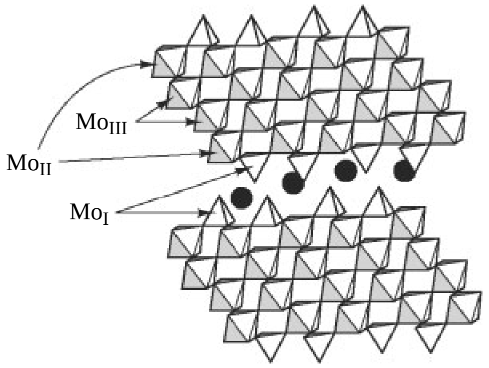
As an example of this type of analysis let us discuss the DOS of the [M(C_5H_5)] chain (**60**).[13] As mentioned in



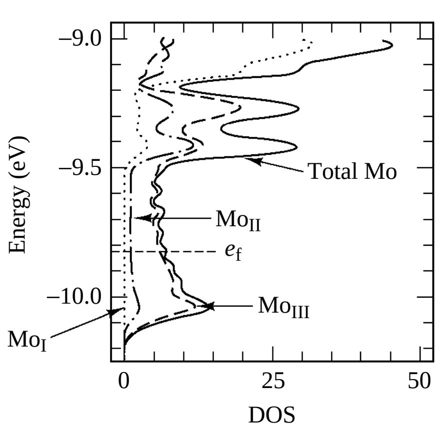
(**84**)

Section 4, the more important interactions in the polymer are those of the *xz* and *yz* (e_1) orbitals with the ligand π-type orbitals of the same symmetry. The total DOS for the infinite chain [$M(C_5H_5)$] as well as the projected densities of states for the orbitals $\pi(e_1)$, $(x^2 - y^2, xy)$, z^2, (xz, yz), and $\pi(e_2)$ are shown in (**84**). Notice how the contributions of the interacting e_1 orbitals, π and (xz, yz), are split into two regions. The lower energy orbitals, $\pi(e_1)$, are most heavily weighted in the lower energy contribution and the higher energy orbital (xz, yz) most heavily represented in the upper energy contribution. This is the equivalent of our understanding of the interaction of two nondegenerate orbitals in molecules. The contribution of these interacting orbitals extends over a considerable energy range because the two types of orbitals are well oriented to interact, leading to dispersive energy bands. As mentioned, the z^2 orbital does not interact well with the $\pi(a_1)$ ligand orbital. Consequently, the projected contribution of this orbital appears as a very localized contribution. The $x^2 - y^2$ and *xy* orbitals can interact with the ligand $\pi(e_2)$ ones, which are higher lying in energy, and both types of orbital appear split into two contributions. However, the interactions are less effective than those of the *xz* and *yz* orbitals, because the $x^2 - y^2$ and *xy* orbitals are not directed towards the π orbitals of the ligand. As shown in (**84**), the mixing is weaker and the dispersion of the corresponding bands is smaller for the $(x^2 - y^2, xy)$ and $\pi(e_2)$ orbitals than it was for the (xz, yz) and $\pi(e_1)$ orbitals. The main conclusions of this analysis parallel those of Section 4 as well as those reached when the orbital interactions in the molecular $(C_5H_5)_2M$ are considered.[1] Thus the use of projected or local DOS can be a very powerful tool to analyze the electronic structure of complex solids and to help establishing a link between our understanding of the electronic structure of molecules and solids.[17]

Some solids with interesting physical properties possess large and complex unit cells. In understanding the physical properties of such systems, it is important to have some guidelines by which to single out the parts of their crystal structure essential for the description of these properties. For instance, the purple bronze KMo_6O_{17} is a 2D metal and exhibits a resistivity anomaly at 120 K.[18] KMo_6O_{17} has separated metal–oxygen layers of composition Mo_6O_{17}, which are made up of both MoO_6 octahedra and MoO_4 tetrahedra (**85**). The K^+ cations reside in between these layers. As shown in (**85**), there are three different types of Mo atoms in KMo_6O_{17}: the Mo atoms of the MoO_4 tetrahedra (Mo_I in **85**), those of the MoO_6 octahedra in the outer two octahedral sublayers (Mo_{II} in **85**), and those of the MoO_6 octahedra in the inner two octahedral sublayers (Mo_{III} in **85**). According to the usual oxidation formalism of K^+ and O^{2-}, there are three electrons to fill the lower d-block levels of the Mo_6O_{17} layers. Thus it is interesting to enquire if the electrons responsible for the metallic properties (i.e. those near the Fermi level) are delocalized all over the layer or if they are confined into one of the sublayers. Shown in (**86**) is the projection of the Mo contribution to the DOS as well as the individual contributions of Mo_I, Mo_{II}, and Mo_{III}. It is clear from these results that the conducting electrons are those associated with the two inner sublayers of $Mo_{III}O_6$ octahedra. Consequently, the conducting electrons are quite well screened from the random potentials generated by possible alkali nonstoichiometry in these and related molybdenum bronzes.

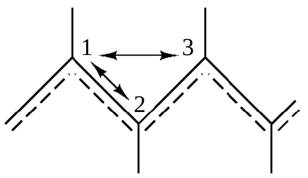


(**85**)

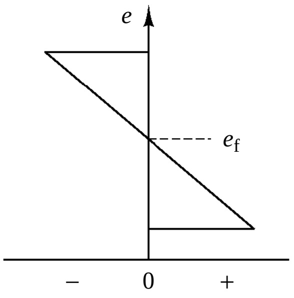


(**86**)

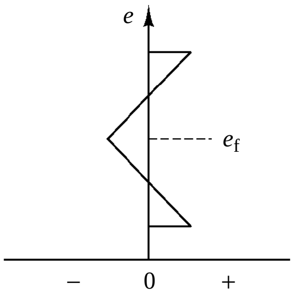
Useful as they are, local DOS do not allow us to know whether the levels in a certain energy range contribute to the bonding between a given pair of atoms. In molecular chemistry, this is often discussed on the basis of the so-called Mulliken overlap population.[15] This concept is related to the contribution $2c_1c_2S_{12}$ of equation (40). This term, an overlap population, is a characteristic of the bonding between the two centers 1 and 2. If the overlap integral is taken as positive, then this quantity is positive when the combination between the two orbitals is bonding and negative when the combination is antibonding. The Mulliken overlap population is the addition over all the orbitals on the two atoms over all occupied MOs of $2c_ic_jS_{ij}$. Exactly as was done for the local DOS, the quantities $2c_ic_jS_{ij}$ of interest can be evaluated for the different energy levels of a solid and projected from the total DOS. These overlap-population-weighted DOS curves are usually known as COOP curves (*Crystal Orbital Overlap Population*).[19]



(**87**)



(**88**)

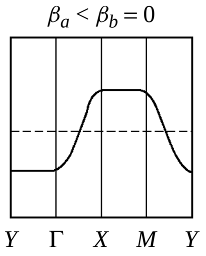


(**89**)

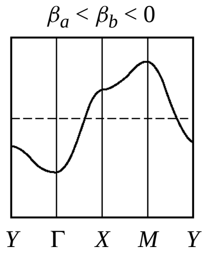
A very simple example of COOP curves are those corresponding to the 1,2 and 1,3 interactions in ideal polyacetylene (**87**). As discussed in Section 4, all the 1,2 interactions are bonding at the bottom of the lower band (**39a**) but antibonding at the top of the upper band (**39b**). The levels at the top of the lower band and bottom of the upper band are essentially nonbonding (**40**). Thus the COOP curve for the 1,2 interactions will be as schematically shown in (**88**). The 1,3 interactions are bonding both at the top of the upper band (**39b**) and the bottom of the lower band (**39a**). However, they are antibonding at the top of the lower band and the bottom of the upper band (**40**). Since these interactions are weaker than the 1,2 ones, the corresponding COOP curve should be as schematically shown in (**89**). COOP curves have been very useful in understanding the structure of complex solids as well as in chemisorption studies.[20]

6 FERMI SURFACE[21]

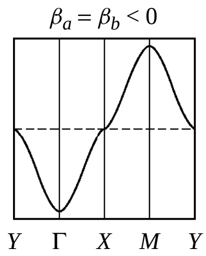
In order to examine the concept of Fermi surface, let us consider the case of the 2D lattice (**14**) for which the band dispersion relationships are given by equation (15). Diagrams (**90a–c**) show the band dispersion relations along $\Gamma \rightarrow X \rightarrow M \rightarrow Y \rightarrow \Gamma$ for cases (a) $\beta_a < \beta_b = 0$, (b) $\beta_a < \beta_b < 0$, and (c) $\beta_a = \beta_b < 0$, respectively. There is no interaction along the b-direction in case (a), so that the band is dispersionless along $\Gamma \rightarrow Y$ and $X \rightarrow M$. In case (b) the interaction along the b-direction is weaker in magnitude than that along the a-direction. In case (c) the interactions along the a- and b-directions are equally strong. The dashed lines of (**90a–c**) refer to the Fermi level when the band is half filled. For a partially filled band, wave vectors in a certain region of the BZ lead to occupied band levels (i.e. levels below the Fermi level), and wave vectors in the remaining region of the BZ lead to unoccupied band levels (i.e. levels above the Fermi level). The region of the occupied and unoccupied band levels for (**90a–c**) is shown in (**91a–c**), respectively, where shading corresponds to the wave vectors of the occupied levels. Since all k points of the BZ are equally allowed, the occupied region in each of (**91a–c**) is one-half the area of the BZ. For a completely filled band, all the wave vectors of the BZ are occupied. Diagrams (**91d**) and (**91e**) show the region of the occupied and unoccupied band levels of case (**c**) when the band is less-than-half and more-than-half filled, respectively.



(**90a**)

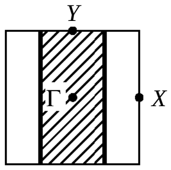


(**90b**)

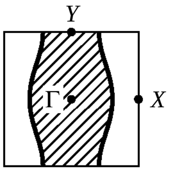


(**90c**)

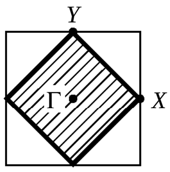
The boundary surfaces dividing the region of the occupied and unoccupied wave vectors are known as Fermi surfaces. Thus a Fermi surface occurs as a surface in a 3D band description, a line in a 2D band description, and a pair of points in a 1D band description. The wave vectors lying on the Fermi surface are called the Fermi vectors, which



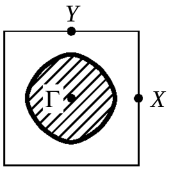
(**91a**)



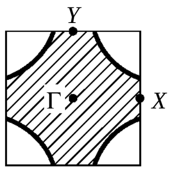
(**91b**)



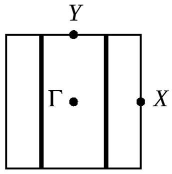
(**91c**)



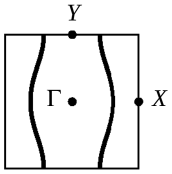
(**91d**)



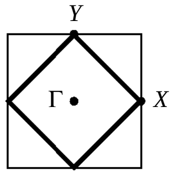
(**91e**)



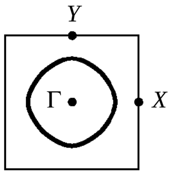
(**92a**)



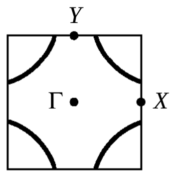
(**92b**)



(**92c**)



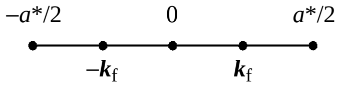
(**92d**)



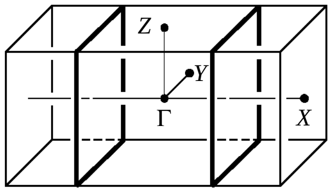
(**92e**)

are denoted by $\boldsymbol{k}_{\mathrm{f}}$. Thus the Fermi surfaces of (**91a–e**) are given by (**92a–e**), respectively. The Fermi surfaces of (**92a**) and (**92b**) consist of isolated lines, and hence are 1D Fermi surfaces. The Fermi surfaces of (**92c–e**) are closed loops, and therefore are 2D Fermi surfaces. (For (**92e**) the Fermi surface pattern needs to be repeated in reciprocal space to recognize the closed loops.) Carriers of metals are those electrons at the Fermi level. When a certain wave vector direction does not cross a Fermi surface (e.g. $\Gamma \rightarrow Y$ in (**92a**)), there are no electrons at the Fermi level having momentum along that direction and the system is not metallic along that direction. Therefore the Fermi surfaces of (**92a**) and (**92b**) correspond to 1D metals with metallic properties along the a-direction, while those of (**92c–e**) represent 2D metals. Fermi surfaces resulting from less-than-half and more-than-half filled bands are often referred to as electron and hole Fermi surfaces, respectively. For example, the Fermi surfaces of (**92d**) and (**92e**) (see also (**91d**) and (**91e**)) are electron and hole Fermi surfaces, respectively.

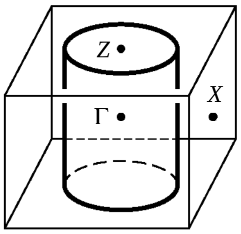
Let us now generalize our discussion of the Fermi surface. Within a 1D representation, the Fermi surface of a half-filled band is given by two k points ($\pm 0.25\ \boldsymbol{a}^*$ or, equivalently, $\pm \mathbf{k}_{\mathrm{f}}$) (**93**). Within a 2D representation, the Fermi surface of the half-filled 1D metal for $\beta_a < \beta_b = 0$ is given by two lines perpendicular to $\Gamma \rightarrow X$, as already seen from (**92a**). Within a 3D representation, the Fermi surface of the half-filled 1D band for $\beta_a < \beta_b = \beta_c = 0$ is given by two parallel planes, that is, $(\pm 0.25, y, z)$, perpendicular to $\Gamma \rightarrow X$ (see (**94**)). Likewise, the 2D Fermi surface of (**92d**) will be given by a cylinder in a 3D representation ($\beta_a = \beta_b < \beta_c = 0$) as shown in (**95**).



(**93**)



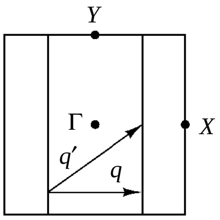
(**94**)



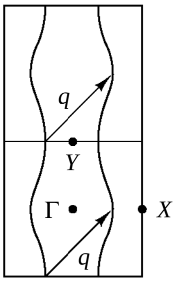
(**95**)

The concept of Fermi surface does not only play a key role in understanding the dimensionality of the transport properties of metals but also in explaining the electronic instabilities of partially filled band systems. When a piece of a Fermi surface can be translated by a vector $\boldsymbol{q}$ and superimposed on another piece of the Fermi surface, this Fermi surface is said to be nested by the vector $\boldsymbol{q}$. Since the Fermi surface of (**92a**) consists of two parallel lines, it is nested by an infinite number of wave vectors, two examples of which are shown in (**96**). In discussing Fermi surface nesting, it is important to consider Fermi surfaces in the entire reciprocal space, which is achieved by repeating the Fermi surface pattern of the first

BZ in reciprocal space. For example, the Fermi surface of (**92b**) is repeated along $\Gamma \rightarrow Y$ to generate (**97**). Then it is evident that the Fermi surface of (**97**) is nested by the vector $\boldsymbol{q}$ shown.

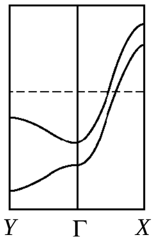


(**96**)

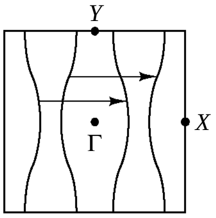


(**97**)

As a slightly more complicated example of Fermi surface nesting, consider the two partially filled 1D bands shown in (**98**). These two bands have an identical slope along $\Gamma \rightarrow X$ but opposite slopes along $\Gamma \rightarrow Y$. Then the Fermi surface resulting from the two bands of (**98**) is found to have four separate pieces as shown in (**99**). In (**99**) the inner two pieces of the Fermi surface result from the upper band whereas the outer two pieces result from the lower band, and there are two pairs of nested pieces with an identical nesting vector. The importance of Fermi surface nesting lies with the fact that a metallic system with a nested Fermi surface possesses electronic instability and therefore is likely to undergo a metal-to-insulator phase transition. As will be discussed in the next section, the latter opens a band gap at the Fermi level, thereby destroying the Fermi surface.



(**98**)



(**99**)

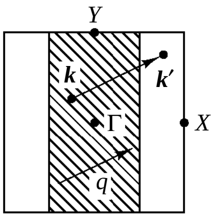
7 ELECTRONIC STATES DERIVED FROM A METALLIC STATE[5,22]

In discussing metal-to-insulator and metal-to-superconductor transitions, it is convenient to describe the insulating and the superconducting states as a consequence of a perturbation on the metallic state. In the following, we first examine why Fermi surface nesting is likely to induce a metal-to-insulator transition from the viewpoint of band orbital mixing. Then we discuss how the phenomenon of electron localization may be understood and also how a superconducting state can be described in terms of band orbital mixing.

7.1 Charge Density Wave and Spin Density Wave States

A metallic state predicted by one-electron band theory is not stable when its Fermi surface is nested, and becomes susceptible to a metal-to-insulator transition under a suitable perturbation. We now examine the nature of the nonmetallic states that are derived from a normal metallic state upon mixing its occupied and unoccupied band levels. For simplicity, consider the 2D representation of the nested Fermi surface shown in (**100**), where the vector $\boldsymbol{q}$ is one of many possible nesting vectors. The occupied and unoccupied wave vectors are denoted by $\boldsymbol{k}$ and $\boldsymbol{k}'$, respectively. Each unit cell will be assumed to contain one AO χ. Suppose we choose the $\boldsymbol{k}$ and $\boldsymbol{k}'$ values to satisfy the relationship

$$\boldsymbol{q} = \boldsymbol{k} - \boldsymbol{k}' \tag{41}$$



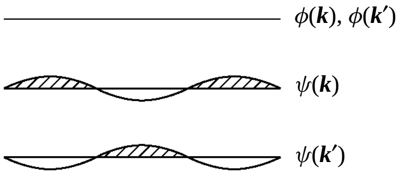
(**100**)

The orbitals $\phi(\boldsymbol{k})$ and $\phi(\boldsymbol{k}')$ are eigenfunctions of the unperturbed Hamiltonian H°. If a certain perturbation H' is introduced and the interaction matrix elements $\langle\phi(\boldsymbol{k})|H'|\phi(\boldsymbol{k}')\rangle$ are nonzero, these orbitals will not be eigenfunctions of $H^\circ + H'$ anymore. They will interact to give modified orbitals $\psi(\boldsymbol{k})$ and $\psi(\boldsymbol{k}')$

$$\begin{aligned} \psi(\boldsymbol{k}) &\propto \phi(\boldsymbol{k}) + \gamma\phi(\boldsymbol{k}') \\ \psi(\boldsymbol{k}') &\propto -\gamma\phi(\boldsymbol{k}) + \phi(\boldsymbol{k}') \end{aligned} \tag{42}$$

where γ is a mixing coefficient.

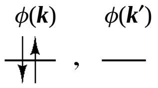
The electron density distributions of the modified orbitals, $\psi(\boldsymbol{k})$ and $\psi(\boldsymbol{k}')$, differ from those of the unmodified ones, $\phi(\boldsymbol{k})$ and $\phi(\boldsymbol{k}')$. As shown by Whangbo,[23] $\psi(\boldsymbol{k})$ and $\psi(\boldsymbol{k}')$ each have density wave character with respect to $\phi(\boldsymbol{k})$ or $\phi(\boldsymbol{k}')$, with periodicity in real space given by the term $\cos(\boldsymbol{q}\cdot\boldsymbol{R})$. $\psi(\boldsymbol{k})$ leads to density accumulation where $\psi(\boldsymbol{k}')$ has density depletion, and vice versa. If the density distribution arising from $\phi(\boldsymbol{k})$ or $\phi(\boldsymbol{k}')$ is represented by a straight line, then the density accumulation and depletion associated with $\psi(\boldsymbol{k})$ and $\psi(\boldsymbol{k}')$ occur in a waveform as shown in (**101**), where shaded



(**101**)

and unshaded half waves represent density accumulation and depletion, respectively.

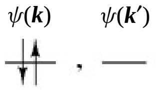
Suppose that the orbital mixings defined in equation (42) are carried out for all occupied $\boldsymbol{k}$ under the condition $\boldsymbol{q} = \boldsymbol{k} - \boldsymbol{k}'$ to obtain sets of modified orbitals $\{\psi(\boldsymbol{k})\}$ and $\{\psi(\boldsymbol{k}')\}$ from sets of unmodified orbitals $\{\phi(\boldsymbol{k})\}$ and $\{\phi(\boldsymbol{k}')\}$. The normal metallic state is one in which all the $\phi(\boldsymbol{k})$ orbitals are doubly occupied (**102**). Then, as illustrated in (**103**) for a 1D chain, each site has no magnetic moment and has an identical amount of charge. A charge density wave (CDW) state occurs when the $\psi(\boldsymbol{k})$ orbitals are doubly occupied (**104**). As illustrated in (**105**) for a 1D chain, a CDW state has no local magnetic moment but charge densities on atomic sites which vary in a wave manner. When $\psi(\boldsymbol{k})$ and $\psi(\boldsymbol{k}')$ are each singly occupied by up-spin and down-spin electrons (**106**), respectively, a SDW state results. As shown in (**107**) for a 1D chain, the SDW state has a local magnetic moment at atomic sites but the total charge density on each atomic site is identical. The driving force leading to a CDW or an SDW state is the energy gain that results from the interactions of occupied levels $\phi(\boldsymbol{k})$ with unoccupied levels $\phi(\boldsymbol{k}')$, that is, $\langle\phi(\boldsymbol{k})|H'|\phi(\boldsymbol{k}')\rangle$, where the perturbation H' is the lattice vibration and electron–electron repulsion for CDW and SDW, respectively.



(**102**)

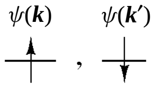
(**103**)

The orbital mixing between $\phi(\boldsymbol{k})$ and $\phi(\boldsymbol{k}')$ becomes more favorable as the energy difference between them decreases, that is, when the $\boldsymbol{k}$ value approaches the Fermi surface. The orbital mixing lifts the degeneracy between $\phi(\boldsymbol{k})$ and $\phi(\boldsymbol{k}')$ when $\boldsymbol{k}$ is on the Fermi surface, and increases the energy difference between $\phi(\boldsymbol{k})$ and $\phi(\boldsymbol{k}')$ when $\boldsymbol{k}$ does not lie on the Fermi surface. As illustrated in (**108**) for a partially filled 1D band system, the orbital mixing between $\phi(\boldsymbol{k})$ and $\phi(\boldsymbol{k}')$ changes their energies in the vicinity of the Fermi level most

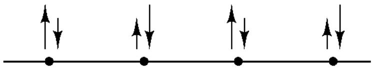


(**104**)

(**105**)

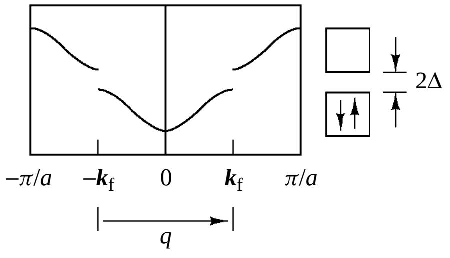


(**106**)



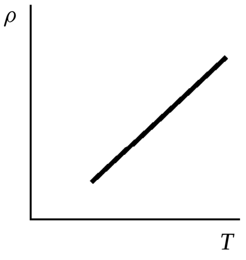
(**107**)

significantly and opens a band gap at the Fermi level. In (**108**) the band gap is given by 2Δ, where $\Delta = \langle\phi(\boldsymbol{k})|H'|\phi(\boldsymbol{k}')\rangle$ evaluated for $\boldsymbol{k} = \boldsymbol{k}_\mathrm{f}$. When there exists a Fermi surface nesting, the favorable orbital mixing can be achieved for a large region of $\boldsymbol{k}$ values in the vicinity of the Fermi surface. This explains why a metal with a nested Fermi surface is susceptible toward a phase transition that leads to orbital mixing between the levels around the Fermi level, thereby creating a band gap.

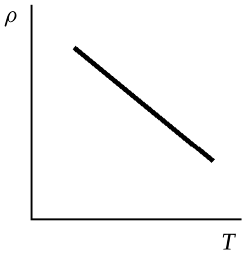


(**108**)

Metals and semiconductors have positive and negative slopes in their electrical resistivity (ρ) vs. temperature (T) curves as schematically shown in (**109**) and (**110**), respectively. By definition, the Fermi surface disappears when a band gap opens at the Fermi level. If the Fermi surface nesting is complete, all the Fermi surface is removed by the appropriate orbital mixing. However, if the Fermi surface nesting is incomplete, only the nested portion of the surface is removed by orbital mixing. The unnested portion is left as small Fermi surface pockets. The system will thus retain its metallic properties although the number of carriers (i.e. those electrons at the Fermi level) will be

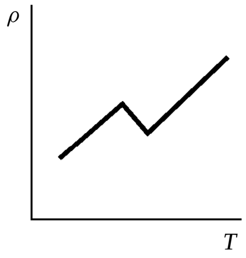


(**109**)

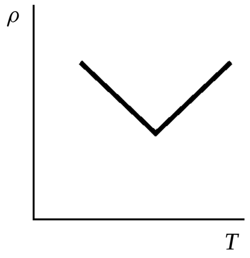


(**110**)

smaller. If a phase transition induced by temperature lowering gives rise to such Fermi surface change, the resistivity vs. temperature plot for the system will be as shown in (**111**) (i.e. a metal-to-metal transition). However, if the Fermi surface nesting is complete, (**112**) will be observed (i.e. a metal-to-semiconductor or metal-to-insulator transition). The CDW instabilities of $NbSe_3$,[24] Mo_4O_{11},[25a–c] and KMo_6O_{17}[18,25a,b] are associated with metal-to-metal transitions, while those of TaS_3,[24] $K_{0.3}MoO_3$,[26] and $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$,[10] with metal-to-semiconductor transitions. The charge transfer molecular conductor $(TMTSF)_2PF_6$ undergoes a metal-to-insulator transition near 12 K at ambient pressure as a result of an SDW instability.[27a]



(**111**)

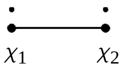


(**112**)

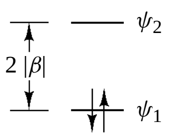
7.2 Electron Localization[28]

In order to examine the role of the on-site electron–electron repulsion U, let us first discuss the relative energies of the low- and high-spin states of a dimer. Consider a dimer with one orbital and one electron on each atomic site (**113**), the MOs of which are expressed as

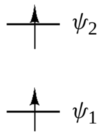
$$\Psi_1 = \frac{(\chi_1 + \chi_2)}{\sqrt{2}}$$
$$\Psi_2 = \frac{(\chi_1 - \chi_2)}{\sqrt{2}} \qquad (43)$$



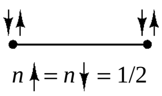
(**113**)



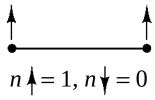
(**114**)



(**115**)



(**116**)



(**117**)

provided that the overlap integral $\langle\chi_1|\chi_2\rangle$ is neglected. Then, the energies of these orbitals are given by $e_1 = \alpha + \beta$ and $e_2 = \alpha - \beta$, where β is the resonance integral $\langle\chi_1|H^{\text{eff}}|\chi_2\rangle$. With two electrons, one may construct the low-spin state (**114**) or the high-spin state (**115**). In a one-electron picture, in which electron–electron repulsion is neglected, the low-spin state is always more stable than the high-spin state. However, this is not necessarily the case when electron–electron repulsion is taken into consideration. To simplify our discussion, we neglect all repulsion integrals except the on-site repulsion $U = \langle\chi_1\chi_1|\chi_1\chi_1\rangle = \langle\chi_2\chi_2|\chi_2\chi_2\rangle$. Then, in any electronic state, an atomic site with the up- and down-spin electron densities $n\uparrow$ and $n\downarrow$, respectively, contributes the amount of repulsion given by $n\uparrow n\downarrow U$. The on-site charge densities associated with the low-spin (**114**) and high-spin (**115**) states are depicted in (**116**) and (**117**), respectively. In terms of the on-site repulsion, the low-spin state is less stable than the high-spin by $U/2$. In terms of the orbital energies, however, the low-spin state is more stable than the high-spin state by $2|\beta|$, which is equal to $W/2$, where W is the bandwidth (see **4**) of the corresponding 1D chain (**1**). Therefore, when electron–electron repulsion is taken into consideration, the high-spin state becomes more stable if $U > W$. A similar reasoning for chain (**1**), assuming the cosine like e(k) vs. k relationship of equation (4), leads to the analogous localization condition, $U > (4/\pi)W$. In general, for a solid in which $U > W$, the total energy can be lowered by introducing spin polarization on each lattice site (i.e. $n\uparrow \neq n\downarrow$) because it reduces the contribution of on-site repulsion to the total energy. This situation is realized in an SDW state as discussed in the previous section.

(**118**)

(**119**)

So far our discussion has been limited to those electronic states that originate from a normal metallic state, and is therefore appropriate when the on-site repulsion is small compared with the bandwidth (i.e. $W > U$). When $U \gg W$, electrons are localized on lattice sites. Consider the 1D lattice (**118**) that has one orbital and one electron per site, a typical half-filled band system. When $U \gg W$, favorable electronic states are those in which each site has one electron with either up or down spin. All these states are insulating in nature, because electron hopping from one site to another leads to a situation in which two electrons reside on a single site, thereby causing on-site repulsion (see **119**). Such insulating states resulting from partially

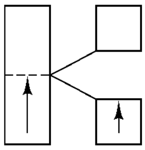
filled bands are referred to as Mott–Hubbard localized states (*see Mott–Hubbard Transition*). Diagrams (**120**) and (**121**) represent ferromagnetic (*see Ferromagnetism*) and antiferromagnetic (*see Antiferromagnetism*) arrangements of spins, respectively. These two states have a long-range order. The spin arrangement of (**122**) is an example with no long-range order. Within the one-electron band picture, the ferromagnetic state (**120**) is represented by the electronic structure that results when all the band levels are singly occupied with an identical spin, as depicted in (**123**), which is a solid-state analog of the dimer high-spin state (**115**). If one neglects electron–electron repulsion terms except for the on-site and the nearest-neighbor intersite Coulomb repulsions, the electronic energies of the three states (**120**–**122**) are identical. Consequently, the high-spin band filling scheme (**123**) may be used to represent any localized electronic state arising from a half-filled band. This high-spin band filling scheme is useful. For instance, if a 1/4-filled band system adopts a low-spin band filling (i.e. each band level is occupied by up- and down-spin electrons) as shown in (**51a**), it is susceptible to a tetramerization. However, when this system adopts a high-spin band filling, it would undergo a dimerization instead of tetramerization because band gap opening at the Fermi level can be achieved only by a dimerization (see (**124**)). In 1D systems, the distortion (e.g. (**51a**)) arising from a low-spin band filling ($U < W$) is called a $2k_f$ distortion, since the nesting vector is given by $\boldsymbol{q} = k_f - (-k_f) = 2k_f$. The distortion arising from a high-spin band filling ($U > W$) (e.g. (**124**)) is referred to as a $4k_f$ distortion.[29] An example of $4k_f$ distortion is provided by the organic charge transfer salt MEM^+ $(TCNQ)_2{}^-$.[12,30]

(**120**)

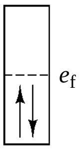
(**121**)

(**122**)

(**123**)



(**124**)



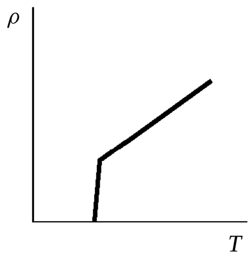
(**125**)

For a half-filled system, the low-spin metallic band filling (**125**) is appropriate when $U < W$. The energies for the low-lying excited states of the metallic state (**125**) are well described by the band orbital energy differences in the vicinity of the Fermi level. In contrast, it is difficult to describe the energies for the low-lying excited states of a Mott–Hubbard localized state (e.g. the energy differences between the states (**120**) and (**121**)) within a band electronic structure theory, because this theory is based upon the assumption that electrons are delocalized throughout the lattice. Localized electronic systems are typically examined in terms of model Hamiltonians (e.g. spin and Hubbard Hamiltonians) designed to study their low-lying excited states.[28b]

In addition to Mott–Hubbard localization, there is another common source of electron localization, which arises when a lattice is under a random potential (e.g. a random distribution of alkali metal ions in alkali metal containing transition metal oxides). For a metal, a practical consequence of a random potential is to open a band gap at the Fermi level. Insulating states induced by random potentials are referred to as Anderson localized states (*see Anderson Localization*).[31]

7.3 Superconducting State[32,33]

Upon lowering the temperature, a metal may become susceptible to another type of electronic instability, that is, formation of a superconducting state (*see* **126**; also ***Superconductivity***). Charge carriers of a superconducting state are not individual electrons as in a normal metallic state, but pairs of electrons (called Cooper pairs; *see Cooper Pair*) having opposite momenta (i.e. opposite wave vectors). Thus Cooper pairs are described by-product functions $\phi(\boldsymbol{k})\phi(-\boldsymbol{k})$ and $\phi(\boldsymbol{k}')\phi(-\boldsymbol{k}')$, where $\boldsymbol{k}$ and $\boldsymbol{k}'$ refer to occupied and unoccupied wave vectors of a normal metallic state, respectively. The energy lowering that brings about superconductivity is induced by the interaction of an occupied pair function $\phi(\boldsymbol{k})\phi(-\boldsymbol{k})$ with an unoccupied pair function $\phi(\boldsymbol{k}')\phi(-\boldsymbol{k}')$, that is, $\langle\phi(\boldsymbol{k})\phi(-\boldsymbol{k})|H'|\phi(\boldsymbol{k}')\phi(-\boldsymbol{k}')\rangle$, where the perturbation H' causing this mixing is electron–phonon interaction in traditional superconductors described by the BCS theory.[33] As a consequence of the interaction between the pair functions, the character of the unoccupied pair function is mixed into that of the occupied pair function. In this indirect way, a superconducting state incorporates unoccupied orbital character into the occupied orbital character.[22] Interactions between the pair functions $\phi(\boldsymbol{k})\phi(-\boldsymbol{k})$ and $\phi(\boldsymbol{k}')\phi(-\boldsymbol{k}')$ introduce an energy gap at the Fermi level, as do the



(**126**)

interactions between $\phi(\boldsymbol{k})$ and $\phi(\boldsymbol{k}')$ in forming CDW and SDW states. It should be recalled that charge carriers of a superconducting state are Cooper pairs. A superconducting energy gap prevents Cooper pairs from breaking up when there is no excitation energy greater than the gap. The latter is a few multiples of $k_B T_c$ at absolute zero temperature, where T_c is the superconducting transition temperature, and gradually decreases to zero at T_c.

For traditional superconductors, Cooper pair formation is induced by the electron–phonon interaction.[33] Simply speaking, a moving electron causes a slight, momentary lattice deformation around itself. The deformation affects the motion of a second electron (moving in the opposite direction) in the wake of the first in such a way that, effectively, the two electrons move as an entity as if bound together by an attractive force. Among the factors affecting the magnitude of the superconducting transition temperature T_c, the most important one is the electron–phonon coupling, the extent of which is measured by the electron–phonon coupling constant λ. In general, T_c increases with increasing λ. In addition, a large λ results when the lattice has a low-frequency phonon spectrum (i.e. soft phonons arising from vibrations with shallow potential wells). Therefore, when the lattice is soft toward the low-frequency phonons crucial for superconductivity, the electron–phonon coupling constant λ is large, thereby raising the T_c.

In order to become superconducting, a metal should avoid the electronic instability toward a metal-to-insulator transition leading to a CDW or an SDW state. The Fermi surface of a 1D metal is generally well nested so that a 1D metal rarely becomes superconducting. However, the preference for the CDW, SDW, or superconducting states sometimes can be delicately balanced by changes in pressure, temperature, or electron filling. For instance, the 12 K metal-to-insulator transition associated with the SDW instability of $(TMTSF)_2PF_6$ can be suppressed under an applied pressure of 9 kbar and the system becomes superconducting at 0.9 K.[27b] An interesting situation occurs for the $x^2 - y^2$ band of the CuO_2 layers in high T_c copper oxide superconductors. When this band is half filled, its 2D Fermi surface (see **91c**) is well nested and the CuO_2 layers are not metallic but antiferromagnetic, which is a particular case of a SDW state. This situation applies for stoichiometric La_2CuO_4. When some electrons are removed or added as in $La_{2-x}Sr_xCuO_4$ and $Nd_{2-x}Ce_xCuO_4$ respectively, the Fermi surfaces are no longer nested (see **91d** and **91e**) and the CuO_2 layers are metallic and eventually become superconducting.[34]

8 COMPUTATIONAL APPROACHES

The combination of impressive developments both at the computational level and in quantum mechanical methods during the last decade has made very precise descriptions of the electronic structure of solids with quite large unit cells possible. The solid-state chemist who needs to put on a firm, more quantitative basis the concepts developed in this article for the materials in which he or she is interested is frequently faced with a large series of approaches and computing codes. In this section, we will give a succinct description of some of the more often used approaches in the chemical literature. The interested reader will find detailed information about their basis and computational implementations in the web page addresses we provide.

Among semiempirical methods, the more frequently used has been the Extended Hückel method.[11,35] This approach has deep roots in the way chemists think about the electronic structure of molecules and has been successfully adapted to the peculiarities of infinite systems. This is an LCAO and non self-consistent approach in which overlap is retained. The diagonal elements of the Hamiltonian are considered to be the corresponding ionization potentials and the nondiagonal elements are evaluated on the basis of a Wolfsberg-Helmholz type approximation. The simplicity and transparency of the method has made it very popular and extremely useful in understanding the electronic structure of a wide variety of materials. The information that can be obtained is mostly qualitative and thus it is specially useful in looking at trends (for instance, it is an approach which cannot be used for structural optimizations). However, in some fields (for instance, in low-dimensional materials) the method has provided almost quantitative, and in some cases even provides predictive, information. There is no doubt that even if more sophisticated approaches are by now routinely used, the ideas originating from this approach will continue to provide a simple yet powerful way to discuss the electronic structure of solids.

Density Functional Theory (DFT) has become the method of choice for the study of the electronic structure of solids. Advances in computer technology have made possible the development of DFT-based codes providing a detailed ab initio description of the electronic structure of complex materials. Following the two celebrated papers by Hohenberg and Kohn[36a] and Kohn and Sham,[36b] a wide variety of approaches have been developed and turned into very efficient computational tools. These approaches differ in the way they represent the density, potential, and Kohn-Sham orbitals. Essentially DFT approaches can be classified in two main groups: all electron methods and pseudopotential methods.

The use of a pseudopotential is one of the ways to remedy for the more notorious deficiency of plane waves basis sets: the impossibility of describing correctly the rapid oscillation of the valence wave functions in the region around the ion cores. However plane waves offer several advantages (unbiased representation, arbitrarily good convergence accuracy, easiness of mathematical and computational implementation) which lie at the heart of their widespread use. In the pseudopotential approximation, the nucleus and core electrons are

considered as a frozen core and the interaction of the valence electrons with this core is described by a pseudopotential which reproduces the eigenvalues and wave functions outside the core. Of course, this approach assumes that the exchange-correlation potential is separable into a core and a valence part. This assumption is never exact and although it works effectively in many cases, it can be problematic for transition metal atoms for instance. The partial nonlinear core correction scheme can be used in these cases. The use of pseudopotentials is not limited to plane wave approaches; although in this case it is not really needed, it can also be used when localized AOs-like basis sets are used. In that way, only the valence electrons are treated explicitly.

A number of efficient computer codes using the pseudopotential approach are presently available. Some of the more widely used include ABINIT,[37] VASP,[38] SIESTA,[39] CASTEP,[40] Spinor[41] and FH98md.[42] Every one of them has its own peculiarities, for instance, VASP is one of the fastest because of its use of ultrasoft pseudopotentials, Spinor includes spin-orbit coupling and generalized noncollinear magnetism, and ABINIT allows both DFT and density functional perturbation theory calculations. All of these codes use plane wave type basis sets. SIESTA differs from them in that it uses a numerical LCAOs basis set. Because of the localized nature of the basis, the computer time and memory scale linearly with the number of atoms allowing the study of very large systems. The code is very flexible, allowing both very fast simulations using minimal basis sets and very accurate calculations using multi-ζ and polarized bases depending on the required accuracy and available computational power. A nonnegligible advantage of the code, like all methods using local basis sets, is that it greatly facilitates the analysis of the results in familiar chemical terms.

All electron approaches in which no approximation concerning the shape of the potential is made are known as full potential schemes. The more widely used all-electron approach is the LAPW (linear augmented plane wave) method.[43] Its basis lies on the observation that near the nucleus the wave function and potential are close to those in the atom in that they are strongly varying and nearly symmetrical. However, between the atoms the wave function and potential are smoother. Thus, in the LAPW approach the unit cell of the system is divided into a series of nonoverlapping atomic spheres centered on the atoms and an interstitial region. In order to build the basis functions (not the potential), it is assumed that the potential is spherically symmetric inside the atomic spheres but constant outside (i.e. the so-called muffin tin approximation). As a result each plane wave is augmented by an atomic type function inside every atomic sphere. There are different schemes of varying accuracy in order to perform such augmentation. The more widely used code implementing these ideas is WIEN2k.[44]

Other full potential all-electron approaches have been developed. For instance, the FPLO (full potential local orbital) code[45] uses numerical orbitals constrained to be relatively short range. The use of linear muffin tin orbitals (LMTO)[46] has led to the development of a series of approaches of different degrees of complexity and accuracy from LMTO-ASA (linear muffin tin orbital-atomic spheres approximation) to full potential LMTO.[47]

The choice of one or the other of these approaches depends not only on the computing resources but more specially on the nature of the problem. It is obvious that properties relying on the density near the nucleus, hyperfine fields for instance, require the use of an all-electron method. In contrast, efficient structural optimizations when the unit cell changes are much more easily performed in pseudopotential approaches.

The very important work by Car and Parrinello[48] made feasible ab initio molecular dynamics studies for systems of practical interest. More importantly, the success of the method launched an enormous interest in the field and led to the development of several schemes that have made ab initio molecular dynamics practically a standard tool in materials science.[49] Besides the Car-Parrinello molecular dynamics code CPMD,[50] several of the above-mentioned codes like VASP, CASTEP, FH98md or SIESTA also allow molecular dynamics calculations for large systems. Judging from the fast growing number of studies using ab initio molecular dynamics to perform realistic simulations on materials of increasing complexity, there is no doubt that the technique will have a strong impact on our understanding of the structural and physical properties of materials.

Although the Hartree-Fock (HF) approach has been the more widely used and successful for ab initio studies of the electronic structure of molecules, this is not the case for solids. Here, as mentioned, DFT dominates the scene and most likely will continue to do it in the future. Nevertheless all electron ab initio LCAO periodic HF calculations for a variety of different materials have been reported. The best developed computer code implementing the all-electron ab initio LCAO periodic HF approach is CRYSTAL03.[51] The main drawbacks of the approach are the neglect of correlation energy, limitations in the choice of the basis set, and inaccuracies arising from the numerical approximations introduced in the implementation of the self-consistent field equations. The code is quite versatile and can perform both HF and DFT type calculations. All electron and valence-only basis sets with effective core pseudopotentials can be used. Despite the above-mentioned limitations, as well as quite severe computing time and memory requirements, the code has been successfully used for a variety of purposes like structural, elastic, vibrational and magnetic properties, chemisorption studies, and so on.

9 CONCLUDING REMARKS

The objective of this contribution is to convince chemists that the jargon of solid-state physics is not as impenetrable as at first sight it might seem. As a matter of fact, many of the main ideas of band theory have their equivalent in MO theory. In particular, the concept of orbital interaction can be used very easily to construct the band structure of many chemically interesting systems. Although there are some technical details that need to be considered carefully, the effort of building step-by-step the band structure of a solid from the orbitals of chemically significant fragments of the structure is worth doing. A clean, qualitative understanding of the relationship between the crystal and electronic structure emerges. Sometimes, when the complexity of the system increases, it can be better to focus on the analysis of the DOS instead of the band structure. Even there the orbital interaction language can be used to understand the problem. The importance of the use of the orbital interaction analysis is that it helps in looking for analogies and contrasts between the electronic structure of molecules and solids. Alternative approaches, like those based on the moments method,[52] for instance, can also be very useful in rationalizing structural choices. The impressive development during the last decade of very efficient ab initio approaches and codes applicable to very large solids provides an invaluable tool for the solid-state scientist who wants to approach the search for new materials in a more rational way. However, these advances should not make us forget the need for the development of new simple theoretical tools that are well adapted to the unravelling of the challenging problems that solid-state materials continuously bring to the fore.

1 INTRODUCTION

The solid-state chemistry of fluorides is a unique chapter owing to the extreme position of fluorine in the periodic system. The most electronegative element fluorine, reacting with nearly all other elements, forms the most ionic bonds. The fluoride ion is the smallest (ionic radius for coordination number (CN) 2 1.28 Å[1]) and most rigid ion. Its *Polarizability* is, for example, four times lower than that of oxygen. Fluorides belonged to the first subjects of investigation at the beginning of scientific chemistry. Synthetic cryolite Na_3AlF_6 or $MnF_3(H_2O)_3$, for instance, was described by Berzelius already in 1824.[2] Many 'famous' compounds, like the first rare-gas compounds, are fluorides. Spectacular high oxidation states like Ag^{IV} or Au^{V} have been stabilized in fluorides.

The structural chemistry of inorganic fluorine compounds is dominated by simple electrostatic and geometrical principles such as sphere packing and Pauling's rules. The ionic radii of nearly all transition metals in oxidation states +2, +3, and +4 are in the range where with fluoride ions CN 6 is favored as octahedral coordination. Thus, fluorometalate anions $[M^{n+}F_6]^{6-n}$ are formed, the charge of which is compensated by ligand sharing or counter cations or a combination of both. In binary compounds, only ligand sharing is possible and, for example, in AlF_3 all F atoms of $[AlF_{6/2}]$ octahedra are shared with neighbors. In some ternary compounds, for example, in the cryolite structure of Na_3AlF_6,[3] quasi-isolated $[AlF_6]^{3-}$ anions may form, whereas in others, poorer in F, for example, Tl_2AlF_5, fewer counter cations are needed to compensate for the charge of the octahedra, as these are linked to chains $[AlF_4F_{2/2}]^{2-}$. On the basis of these simple structural principles, a limited number of very large families of isostructural compounds are observed if the ratio of ionic radii is in a comparable range. The structural chemistry of fluorides is rather different from that of the compounds of the higher group VII elements because Cl, Br, and I are much larger in size, more covalent in bonding, and are easier to oxidize. There are some analogies between the structures of fluorides and oxides. However, isostructural compounds like the perovskites $K^{1+}Ni^{2+}F_3{}^{1-}$ and $Ba^{2+}Mn^{4+}O_3{}^{2-}$ present very different electronic situations and different physical properties owing to the different formal charges. Closer relationships are found to the structures of hydrides (*see* ***Hydrides: Solid State Transition Metal Complexes***) and in part even cyanides (*see* ***Cyanide Complexes of the Transition Metals***).

A certain orbital overlap of metal d and fluorine p orbitals occurs leading to magnetic superexchange interactions in M – F – M bridged transition metal compounds, although the bonding in metal fluoro compounds is mainly ionic, along with the short bond lengths. Fluorides have therefore been used as suitable model compounds for studies of magnetic properties. Along with the normally strong localization of electrons in fluorides, special optical properties are found, giving rise to technical applications, for example, for laser optics. For the same reason, fluorides are normally good insulators. However, some examples of fluorine compounds are mentioned in the final section of this article where ionic and even metallic and superconductivity is observed.

2 SYNTHESIS

While the preparation of oxides, sulfides, higher halogenides, and so on is routine in many laboratories, the number of groups dealing with preparative fluorine chemistry is rather limited because in many cases it is necessary to work with hazardous HF or even F_2 (*see* ***Fluorine: Inorganic Chemistry***). Owing to easy hydrolysis of most fluorides through mechanisms such as (1):

$$MF_3 + H_2O \longrightarrow MF_2(OH) + HF$$
$$(\text{–O})_3Si\text{–}OH + HF \longrightarrow (\text{–O})_3Si\text{–}F + H_2O \qquad (1)$$

contact of fluorides with moisture and with glass or quartz surfaces has to be avoided, at least at higher temperatures. Solid-state reactions have to be performed in Pt or Au tubes

using dry starting materials. Excellent comprehensive surveys on preparative methods in fluorine chemistry have been given by Grannec and Lozano[4] as well as Lutar, Borrmann, and Leblanc.[5] The most important techniques and some recent developments are presented in the following sections.

2.1 Gas Flow Fluorination

The most common methods of preparing anhydrous binary metal fluorides in the laboratory are based on reactions of gaseous HF or F_2 with suitable solid substrates. With HF, the oxidation state of the starting material is preserved, whereas with F_2, the fluoride with the highest stable oxidation state is obtained. The reactions are mostly carried out in tubes of Monel (a Cu/Ni alloy) at temperatures up to about 400–600 °C. As starting materials, hydrated fluorides (obtained from aqueous HF solutions), chlorides, carbonates, or easy decomposable ternary compounds like NH_4MnF_3 may be used, as shown by the following examples (2–4):

$$CrCl_3 + 3HF \xrightarrow{550\,^\circ C} CrF_3 + 3HCl \tag{2}$$

$$FeCl_3 + 6F_2 \xrightarrow{400\,^\circ C} FeF_3 + 3ClF_3 \tag{3}$$

$$NH_4MnF_3 \xrightarrow{F_2/450\,^\circ C} MnF_3 + \cdots \tag{4}$$

Worldwide significance of such fluorination reactions was attained in the course of the Manhattan project to produce UF_6 for isotope separation (5).[6]

$$\begin{aligned} UO_2 + 4HF &\longrightarrow UF_4 + 2H_2O \\ UF_4 + F_2 &\longrightarrow UF_6 \end{aligned} \tag{5}$$

The purity and dryness of binary fluorides is crucial if they are used for solid-state reactions. First, the reliability of composition of the desired compound is limited by the purity of the components used; second, moisture brought in by traces of water in the starting materials may lead to partial hydrolysis of the product and even bursting of the ampoule. Often commercially obtainable binary fluorides do not fulfill these crucial requirements.

Other possible gaseous fluorination agents are ClF_3 (oxidizing) or SF_4 (nonoxidizing).

2.2 Solid-state Reactions

The classical way to synthesize polynary anhydrous fluorides is by heating a stoichiometric and well pulverized mixture of the binary components in sealed platinum or gold tubes, for example, along equation (6).[7]

$$NaF + VF_3 \xrightarrow{800\,^\circ C} NaVF_4 \tag{6}$$

A special case of symproportionation in a solid-state reaction is shown in equation (7):[8]

$$Cs_2Mn^{IV}F_6 + Mn^{II}F_2 \xrightarrow{800\,^\circ C} 2CsMn^{III}F_4 \tag{7}$$

It has the advantage with respect to the alternative reaction of hygroscopic CsF and air-sensitive MnF_3 that both starting compounds are air-stable and obtainable without use of elemental F_2. The reaction demonstrates that some common rules for aqueous chemistry like that expecting the disproportionation of Mn(III) to Mn(II) and Mn(IV), are no longer valid for fluorides in the solid state.

The necessary alkali and alkaline earth fluorides for such reactions are accessible by dissolving the respective carbonates in aqueous HF. After reducing to a small volume, the precipitated bifluorides or fluorides are heated up to about 500 °C to obtain the anhydrous fluorides, which are highly hygroscopic for the larger alkali ions K^+, Rb^+, Cs^+.

High-pressure methods using *belt* type apparatus (*see* ***High Pressure Synthesis of Solids***) have been applied for synthesizing metastable high-pressure modifications of fluoro compounds. The structure of PdF_2, for example, transforms from rutile type to a variant of the fluorite type at 5 GPa and 400 °C.[9] As sample containers, gold cylinders were used mostly because they keep tight during the deformation and are not attacked at pressures up to 10 GPa and temperatures up to about 800 °C.

Decomposition Reactions. In some cases anhydrous fluorides can be obtained by decomposition of hydrated compounds like in equation (8)[10,11]

$$\begin{aligned} (NH_4)_2FeF_5(H_2O) &\xrightarrow{98\,^\circ C} \alpha\text{-}(NH_4)_2FeF_5 + H_2O \\ &\xrightarrow{109\,^\circ C} \beta\text{-}(NH_4)_2FeF_5 + H_2O \end{aligned} \tag{8}$$

In this way, low-temperature forms can be obtained, but, of course, as polycrystalline powders only.

2.3 Flux Methods

A series of binary, ternary, and even quaternary fluorides have been crystallized from melts. In most cases, chlorides or mixtures of chlorides are used because of their lower melting points and greater solubilities with respect to corresponding fluorides. It is advantageous to add an excess of the alkali chloride when an alkali fluorometalate is synthesized, as shown in the typical example of equation (9).[12]

$$LiF + 4ThF_4 \xrightarrow{LiCl/ZnCl_2} LiTh_4F_{17} \tag{9}$$

Using a flux, the reaction temperature can be chosen much lower than in a solid-state reaction, for example, 600 °C in

the above reaction (9). Other suitable dichlorides are $PbCl_2$, $CoCl_2$, $NiCl_2$, or $MnCl_2$.

A flux serving at the same time as a reaction partner was used, for instance, for the preparation of crystalline K_3MnF_6[13] (equation 10).

$$Mn_2O_3 + 6KHF_2 \xrightarrow{nKHF_2} 2K_3MnF_6 + 3H_2O \qquad (10)$$

2.4 Syntheses in Solution

Precipitation from aqueous solution, normally containing HF, is the oldest and the most used method of preparing fluorides. Berzelius, for example, reported the synthesis of fluorides from aqueous HF as long ago as 1824.[2] Sophisticated variants of this simple method are increasingly replacing the classical solid-state syntheses and gas flow techniques.[14]

In addition to simple precipitation reactions after mixing solutions of binary compounds in aqueous HF, simultaneous redox reactions may take place. By variation and optimization of concentrations and the pH of the solution and combination with diffusion techniques, the synthesis of different pure phases from the same system is possible, often as good crystals. In contrast to the high-temperature reactions, metastable phases can be obtained that are not otherwise accessible or that can be crystallized under avoidance of an intermediate phase transition. A good example is the system 4,4′-bipyridine/Mn(III)/HF/H_2O: Under slightly different conditions, either a salt 4,4′-bipy$H_2[MnF_4(H_2O)_2]_2 \cdot 2H_2O$[15] or the neutral 2D-coordination polymer 4,4′-bipyMnF_3 can be obtained.[16]

If the solution has high fluoride concentration and low pH values, anhydrous fluorides can be crystallized. The risk of substituting fluoride ligands by OH^- ions increases when the pH approaches the neutral regime; the formation of mixed aqua-fluoro complexes is favored at lower fluoride concentrations and low temperature.

During the last few years, many attempts have been made to design specific syntheses of fluorine compounds with, for instance, oligomeric anions, linear chain anions, layer structures, or framework structures using organic amines as templates, which serve mostly, after protonation, at the same time as counter cations (see Refs. 5, 17, 18, or for oxyfluorides with open framework structures Ref. 19).

Organic Solvents. Owing to the low solubility of most binary fluorides in organic solvents, few reactions are known that were carried out in such solutions, like reaction (11) in methanol.[20]

$$6NH_4F + AlBr_3 \xrightarrow{CH_3OH} (NH_4)_3AlF_6 + 3NH_4Br \qquad (11)$$

However, it has been found to be a good way to obtain crystals, after performing a reaction in aqueous HF solution, to diffuse a mixable organic solvent like methanol, ethanol, or even acetone into the reaction vessel.

In contrast, like in oxide systems, amorphous high-surface fluoride materials for catalytic purposes can be synthesized from organic solvents and anhydrous HF, as shown recently for 'HS-AlF_3'[21] (HS = high surface).

Crystalline 'pyr-FeF_3', a metastable cubic form of FeF_3 with pyrochlore-related structure, was obtained in a topotactical oxidation reaction of $NH_4Fe_2F_6$ with Br_2 in acetonitrile. At this example, the designation '*chimie douce (soft chemistry)*' for this type of solid-state reaction under low-temperature conditions was propagated in the 1980s.[22]

Hydrothermal Reactions. In the attempts mentioned to build framework structures, often including other bridging ligands as phosphate, carbonate, oxalate and so on, working under hydrothermal conditions in aqueous HF has been found to be very useful. Such reactions are performed in Teflon containers or sealed platinum or gold tubes surrounded by steel autoclaves at pressures up to 1 GPa. Recently, microwave heating has been used for the hydrothermal synthesis of 'hybrid' compounds $[NH_3\text{-}(CH_2)_n\text{-}NH_3][AlF_5]$.[23] A big advantage is the favored formation of good crystals under these conditions. The higher the pressure and temperature, the higher is the probability of obtaining anhydrous fluorides. In a few laboratories, hydrothermal reactions are performed in anhydrous HF or other fluorinating solvents like BrF_3, BrF_5, IF_5, SeF_4 or SbF_5, especially for the synthesis of fluorides in high oxidation states like NiF_3[24] or AgF_3.[25] The most drastic fluorinating conditions are achieved by using elemental fluorine under high pressure.[4,26] In Monel or Ni reactors, F_2 is condensed – possibly together with HF, O_2, Ar – under cooling with liquid nitrogen. After closing, the vessel is heated up to 300–500 °C, generating pressures up to about 500 MPa. Under these conditions, compounds like A_2CoF_6 (A = K, Rb, Cs),[27] $O_2Pt_2F_{11}$,[28] or CrF_4[29] could be prepared in the form of single crystals, which were otherwise not accessible owing to easy thermal decomposition. Single crystals of metastable high-pressure phases could be obtained in HF solution under hydrothermal conditions in a *belt* apparatus at pressures of 3 GPa and 250 °C.[30]

3 STRUCTURAL CHEMISTRY

At least in compounds with metals of lower oxidation states up to three or four, the metal–fluorine bond is almost purely ionic and the small, least polarizable fluoride ion behaves as a small hard sphere with an ionic radius which varies, depending on the coordination number, between 1.285 (CN 2) and 1.320 Å (CN 6).[1] The structures of fluorides are therefore determined mainly by simple geometrical and electrostatic principles, such as *sphere packing*, the *rigid sphere concept*, which allows derivation of the coordination number around

a central cation from the ratio of ionic radii, and *Pauling's rules*,[31] which postulate optimum local charge balance.

The structural chemistry of fluoro compounds is relatively simple, therefore. Many of them can be grouped into a few large structure families. Applying the above criteria, it is often possible to predict the structural type or even geometrical details for a given stoichiometric composition. On the other hand, it is possible to attribute individual deviations in the bonding geometry of transition metal fluorides to their specific electronic situation. That is why fluoro compounds are preferably used as model systems for studies of correlations between structure and electronic configuration, magnetic properties, and so on.

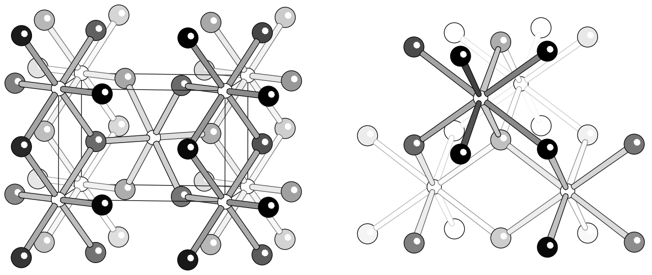
The main body of structural material in the solid-state chemistry of fluorides has been elaborated in the 1960s to the 1980s and is collected and discussed in several reviews.[32–34] A good collection of data is tabulated in Ref. 35. A recent survey from the point of view of materials science is given in Ref. 36. Here, a short survey will be given on the most important basic structural features and relations in binary and ternary (and higher) compounds, combined with an attempt to account for modern developments.

3.1 Binary Fluorides

AF Compounds. The structures of the a*lkali fluorides* are all of the NaCl type; however, the sensitivity to moisture for the K, Rb, and Cs compounds and their high-pressure phase transitions to the CsCl type show an increasing tendency to adopt the higher coordination number 8 with increasing ionic radius. In ternary compounds, it is mostly easier to adopt a more suitable coordination sphere of fluoride ligands: Li^+ may have tetrahedral coordination such as in scheelites $LiMF_4$ and a few other compounds[33] (see Section 3.2.13) but has normally CN 6. Na^+ shows CN 6–8 with a certain favoring of CN 7. K^+ clearly prefers CN 8, and Rb^+ and Cs^+ CN 10 to 12, in some cases up to 18.

MF_2 Compounds. The *alkaline earth fluorides* show quartz type structures for BeF_2 (CN 4), rutile-type (CN 6) for MgF_2 (Figure 1(a)), and the fluorite type (CN 8, Figure 1(b)) for CaF_2, SrF_2, and BaF_2. Fluorite, CaF_2, is not only of unique industrial importance as a starting material to produce HF, but also owing to the low optical absorption in the UV range, the production of large single crystals became important for laser optics used in the semiconductor industry.

Difluorides of the first transition metal row have the rutile structure (M = V, Cr, Mn, Fe, Co, Ni, Cu, Zn; Figure 1(a)). The electronic properties of the $3d^4$ and $3d^9$ configurations are manifested in strong Jahn–Teller distortions for the Cr^{2+} and Cu^{2+} case. The difluorides of the higher group 14 elements show characteristic influence of the lone pair: GeF_2 has a zig-zag chain structure with vertex-connected $[GeF_3]$ pyramids further connected by weak Ge···F contacts to a 3D net (Figure 2). For SnF_2, three polymorphs are known with the



(a) (b)

Figure 1 (a) Rutile; (b) CaF_2

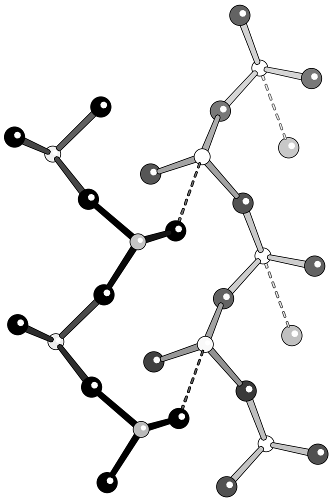


Figure 2 GeF_2

CN at Sn between 4 and 5. The monoclinic α-form is built from 4-membered rings (CN 3 + 2); the orthorhombic β-form has a 3D structure with meshes of three and of four $[SnF_5]$ Ψ-octahedra. In the tetragonal γ-form, a 3D network is formed by 6-membered rings of Ψ-octahedral $[SnF_4]$ units. PbF_2 also exists in two polymorphs: The α-form has the widespread $PbCl_2$ structure with 7 + 2 coordination (distorted tricapped trigonal prism), the β-form shows the fluorite-type structure (CN 8) and is – owing to disorder in the anion lattice – an F^- ion conductor. CdF_2, EuF_2, and SmF_2 also belong to the CaF_2 type but deviation from the stoichiometry is observed for the latter. AgF_2 has a buckled layer structure of corner-sharing planar AgF_4 units (Ag-F 2.085 Å).[37] The planes are staggered in a way that additional weak contacts (Ag···F 2.592 Å) complete the Ag coordination to an elongated octahedron (dashed bonds in Figure 3) as expected for this Jahn–Teller system.

Another interesting case is PdF_2: Besides a rutile-type phase[38] it forms a metastable high-pressure modification with a new cubic AF_2 structure type[39,40] (Figure 4) where the $[PdF_6]$ octahedra show vertex-sharing only but with 12 surrounding octahedra. The HP phase is 9% higher in density although

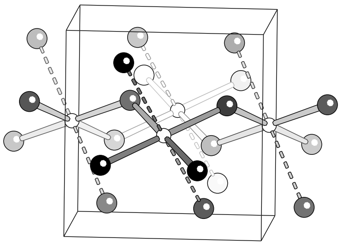

Figure 3 AgF_2

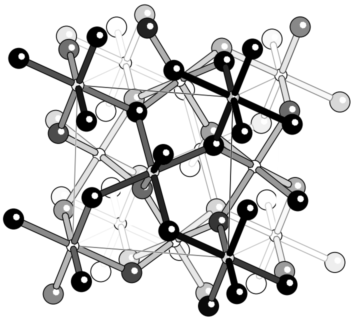

Figure 4 HP-PdF_2

the coordination of Pd^{2+} and F^- (CN 3) is the same in both phases, and even edge-sharing of octahedra takes place in the rutile structure. This is probably due to an angular distortion of the octahedra allowing for two additional weak Pd···F contacts (3.167 Å), and therefore relations to the CaF_2 and the FeS_2 type are discussed. Disordered variants of the HP-PdF_2 type are found in $CdPdF_4$ and $HgPdF_4$.

MF_3-Compounds. With the exception of the large rare-earth elements, the structures of the thermodynamically stable phases of MF_3 compounds derive from the cubic *ReO_3 structure type*. The cubic aristotype with an M–F–M bridge angle of 180° is realized only in NbF_3; in many other compounds it was found as a high-temperature form while at room temperature (r.t.), distorted variants, mainly of the *VF_3 type* (see Figure 5, Table 1), are realized. The ReO_3 structure can be described as face-centered cubic (fcc) packing of anions with 1/4 ordered vacancies where all octahedral sites having no neighboring vacancy (1/4 of all) are occupied. As the resulting 3D net of corner-connected octahedra has large cavities (which in the perovskite-type AMX_3 are occupied by the large A ions), the MF_3 structures tend to reduce these cavity volumes by rotation of the octahedra around a 3-fold axis and thus the bridge angle becomes bent from 180° in NbF_3 down to 132° in IrF_3. The symmetry is lowered to rhombohedral (space group $R\bar{3}c$) in that way. Depending on the size of the M^{III} ion, there is a continuous transition from cubic geometry (rhombohedral angle $\alpha = 60°$) down to $\alpha = 54.13°$ (IrF_3). At this angle, the rotation of anion layers of the former fcc packing achieves the hexagonal close packing (hcp) position where the vacancy completely disappears.[41] In between both extremes are the stable phases of the trifluorides of Al, Ga, In, Ti, V, Cr, Fe, Co, Mo, Ru, Rh. The rhombohedral symmetry is lowered to the monoclinic subgroup C2/c in MnF_3[42] owing to strong Jahn–Teller distortion of the d^4 configuration. During the last decade, an interesting variety of additional metastable MF_3 phases has been synthesized, using various thermal decomposition methods, mainly for AlF_3, shown here as an example. In addition to the thermodynamically stable VF_3-type α-AlF_3 (Figure 5), six further AlF_3 modifications have been reported here, the characteristics of which are collected in Table 1. Especially the amorphous forms and β-AlF_3 (Figure 6) are used nowadays as catalysts for Cl/F exchange and fluorination of chlorofluoro- carbons.[43–45] The higher the specific surface (e.g. up to $206\,m^2g^{-1}$ for 'high-surface' HS-AlF_3), the better the activity.

In the rhombohedral structure of NiF_3,[24] the symmetry of the VF_3 type is lowered from $R\bar{3}c$ to $R\bar{3}$ because it has to be formulated as $Ni^{II}Ni^{IV}F_6$ with ordering of larger (Ni^{II}-F 1.951 Å) and smaller [NiF_6] octahedra (Ni^{IV}-F 1.824 Å). The very strong oxidant NiF_3 as well as MnF_3 and CoF_3 may serve as catalysts for perfluorination of organic compounds. A unique 6_1 helical chain of [MF_4] squares is formed by AgF_3 and AuF_3[51] (Figure 10). The coordination of the d^9 ions is extended to elongated octahedra by two weak contacts to F ligands of neighboring chains.

Higher coordination numbers of $8 + 1$ are adopted in the LT-YF_3 type by the trifluorides of the larger ions Tl^{3+}, Bi^{3+} and the smaller rare-earth ions Sm to Lu. The tysonite or LaF_3 type with CN $9 + 3$ is found for the trifluorides of the larger 4f and the 5f elements[52] (*see* ***Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry***).

MF_4 Compounds. Formation of an octahedral coordination for a composition MF_4 requires bridging of four fluoride ligands according to a formulation [$MF_{4/2}F_2$]. One possibility is realized in the structure of the SnF_4 type (space group (s.g.) P4/nmm, Figure 11) with perovskite like layers and two trans-terminal F ligands. This structure is found for the Sn, Pb, Nb, and Ru compounds and, in a distorted variant, in VF_4. A 3D network with meshes of six octahedra is formed in the PdF_4 structure where the nonconnected ligands are *cis*-terminal (Figure 12). This structure (adopted also by the tetrafluorides of Rh, Re, Os, Ir, Pt) can be described as rutile structure with 1:1 ordered vacancies along the edge-connected octahedral chains.

The tetrafluorides of the larger ions Ce, Pr, Tb, Hf, Th – Bk crystallize in the β-ZrF_4 type, a highly connected 3D structure in which the metal has (square antiprismatic) CN 8 and fluoride CN 2.[53,54]

Interestingly, very different structures have been found for the tetrafluorides of the 1st transition metal series. These provide good textbook examples to demonstrate the

Table 1 Polymorphs of AlF_3

various possibilities to afford the $[MX_4]$ stoichiometry by connecting $[MX_6]$ octahedra leaving two cis-terminal F ligands: In TiF_4,[55] a triple chain of vertex-connected $[TiF_6]$ octahedra is observed as found in the $[MF_4]^-$ anions of $CsAlF_4$, $KCrF_4$, and $CsCrF_4$. The α-form of CrF_4 obtained by fluorination of Cr under pressure of F_2, HF, and Ar at 300 °C exhibits a double-chain of edge-connected octahedra[29] (Figure 13(c)), similar to that in several oxide-halides like $NbOCl_3$. Recently, a β-form was reported, formed by thermal decomposition of CrF_5, which shows unique quadruple-chains formed by trans-linking of tetrameric rings[56] (Figure 13(d)). α-MnF_4[57] is built from strands of corner-connected $[MnF_6]$ octahedra, all with *cis*-terminal F ligands as well, which are further linked to a 3D network (Figure 13(b)). The β-form[57] seems to be a variant of the VF_3 type with vacancies. Thermodynamically unstable MnF_4 evolves elemental F_2 on thermal decomposition. This is the crucial step in the famous 'chemical synthesis of fluorine'[58] (equation 12), which broke a dogma like that of the nonexistence of noble gas compounds.

$$K_2MnF_6 + 2SbF_5 \longrightarrow 2KSbF_6 + [MnF_4]$$
$$[MnF_4] \longrightarrow MnF_3 + \tfrac{1}{2}F_2 \qquad (12)$$

The starting materials can easily be prepared from aqueous HF.

VF_4 has a layer structure with trans-terminal ligands, as mentioned above. The transition to molecular crystal structures (isolated molecules with Ψ -octahedral structures) is achieved in the group 16 tetrafluorides SeF_4 and TeF_4.

MF_5 Compounds. For this stoichiometry, two bridging fluorine ligands only are needed for each octahedral $[MF_6]$ unit. This can be realized by forming *cis*-chains as in VF_5 (Figure 14(a)), trans-chains like α-UF_5[59] (Figure 14(b)), four-membered rings in a more regular manner as in NbF_5[60] or MoF_5 (s.g. C2/m, Figure 14(c)), or distorted as in RuF_5[61] (s.g. $P2_1/c$, Figure 14(d)), OsF_5, or PtF_5. A molecular dimer is found in AuF_5[62] (Figure 14(e)), and a 3D structure is formed

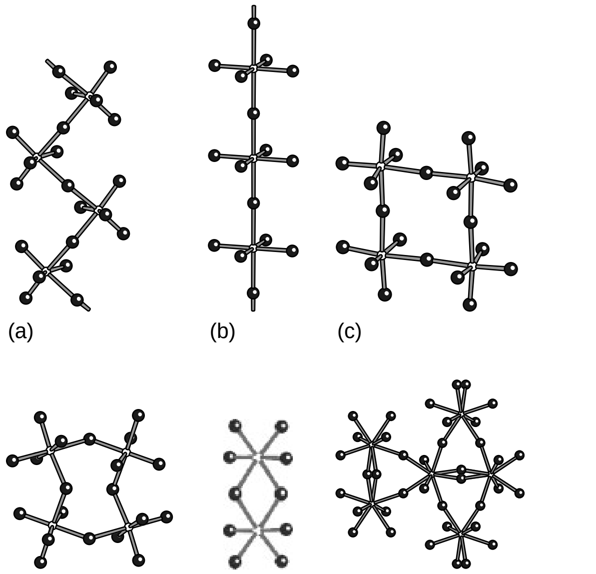

Figure 14 Structures of MF_5 compounds: (a) VF_5; (b) α-UF_5; (c) NbF_5; (d) RuF_5; (e) AuF_5; (f) Section of β-UF_5

in the β-form of UF_5[63] with edge- and corner-connection between square antiprismatic [UF_8] polyhedra (Figure 14(f)).

MF_6 and MF_7 compounds have typical molecular structures and thus are outside the scope of this chapter.

3.2 Ternary and Quaternary Fluorides

The structures of ternary compounds can be understood often by comparing the anionic substructure $[M^{x-n}F_x]^{n-}$ with that of the corresponding binary fluoride MF_x. Owing to strong contributions to the lattice energy when building structures from anions with saturated coordination spheres as bricks and countercations as mortar, ternary compounds are mostly more stable and easier to synthesize than their binary constituents; the higher the oxidation state of the metal the more important is this effect. By the choice of suitable electronically or magnetically 'inert' counter cations, compounds can be tailored with certain desired structural properties in the anionic substructure. The ternary and higher compounds are compiled in classes with structures deriving from a common simple parent structure type, in the following discussion.

3.2.1 Rutile Related Structures

A formal ordered 1:1 substitution of the divalent metal in the rutile $M^{II}F_2$ (Figure 1) by a univalent and a tervalent metal may explain the topology of the structures of compounds $LiM^{III}F_4$ (M = Mn,[64] Co[65]) and $NaMnF_4$[66] (Figure 15(a)). Looking at the [$M^{III}F_6$] octahedra only, the compounds are

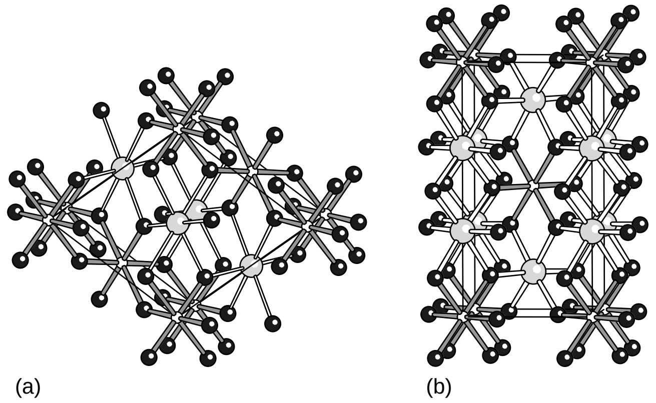

Figure 15 (a) $LiMnF_4$ structure (large grey spheres: Li); (b) trirutile Li_2MoF_6

layer structures built from quadratic meshes of corner-sharing octahedra comparable with that of the $TlAlF_4$ type. Another order variant of rutile is the 'trirutile' structure formed by several $Li_2M^{IV}F_6$ and $LiM^{II}M^{III}F_6$ compounds, and well known in oxide systems. According to an isomorphous group-subgroup transition, M^{IV} and Li^I (Figure 15(b)) or Li^I and disordered M^{II} and M^{III} atoms occupy the octahedral sites in a 1:2 ratio leading to a unit cell with triple c-axis.

The trirutile structure can also be described as deriving from a hcp-packing of anions and ordered occupation of half of the octahedral sites. Two alternative order variants based on the same hcp anionic substructure have been found for such Li and Na compounds: the Na_2SiF_6-type and the Li_2ZrF_6-type structures. Like the trirutile structure, the Na_2SiF_6-type is realized also by some $LiM^{II}M^{III}F_6$ compounds. For the Li_2ZrF_6-type, corresponding $LiM^{II}M^{III}F_6$ relatives are ascribed to the $LiCaAlF_6$-type. A detailed survey on compounds and structural relations in this structure family can be found in Ref. 33.

3.2.2 Structures Derived from the CaF_2-type

Substitution Variants. The fluorite-type structure is maintained in principle when alkaline earth elements are replaced partially by rare-earth elements. Charge compensation is achieved by occupation of additional interstitial anionic sites.[67] The coordination of the metal atoms may increase from 8 to 9 or even 10 by this. Another way of charge balance is the partial replacement of fluorine by oxygen to form oxyfluorides.[68] Since the possible interstitial positions provide pathways for anion disorder and movement, this class of materials shows fluoride ionic conductivity.

Subtraction Variants of the CaF_2-Type. There is a large and interesting group of structure types, which can formally be derived from the fluorite structure by subtraction of anion and/or cation positions and, of course, by substitutions within

Table 2 Subtraction variants of the fluorite type (□ = vacancy)

Fluorite	$[Ca_4^{[8]}]$	$[Ca_4^{[8]}]$	F_{16}	CaF_2
Weberite	$[Na^{[8]}M_3^{[6]}]$	$[Na_3^{[8]}M^{[6]}]$	$F_{14}\square_2$	$Na_2\ MM'F_7$
Pyrochlore	$[A^{[8]}M_3^{[6]}]$	$[A_3^{[8]}M^{[6]}]$	$F_{14}\square_2$	$A_2{}^{a}M_2F_7{}^{b}$
$RbNiCrF_6$	$[\square\ M_3^{[6]}]$	$[\square_3\ M^{[6]}]$	$F_{12}Rb_2\square_2$	$A^{I}M^{II}M^{III}F_6$
Pyr-FeF_3	$[\square\ M_3^{[6]}]$	$[\square_3\ M^{[6]}]$	$F_{12}\square_2\square_2$	FeF_3, η-AlF_3
$Cs_2NaAl_3F_{12}$	$[\square\ M_3^{[6]}]$	$[\square_3\ Na^{[6]}]$	$F_{12}Cs_2\square_2$	$A_2^{I}NaM_3^{III}F_{12}$

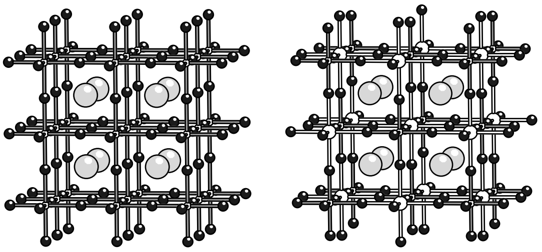
[a] A_2 = Na,Ca, or Na,Cd. [b] The 7th F atom is not part of the octahedral net and may be replaced by O or S in compounds like $Cd_2M_2^{II}F_6O$, cf. also the mineral $(CaNa)Nb_2O_6(OH,F)$.

the resulting structure type.[69,70] In this way, the typical CN 8 of the CaF_2 structure is gradually reduced toward octahedral. Thus, these structures can also be classified using concepts of octahedral nets. They are discussed in detail later on from this point of view. A survey on this structure family and its relations to the CaF_2 structure (set up with doubled axes) are given in Table 2, where the coordination numbers are given as superscripts in brackets.

3.2.3 ReO_3 and VF_3 Related Compounds

A very large structure family derives from the basic motif of a cube of 3D corner-connected octahedra realized in the ReO_3 structure or from its distorted variants, the VF_3 and IrF_3 type, mentioned in the previous chapter (Table 1, Figure 5). The main derivatives are generated by ordered occupation of the octahedral sites and/or by filling the central cavity with a large cation, which becomes part of the fcc packing of the anions. Less frequently, the order of vacancies on the octahedral sites is observed.

Order Variants $M_{0.5}M'_{0.5}F_3 = MM'F_6$. M^{II}/M^{IV} and M^{I}/M^{V} compounds are known in many combinations (surveys in Refs. 33, 71). Their structures can be derived from the parent MF_3 structures (Section 3.1): Some of them crystallize in the cubic ReO_3 type, either with disorder on the metal site (s.g. $Pm\bar{3}m$) as in the recently discovered titanium(II) compound $Ti^{II}Hf^{IV}F_6$ or ordered with double lattice constants ($NaSbF_6$ type, s.g. $Fm\bar{3}m$) as in the vanadium(II) compounds $V^{II}Zr^{IV}F_6$ and $V^{II}Hf^{IV}F_6$.[72] The largest family is that derived from the VF_3 type structure (Figure 5). A few members show cationic disorder (VF_3-type, s.g. $R\bar{3}c$) such as $Pd^{II}Mn^{IV}F_6$, but most belong to the ordered $LiSbF_6$ type (s.g. $R\bar{3}$). A special case of this structure type is the already mentioned mixed-valence $NiF_3 = Ni^{II}Ni^{IV}F_6$.[24] Low-symmetry variants related to the MnF_3 structure have been found in $M^{II}M^{IV}F_6$ compounds with M^{II} = Cr, Cu, Ag. In recent structure determinations, triclinic $LiSbF_6$ variants were confirmed for Ag^{II} compounds.[73] For very large M^{IV} metal ions (r > 0.8 Å), $M^{II}M^{IV}F_6$ compounds are found to crystallize in the LaF_3 type structure.



(a) (b)

Figure 16 (a) Perovskite type (8 unit cells); (b) Elpasolite-type

Perovskites, Elpasolites, and Cryolites. If the cuboctahedral cavity in the cubic ReO_3-type structure is occupied by a cation A, the perovskite-type structure AMX_3 (s.g. $Pm\bar{3}m$, Figure 16(a)) results where the A ion becomes part of the fcc anionic packing (CN 12). In fluorides, this structure is found for many compounds $A^{I}M^{II}F_3$ with A = Na, K, Rb, Cs, NH_4, Tl, Ag and M = Mg, Ca, V, Mn, Fe, Co, Ni, Zn, Cd, Hg. If the octahedral M^{II} site is occupied in an ordered way by a small alkali ion A′ and an M^{III} ion, one arrives at the elpasolite-type structure (K_2NaAlF_6-type, s.g. $Fm\bar{3}m$, Figure 16(b)), a superstructure variant of perovskite. Cubic structures $A^{I}M^{II}F_3$ or $A_2^{I}A^{I\prime}M^{III}F_6$ are found if the tolerance factor $t = (r_A + r_F)/\sqrt{2}(r_M + r_F)$ is in the range 0.88–1.00 (for elpasolites $r_M = (r_{A'} + r_M)/2$). Surveys on the geometrical and structure-systematical rules valid in the structure family of perovskites and elpasolites and a large collection of compounds can be found in Refs. 33, 34. Recently, an investigation of phase transitions in elpasolites appeared.[74] For lower values of t (0.76–0.88), a distorted orthorhombic variant, the $GdFeO_3$-type (space group Pbnm (Pnma)) is realized in AMF_3 compounds (Figure 17(a)) while for $t > 1$, new hexagonal structures are found (see next section). Low t-values are obtained if the A cation (CN 12 in cubic perovskite) becomes too small for this high coordination, for example, in $NaNiF_3$. Thus, by tilting the octahedral network, the CN of the A ion is reduced to eight in the $GdFeO_3$-type structure.

A special case occurs if in elpasolite-type compounds $A_2A'MF_6$ (A: CN 12, A′: CN 6) the same alkali ion A is available for both positions. Thus, in compounds $Na_3M^{III}F_6$ a similar tilting variant of the elpasolite-type structure is observed as the $GdFeO_3$ variant is of the perovskite type. This is the cryolite structure (Figure 17(b)) named after the mineral Na_3AlF_6[3] (monoclinic, s.g. $P2_1/n$). This compound is of great technical significance for aluminium production and is now synthesized in large amounts since the naturally occurring mineral is exhausted. Cryolites are known for many tervalent metals, and the tilting angle of the octahedra can be predicted based on the ionic radii.[75] Based on powder data, a cryolite-like structure has been reported also for Na_2LiMF_6,[76] as suggested for the analogous Ni^{III} and Cu^{III} compounds before. For many compounds A_3MF_6, phase

transitions of ferroelastic type have been found leading to HT forms with the ideal elpasolite space group $Fm\bar{3}m$. A postulated orthorhombic high-temperature form 'β-Na_3AlF_6' (space group Immm,[77] 890 K, R = 0.074) can be described in the elpasolite s.g. $Fm\,\bar{3}m$ as well within the error limits (max. deviation from cubic in lattice constants 0.003 Å, of an atomic position (F2) 0.069 Å at r.m.s. displacements of 0.23–0.47 Å).

For A_3MF_6 compounds with larger alkali cations, only a few single-crystal investigations are known. It seems to be clear that K_3MoF_6 and K_3WF_6[78] crystallize in the cubic elpasolite-type structure, as well as most of the $(NH_4)_3M^{III}F_6$ compounds at room temperature. For $(NH_4)_3ScF_6$, a monoclinic structure variant has been reported recently.[79] Very complicated superstructures with five-fold axes have been found in different laboratories for some K and Rb compounds (see citation in Ref. 33). However, no structure determinations are known to date.

While all these structures derive from the elpasolite aristotype, the $Li_3M^{III}F_6$ compounds (M = Al, Ga, Ti, V, Cr, Fe) exist at room temperature in two modifications. The α-form (e.g. α-Li_3AlF_6[80]) is still a strongly distorted variant of the elpasolite/cryolite family in which the coordination of all lithium ions is reduced to six. The β-form, determined at β-Li_3VF_6[81] and confirmed by recent single-crystal work on the Al, Ga, Ti, and Cr compounds (Ref. 82 and literature cited herein), has a new structure type with part of the lithium ions in tetrahedral coordination.

Perovskite Relatives with Vacancies on Octahedral Sites. A special derivative of the elpasolite-type structure $A^I_2A^{I\prime}M^{III}F_6$ with half-occupation of the A′ site has only been found in compounds of Jahn–Teller ions Mn^{3+} and Cu^{2+}. $K_2(\square_{0.5}Mn^{II}_{0.5})Mn^{III}F_6 = K_4Mn_3F_{12}$, $CsBa(\square_{0.5}Cu^{II}_{0.5})Cu^{II}F_6 = Cs_2Ba_2Cu_3F_{12}$,[83] and recently $Cs_2(\square_{0.5}Pd^{II}_{0.5})Mn^{III}F_6$[84] show the vacancies on the octahedral sites ordered in layers like in the chiolite structure (see Section 3.2.5) and stacked and connected according to a 4_1 screw axis (s.g. $I4_1/amd$, Figure 18(a)) to form a 3D network.

Every second octahedral site of the elpasolite-type structure is unoccupied in compounds $A_2M^{IV}F_6$ of the K_2SiF_6 type, known also as the K_2PtCl_6-type (s.g. $Fm\bar{3}m$, Figure 18(b)). This structure can also be seen as an antifluorite structure if the whole complex $[MF_6]$ anion is compared with Ca. It can be observed for nearly all alkali hexafluorometallates(IV) of the first transition metal series as well as some noble metals like β-Cs_2PtF_6.[85] However, for many such compounds other polymorphs are known, too, and the cubic form is the HT-phase only. These alternative structures are mentioned in the next section. A survey on all of the main structure types mentioned up to now derived from the ReO_3/VF_3 type structure is given in Table 3.

3.2.4 *Hexagonal 'Perovskites' and Derivatives*

If in compounds with perovskite (AMX_3) or elpasolite ($A_2A'MF_6$) composition, the tolerance factor t adopts values larger than 1, that is, the A cation becomes too large for the ReO_3 cage, new trigonal or hexagonal structures are formed with face-sharing $[MF_6]$ octahedra as new structural elements. Though the term 'perovskite' appears somewhat misleading because the typical feature of only corner-connected octahedra is broken, some justification arises since all structures are based on close-packed AF_3^{2-} layers. In the classical cubic perovskites, the stacking is of fcc type **ABC**. As can be seen in the examples of Figure 19, the trigonal and hexagonal 'perovskites' can be described as stacking variants in which the occupation by M^{II} atoms of neighboring octahedral sites in hcp stacking units **ABA** generates face-sharing of octahedra. There are several polytypes with mixed stacking sequences, most structures of which are known from oxides as well. They are named, according to the layers' periodicity, 2L, 3L, 6L structures, and so on. If ordered substitution of the octahedral sites by alkali ions or vacancies is considered, as done above for the derivatives of cubic perovskite, 'trigonal or hexagonal elpasolites' and trigonal or hexagonal $A_2M^{IV}F_6$ structure types, respectively, are the result (Table 4, see also survey in Refs. 32, 33 and recent papers[86,87]). In the case of pure hcp stacking, occupation of all of the octahedral sites formed by fluoride ions only leads to a chain structure of face-connected octahedra (2L *CsNiF₃-type*, Figures 19 and 20(a)). This compound became the subject of many physical investigations as a model for a 1D ferromagnetic chain. Quasi-isolated octahedra result if every second octahedral site remains empty in $K(\square_{0.5}Ge_{0.5})F_3$ (Figure 20(c)) or the 4L K_2MnF_6-type, the hexagonal analog of the 3L case K_2SiF_6, known as the K_2PtCl_6-type structure. An intermediate situation is found in the 2L structure of compounds $Cs_3M_2^{III}F_9$ ($=Cs(\square_{0.33}M_{0.67})F_3$, M = Fe,[88] Ga[89]), $[(CH_3)_4N]Fe_2F_9$[90] and $[(CH_3CH_2)_4N]_3M_2F_9$ (M = Cr, V, Fe)[91] showing the rare case of dimeric $[M_2F_9]^{3-}$ anions with face-sharing of octahedra (Figure 20(b)). In a series of Cs compounds of Ni^{II} (and partly also Mg, Zn, Co), not only analogous $[M_2F_9]$ dimers ($Cs_7Ni_4F_{15}$[92]), but also trimeric ($Cs_4M_3F_{10}$[93]) and even pentameric units ($Cs_6Ni_5F_{16}$[94]) were found, further linked by sharing vertices to form special layer structures.

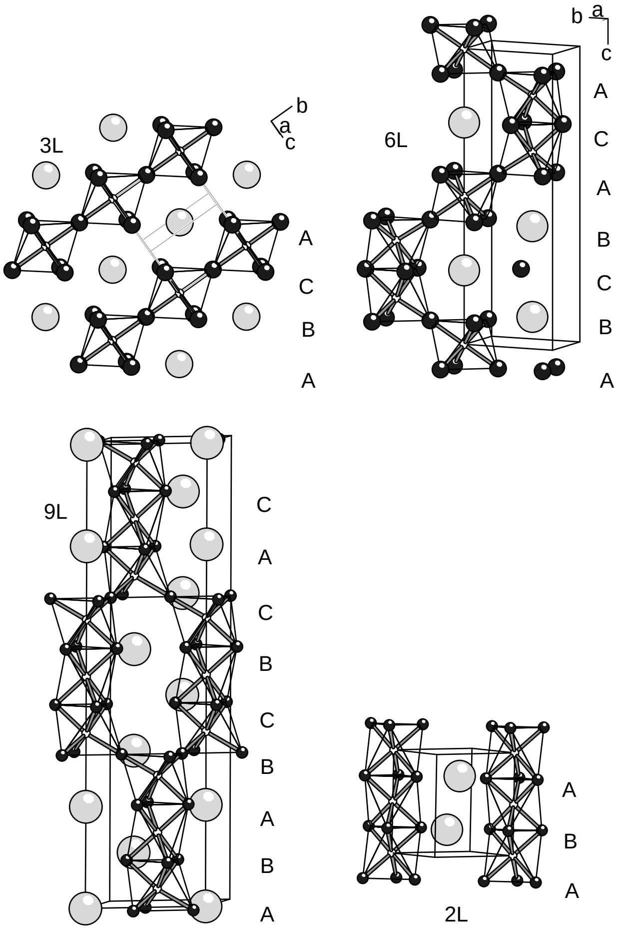

Figure 19 View of cubic (3L) and hexagonal perovskites along the close-packed AF_3 layers. 6L $RbZnF_3$, 9L $CsCoF_3$, 2L $CsNiF_3$

The higher the tolerance factor t the more face-connected octahedra are encountered in hexagonal perovskites. The sequence of structure types with rising t from <1.0 to 1.08 is cubic (3L) – 6L – 12L – 9L – 2L. Under high pressure, metastable AMF_3 or $A_2A'MF_6$ HP-polymorphs can be synthesized with structures corresponding to that of compounds with lower tolerance factors. Though octahedral coordination is maintained in both forms, they show longer M-F distances than in the normal-pressure form. This 'pressure-distance

paradox' can be understood when looking at the A-F distances, the decrease of which overcompensates the volume increase of the octahedra.[30,87]

3.2.5 *Layer Structures Derived from Perovskite-type*

K_2NiF_4-Type. If in a perovskite like $KNiF_3$ (Figure 16), the horizontal layers are separated by formally adding KF, a layer structure K_2NiF_4 results with square meshes of *trans*-corner-connected octahedra (Figure 21(a)). Neutral layers of this type are known from the SnF_4 structure (Figure 11). According to the space group I4/mmm, subsequent layers are shifted by $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$. This structure type is realized by many M^{II} fluoro compounds (M = Mg, Mn, Fe, Co, Ni, Zn, Cd, Ag) with the larger alkali ions K, Rb, Cs, and with NH_4 and Tl (survey in Ref. 33). The K_2NiF_4 structure type is widespread in oxo compounds and became famous as the parent structure of the high-T_c superconductors deriving from La_2CuO_4.

$K_3Ni_2F_7$ or Ruddlesden–Popper-type. If in the perovskite structure AMF_3 the layer separation by addition of AF is performed every second layer only, the double-layer structure type $K_3Ni_2F_7$ is obtained, known in oxides as $Sr_3Ti_2O_7$ or *Ruddlesden–Popper* structure (s.g. I4/mmm, Figure 21(b)).

Structures Derived from $TlAlF_4$-Type. Another way toward layers formally excised from the perovskite structure $A^IM^{II}F_3$ is to add an additional F atom and increase the oxidation state of M from two to three to obtain $A^IM^{III}F_4$ compounds. While in both structure types mentioned before the layers are planar (angles M–F–M 180°), most AMF_4 structures show puckered layers with M–F–M angles decreasing down to 132° with decreasing size of the alkali ion between the layers. Even for the name-giving structure $TlAlF_4$, the aristotype structure (s.g. P4/mmm) with planar layers has been shown to be realized at high temperatures only. Upon cooling, phase transitions occur at 514 K and at 435 K, leading to structures of lower symmetry containing tilted octahedra in space groups I4/mcm and s.g. I2/a, respectively.[95] Structural phase transitions have been reported for several other A^IAlF_4 (A = K, Rb, NH_4, Cs) and A^IFeF_4 compounds (A = K, Rb, Cs). Figure 22 shows as examples the aristotype HT-$TlAlF_4$, the derived γ-$CsFeF_4$ structure[96] with puckered

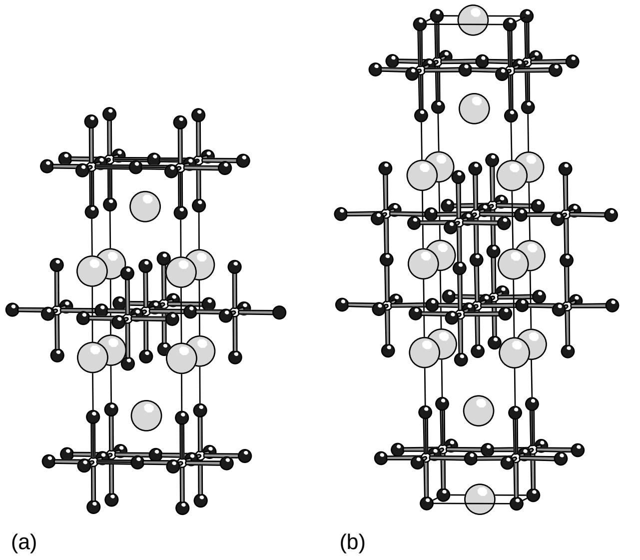

Figure 21 (a) K_2NiF_4-type layer structure; (b) $K_3Ni_2F_7$ or Ruddlesden–Popper type structure

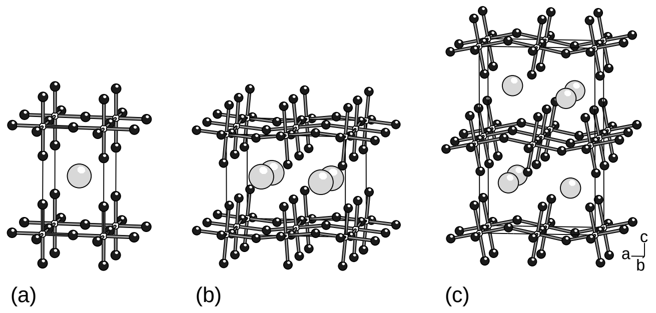

Figure 22 (a) HT-$TlAlF_4$ structure (s.g. P4/mmm); (b) γ-$CsFeF_4$ (s.g. P4/nmm); (c) HT-$KFeF_4$

layers, and $KFeF_4$ with layers alternately shifted by $b/2$ (see a recent paper[97] and references therein). In the corresponding Mn^{III} compounds, *antiferrodistortive* Jahn–Teller ordering of elongated octahedra is observed within the layers (alternating rotation by 90°).[98]

The strongest deformations of the $TlAlF_4$-type structure are encountered at $LiCoF_4$, $LiMnF_4$, and $NaMnF_4$, the structures of which were discussed already as relatives of the rutile structure (Section 3.2.1, Figure 15(a)). Rutile-type structure elements are also found in the related isostructural compounds α-$NaTiF_4$ and $NaCoF_4$ (see discussion in Ref. 65). For other $Na^IM^{III}F_4$ compounds, different structures have been found with partial *cis*-connection of $[MF_6]$ octahedra. They are mentioned below in Section 3.2.7.

Chiolites $A_5^IM_3^{III}F_{14}$. When in a $TlAlF_4$-type layer structure $A^IM^{III}F_4$ (or $A_4M_4F_{16}$), 1/2 of the octahedra (including their terminal F ligands) is removed and formally replaced by additional A atoms (Na or K), the composition

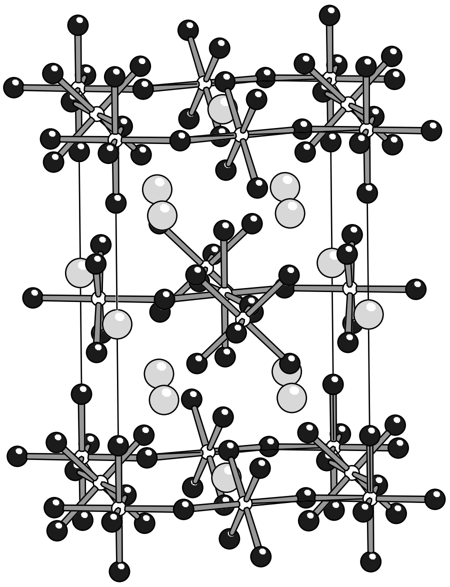

Figure 23 Chiolite structure $Na_5Al_3F_{14}$. Na atoms as grey spheres

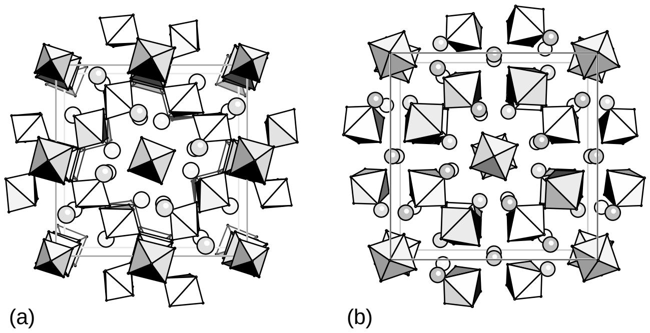
$A_4(AM_3)F_{14}\square_2$ of the chiolite-type structure is obtained (Figure 23). Half of the remaining octahedra are rotated by 45° to achieve cube-like CN 8 for this intralayer alkali atom; the interlayer alkali atoms also have CN 8, but rather distorted. This structure is found in compounds $A_5M_3F_{14}$, mainly with A = Na, but some K analogs and an ammonium compound have also been reported. For most representatives, the tetragonal space group P4/mnc was found such as for the mineral $Na_5Al_3F_{14}$. However, low-symmetry variants and polymorphism have been reported (see Ref. 33), for instance, s.g. $P4_24_12$ for γ-$Na_5Fe_3F_{14}$ or s.g. Pnma for the Jahn–Teller system $Na_5Mn_3F_{14}$.[99,100]

Layer Structures $A^{II}_2M^{II}F_6$. Similar structures with square $[MF_4]$ layers such as in the K_2NiF_4-type are found if the alkali cations are replaced by Ba or Pb^{II} and the higher charge is compensated by additional 'free' fluoride ions, which are located only in the Ba/Pb layers (*Ba_2ZnF_6-type*). These compounds, found for M = Mg, Mn, Fe, Co, Ni, Cu, Ag, Zn, are thus better written $(BaF)_2MF_4$. The structures, in the early literature described in the space group I4/mmm with planar layers, show, at least in some cases, superstructures and puckering of the layers.[33] The Cu^{II} compounds display similar Jahn–Teller ordering as the $AMn^{III}F_4$ structures. Ba_2PdF_6[101] shows isolated $[PdF_4]$ squares ordered in a corresponding layer structure.

3.2.6 Chain Structures with Trans-connected Octahedra

Compounds $A^{II}M^{III}F_5$ and Relatives. Cutting up a perovskite like layer further leads to linear chains of trans-connected octahedra as realized in the structure of α-UF_5 (Section 3.1, Figure 14(b)). Similar trans-chains of composition $[MF_5]$ are found as anionic substructure in compounds $CaM^{III}F_5$ of $CaCrF_5$-type[102] structure (s.g. C2/c, M = Al(α), Ga(α), Ti, Cr, V, Mn, Co, and $CdMnF_5$) or the variant $CaFeF_5$-type[103] (M = Al(β), Ga(β), Fe), found also in $CdGaF_5$ and $CdCrF_5$. In addition, trans-chains are observed in the hydrates $BaFeF_5{\cdot}(H_2O)$[104] and, elongated by the Jahn–Teller effect, in $A^{II}MnF_5{\cdot}$ (H_2O) (A = Sr, Ba).[105] However, the anhydrous compounds of Mn^{III} show *cis*-chains (see below).



(a) (b)

Figure 24 Perspective view (a) of the $BaFeF_5$, (b) of the $Pb_5Cr_3F_{19}$ structure, from the chain direction *c* (Ba or Pb as spheres)

In the anhydrous Sr- and Ba compounds of other tervalent metals, a strange series of interrelated structures has been found, derived from the tetragonal structure of $BaFeF_5$.[106] In this structure (s.g. I4), 'branched' trans-chains were reported (Figure 24(a)) alternating with 'normal' trans-octahedral chains.

In a recent paper, an analogous structure has been described in s.g. I4/m for a mixed crystal $Ba_{0.43}Sr_{0.57}AlF_5$ while in pure $SrAlF_5$, a superstructure was refined in s.g. $I4_1/a$ (like for the related $Ba_5Cr_3F_{18}$[107] before) showing stacked edge-sharing $[Al_2F_{10}]$ dimers in place of the normal trans-chains.[108] The latter compound also crystallizes like $BaFeF_5$ in another polymorph with cis-connected octahedra discussed in the next section. Related structures with different compositions but similar tetragonal unit cells and s.g.s were found for compounds like $Sr_5M_3F_{19}$ (M = V, Cr, Fe)[109,110] where both types of chains are resolved to isolated dimers and isolated octahedra, respectively, or for phases $Pb_5M^{III}_3F_{19}$. In the Cr^{III} compound[111] of the latter type (Figure 24(b)), refined in the polar s.g. 14 cm, trans-chains (at the corners and in the center) alternate with isolated octahedra. Recently, 'structure-property correlations over five phases and four transitions' have been investigated for $Pb_5Al_3F_{19}$.[112]

Compounds $A^{I}_2M^{III}F_5$ and $A^{I}_2M^{III}F_5{\cdot}$ H_2O. In alkali pentafluorometallates(III), the formation of trans-connected octahedral chain anions is mostly restricted to the Mn^{III} compounds where the strong Pseudo-Jahn–Teller effect stabilizes this type of bridging,[113] and induces additional lengthening of the bridging bonds. By choice of the counter cation, the geometry of the chain can be tuned in a wide range.

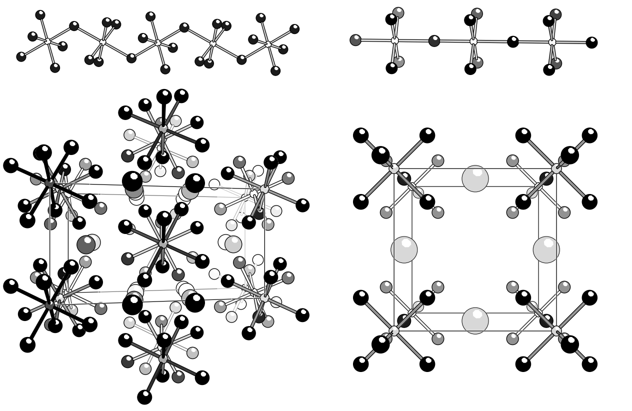


Figure 25 Chain sections and views along the chain axes for the structures of (a) Li_2MnF_5;[114] (b) Cs_2MnF_5[115]

In A_2MnF_5 compounds (A = Li, Na, K, NH_4, Rb, Cs) and the hydrated compounds $A_2MnF_5\cdot H_2O$ (A = K, Rb, Tl, Cs), the bridge angle M–F–M varies between 121.5° (Li) and 180° (Cs) (Figure 25).

The Li, Na, and NH_4 compounds show pseudo-hexagonal and the other ones tetragonal chain packing (Figure 25). The close relations between hydrated and anhydrous compounds are documented in topotactical dehydrations found in experiments on single crystals of $Rb_2MnF_5(H_2O)$[116] and $Cs_2MnF_5(H_2O)$.[115] Similar chain structures were found also for some compounds with protonated organic amines as cations like enH_2^{2+} (en = ethylene diamine), $DAPH_2^{2+}$ (DAP = 1, 3-diaminopropane), $DABH_2^{2+}$ (DAB = 1, 4-diaminobutane), and atriazH^+ (atriaz = 3-amino-1,2,4-triazole). A survey on the structural chemistry of fluoromanganates(III) can be found in Ref. 113. The quasi-isolated anionic chain anions proved to be good model systems for studies of 1D magnetic properties like nonlinear excitations (solitons) (see Section 4.1).

With ‘normal’ M^{III} ions, only few trans-chain compounds $A_2MF_5\cdot(H_2O)$ were found until now, for example, $A_2AlF_5\cdot(H_2O)$(A = K,[117] Rb[118]), β-$(NH_4)_2FeF_5$,[10] or $(CH_3NH_3)_2FeF_5$.[119] The basic structure type for trans-chain compounds A_2MF_5 is known as ‘Tl_2AlF_5-type’ (s.g. $C222_1$[120]). However, it has been shown[121] that the investigated crystal probably was in fact $Tl_2AlF_5\cdot(H_2O)$ and the s.g. Cmcm. The aristotype structure with highest possible symmetry (s.g. P4/mmm) is realized in Cs_2MnF_5 and, probably, the Rb compound also.

An intermediate between perovskite like layer and trans-chain structure is the unique double trans-chain structure of $K(H_5O_2)Al_2F_9$.[122] On the other side, as a link between trans-chain and isolated octahedra, vertex-sharing dimers have been found in $CsBa_2Cr_2F_{11}$[123] and in the aqua-fluoromanganate anion $[Mn_2F_9(H_2O)_2]^{3-}$ of cyclam$H_4[Mn_2F_9(H_2O)_2][MnF_4(H_2O)_2]$[18] (see also Section 3.2.12).

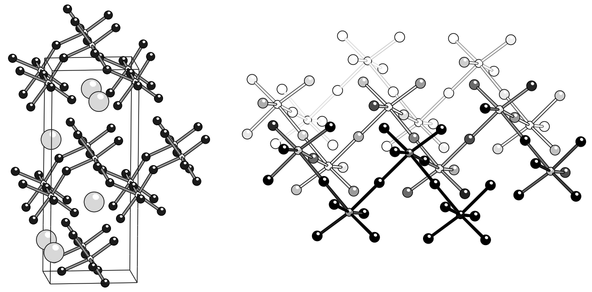

Figure 26 (a) *cis-trans*-linking of octahedra in $BaZnF_4$; (b) pure *cis*-connected layer structure of $Ba_2RbFe_2F_9$

3.2.7 Structures with Cis-connected Octahedra

An alternative way of linking octahedra to 1D, 2D, or 3D structures by sharing vertices is that of using *cis*-corners. The basic structural units may be visualized as formally cut from the ReO_3-type octahedral net as before for the trans-linked octahedral arrays.

Layer Structures. A combination of trans-linking as in the former Section 3.2.6 and of cis-linking leads to puckered layers of octahedra as realized in compounds $NaM^{III}F_4$ (*$NaNbO_2F_2$-type*, s.g. $P2_1/c$, M = V,Cr,Fe) and $A^{II}M^{II}F_4$ (*$BaZnF_4$-type*, s.g. $Cmc2_1$, A = Sr, Ba, M = Mg, Mn, Fe, Co, Ni, Cu, Zn) (see Ref. 33). As a consequence, the $[MF_6]$ octahedra have *cis*-terminal F ligands (Figure 26). According to the polar s.g. of the Ba compounds, ferro- and pyroelectrical properties are observed.

An interesting structure intermediate between pure trans–trans and cis–trans connected layers is realized in $KScF_4$,[124] where alternation of four trans-connections and one cis-connection gives ‘staircase-like’ layers.

A pure *cis*-connection is found in the honeycomb layer structure of *fac*-corner-sharing octahedra in compounds $Ba_2A^IM_2^{II}F_9$[125] (A = K, Rb, Cs; M = Fe, Co, Ni, Zn; Figure 26(b)).

Cis-Chain Structures. When a *cis-trans*-connected layer is cut parallel to the cis-chains, double chains or single chains of *cis*-connected octahedra are retained. Double chains are found in compounds Ba_2ZnAlF_9,[126] Ba_2CoFeF_9,[127] (Figure 27(a)) or $KPbCr_2F_9$.[128] Here similar simple zig-zag strands are formed while in the unique structure of $[O_2]Mn_2F_9$,[129] crenel-like double chains were found (Figure 27(b)).

Single *cis*-chains are found in two main types: a simple zig-zag chain in the $BaGaF_5$-type[130] structures (Figure 27(c)) found also for the analogous Al, Cr, Mn, Co compounds, and crenel-like flat helicoidal chains, for instance, in $SrFeF_5$[131] (Figure 27(d)), α'-$BaFeF_5$,[132] α'-$SrAlF_5$,[133] or $SrVF_5$.[134] Analogous chain structures are formed by $A_2^IM^{III}F_5$

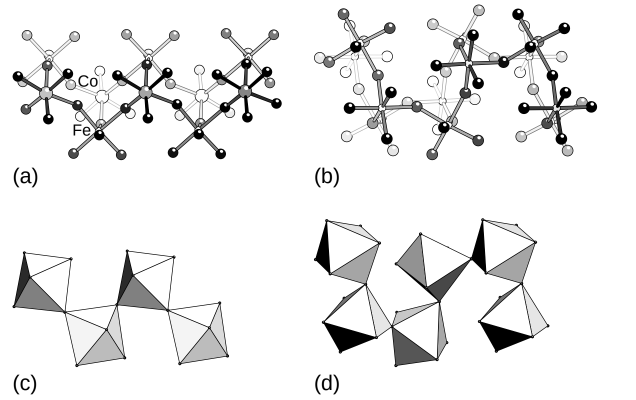

Figure 27 Double-*cis*-chain structures of (a) Ba_2CoFeF_9, (b) $[O_2]Mn_2F_9$, and single *cis*-chains of (c) $BaGaF_5$ and (d) $SrFeF_5$

compounds Rb_2CrF_5 and A_2FeF_5 (A = K (two polymorphs), Rb, NH_4 (α-form), see Ref. 135 and literature given therein).

3.2.8 Structures Based on the (3,6)-Net (Kagomé or HTB Net)

All structures mentioned in Sections 3.2.3 to 3.2.5 are based on simple 2D or 3D nets with four-membered meshes of vertex-connected octahedra. In many structures, additional structural units formed by three vertex-sharing octahedra are encountered combined with the four-membered unit but also with higher aggregates of 5, 6, or more octahedra. 2D nets formed by regular combination of two or more such octahedral n-membered rings are named according to the participating units (n_1,n_2)-net, for instance. The most important mixed net is the (3,6)- or Kagomé net, named also the HTB net after the hexagonal tungsten bronze structure discussed below.

$Cs_2NaAl_3F_{12}$-Type Structure. A representative of this layer type, the $Cs_2NaAl_3F_{12}$-type structure (Figure 28(a)), has been mentioned already in the Section *Subtraction Variants of the CaF_2-Type* as a derivative of the CaF_2 or pyrochlore-type structure, respectively. Here, the large Cs ions are positioned between a six-membered ring of octahedra and a three-membered one of the shifted neighboring layer; the Na ions connect triple units only. This structure type is found in compounds $A^I_2A^{I\prime}M^{III}_3F_{12}$**136–139** with M^{III} = Ti, V, Cr, Mn, Fe, Co, Sc, Ga and other combinations of alkali metals like Cs_2K, Cs_2Li, Rb_2Na, and K_2Na.**140** In compounds with Mn^{III},**141** the octahedra are strongly elongated and show a wind-wheel-like Jahn–Teller ordering pattern (Figure 28(b)).

Weberites. If the metal positions of the (6,3)-net above (Figure 28(a)) are occupied in an ordered way by M^{II} cations forming trans-chains and by linking M^{III} ions, the typical layer of weberites is achieved (Figure 29(a)). Additional replacement of Na atoms connecting in $Cs_2NaAl_3F_{12}$ subsequent shifted layers by M^{III} ions in the weberite structure leads to a 3D framework of two intersecting (6,3)-nets with common $[M^{II}F_6]$ chains (Figure 29(b)).

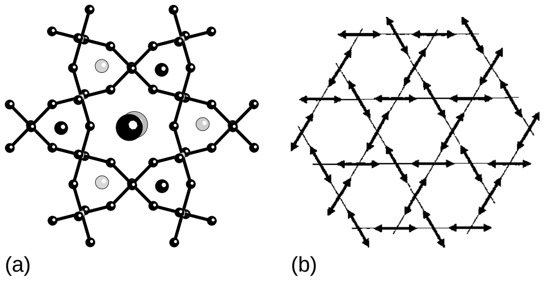

Figure 28 (a) $Cs_2NaAl_3F_{12}$ type. Large spheres Cs, small spheres Na; (b) Jahn–Teller ordering in $A_2A'Mn_3F_{12}$ compounds

An alternative interpretation of the weberite-type structure mentioned already in Section 3.2.3 emphasizes the relationship to the CaF_2-type structure. Formally, in the weberites $Na_2M^{II}M^{III}F_7$, one half of the Ca positions of CaF_2 are replaced by Na ions, retaining CN 8, and one half by M^{II} and M^{III} ions in an ordered way. In Figure 30, the cation distribution in the classical weberite (mineral Na_2MgAlF_7) of O-I type (s.g. Imma) is compared with that of fluorite. By generation of vacancies in the anion sublattice and shifts in some F positions, octahedral coordination is achieved for M^{II} and M^{III} atoms. For a survey of the hitherto found three orthorhombic (O-I, O-II, O-III), two monoclinic (M-I, M-II), and one trigonal variants (T) of weberites, see Ref. 69.

In the orthorhombic types O-I,II,III, the linking octahedra of M^{III} retain two trans-terminal F ligands. The M^{II} chains are therefore all parallel in subsequent layers, leading to the stacking sequence AAA. In the trigonal T-type weberite variant, all linking octahedra have *cis*-terminal ligands; three subsequent layers are rotated each by 120° leading to a stacking sequence ABCA. In the monoclinic M-I structure, only ABAB stacking is realized, and in the M-II type an

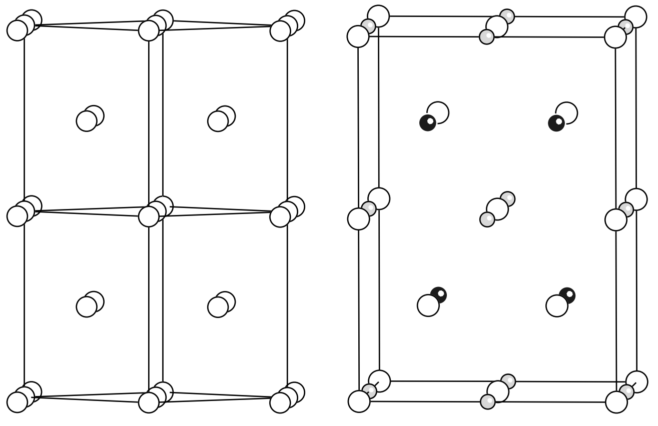

Figure 30 Cation distribution in (a) CaF_2 and (b) weberite O-I (white Na, grey M^{II}, black M^{III})

AABBAA variant is found. The Na ions keep the CN 8 of the parent CaF_2 type. However, depending on the stacking mode, the coordination changes partially from distorted cubic to hexagonal bipyramidal. From a magnetic point of view, weberites are interesting candidates for 1D magnetic behavior if the linking M^{3+} ions are diamagnetic elements. The structure of compounds $M^{II}Fe^{III}F_5{\cdot}2H_2O$ (M^{II} = Mn, Fe, Zn)[142,143] where $[M^{III}F_6]$ octahedra form the trans-chains may be classified as inverse or antiweberite. $[M^{II}F_4(H_2O)_2]$ octahedra are in the linking positions with trans-aqua ligands oriented toward the empty Na positions of the orthorhombic weberite structure.

Pyrochlore- and RbNiCrF$_6$-Type Structures. Closely related to the weberite variants are pyrochlores $AA'M_2F_7$ (A = Na, A′ = Ca, Cd; M = Mg, Co, Ni, Cu, Zn). Here, all octahedra are equivalent and the cubic 3D network can be described as intersecting systems of Kagomé nets with planes parallel to the faces of a tetrahedron. Another approach is the description as cross-linked octahedral chains where at the crossing points typical tetrahedra of corner-connected octahedra are generated (Figure 31).

In the mineral pyrochlore $(NaCa)Nb_2O_6(OH,F)$, this framework is built by the $[Nb_2O_6]$ substructure. The seventh anion is in the center of the large pores and is tetrahedrally surrounded by the disordered Na^+ and Ca^{2+} ions, which keep cubic CN 8. In a fluoride pyrochlore like $NaCaNi_2F_7$, the complete [FNaCa] group can now be replaced by a single large alkali cation if at the same time the charge of the network is increased. The resulting cubic $RbNiCrF_6$ type is realized in a huge number of compounds $AM^{II}M^{III}F_6$.[33] Interestingly, even for a rather different size of M^{II} and M^{III} cations, normally statistical distribution over a single crystallographic site is observed. The alkali ion (K,Rb,Cs) adopts the unusually high CN 18. For smaller ions than Cs^+, off-center positions have been reported. The potassium

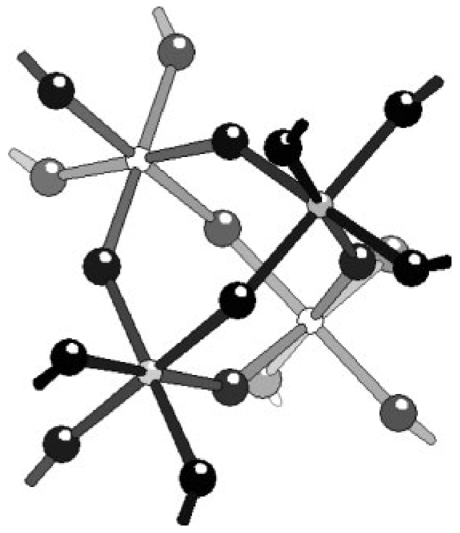

Figure 31 Tetrahedron of octahedra: basic unit of pyrochlore network

compound may reversibly uptake water. Only if mixed-valence compounds like $NH_4Fe^{II}Fe^{III}F_6$ are prepared, charge ordering occurs, and an orthorhombic variant is formed with ordered M^{II} and M^{III} octahedral chains. Related ordered structures are found for special cations like Ag^{2+} and Pd^{2+}.

It is even possible to realize the neutral basic 3D pyrochlore framework $[M_2^{III}F_6]$ free of any further cations or anions in the cavities. As mentioned above, by special 'soft chemistry' preparative methods, metastable low-density forms of trifluorides with pyrochlore-related structures may be obtained: cubic pyr-FeF_3 and η-AlF_3 (see Table 1, Figure 7).

Fluorides with Hexagonal Tungsten Bronze-Type (HTB) Structure. This channel structure, well known from colored mixed-valent oxide phases A_xWO_3 and analogs, is found in fluorides as well. It can be seen as originating from condensation of (3,6)-nets (Figure 28(a)) over the terminal fluorine ligands. The resulting framework has the composition $[MF_3]$, as is also the case for pyrochlores and perovskites. The large hexagonal channels can be empty as in β-AlF_3[48] (Table 1, Figure 6) and its homologous Cr, V,[144] and Fe[145] compounds. Normally they are partially or completely filled by water as in $(H_2O)_{0.33}FeF_3$ or by alkali ions. In the latter case, the typical compositions $A_{0.25}$ MF_3 (or $A_{0.5}M_2F_6$) and A = K, NH_4, Rb, Cs, Tl; M = V, Cr, Fe, Nb (survey in Ref. 33) indicate mixed-valent compounds. The M positions can be occupied statistically by two different metals. In this way, unambiguous single-valence states are achieved like in $Cs_{0.4}Zn_{0.4}^{II}$ $Fe_{1.6}^{III}F_6$.[139] For this example, it could be shown by single-crystal X-ray investigation that in spite of hexagonal metrics the symmetry is in fact lower (here s.g. $P2_1$). The reason is that, like in the orthorhombic $(H_2O)_{0.33}FeF_3$ (s.g. Cmcm), the M–F–M bridges along the channel axis are strongly bent by 159° or even 150° in the latter. A derivative

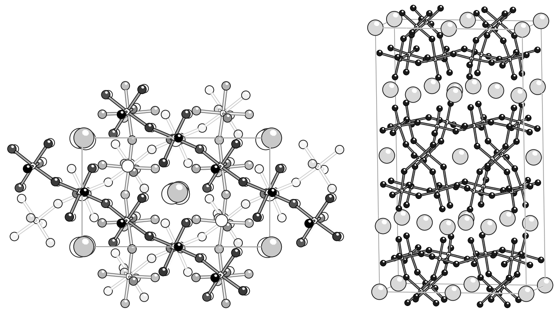

Figure 32 (a) $KCaAl_2F_9$ structure projected along the pseudo-hexagonal channel axis. Ca medium white, K large grey spheres. (b) HTB slab structure of $Rb_2Cr_5F_{17}$

of this HTB-type structure was found in $KCaAl_2F_9$[146] and analogous phases (M = Cr, V, Fe). By ordered substitution of octahedral sites in the Kagomé net by Ca, trans-chains of $[AlF_6]$ octahedra are left similar to the $[M^{II}F_6]$ chains in weberites (Figure 29(a)). Such layers are stacked under rotations corresponding to a 6_1 axis to form a loose 3D framework (Figure 32).

An interesting layer structure has been found in $Rb_2Cr_5F_{17}$ (Figure 32(b)):[147] Here the 3D HTB structure has been formally cut into slabs *parallel* to the hexagonal channels not – as in $Cs_2NaAl_3F_{12}$ above – parallel to the Kagomé layers.

3.2.9 Structures Based on the (3,4,5)-Net (TTB Net)

Fluorides with Tetragonal Tungsten Bronze-Type (TTB) Structure. An alternative channel structure with the same composition $[MF_3]$ can be built based on a net of 3-, 4-, and 5-membered meshes of vertex-connected octahedra. This TTB-type structure is formed under similar conditions as the HTB-phases before. As two types of (smaller) channels can be occupied by alkali ions (mainly K) here, it is favored for higher alkali contents (e.g. TTB for $K_{1.2}Fe_2F_6$, but HTB for $K_{0.5}Fe_2F_6$). However, as has been shown in Table 1 (Figure 9) for κ-AlF_3, the structure can also be realized with empty channels. In addition, the structure has been found for some mixed-metal compounds $KM^{II}M^{III}F_6$. Interestingly, pyrochlore-related $KNiCrF_6$ has a high-pressure phase of this TTB structure (see Ref. 33).

TTB-Type Layer Structures. Like the (3,6)- or Kagomé-net in the $Cs_2NaAl_3F_{12}$-type, the (3,4,5)- or TTB net can be found quasi-isolated in the layer structure of β-$RbAlF_4$-type.[148] This structure (s.g. I4/mcm) is also adopted by β-NH_4AlF_4, the precursor for the κ-AlF_3 synthesis,[49] by $CsCoF_4$,[149] and by β-$CsAlF_4$.[150] In $Cs_4CoCr_4F_{18}$,[151] the vertices of the groups of three octahedra are capped by additional octahedra, alternatingly above and below the layer.

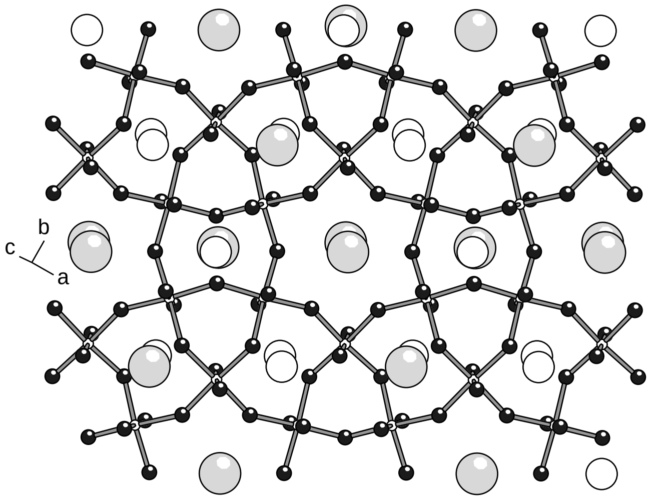

Figure 33 (3,4,6)-net of $CsBaCr_3F_{12}$ (Ba white, Cs grey spheres)

Layer Structure Based on a (3,4,6)-Net. An alternative way to form an $[MF_4]$ net of only vertex-sharing octahedra was found in $CsBaCr_3F_{12}$[152] (s.g. C2/c) (Figure 33).

3.2.10 Chain Structures with Triple-octahedral Units

Connection of triple-octahedral units to triple chains was encountered already in the structure of TiF_4 (Figure 13(a)). In ternary fluorides, corresponding anionic chains separated by the cations have been found in compounds $CsCrF_4$[153] and α-$CsAlF_4$,[154] as well as $KCrF_4$ in an angular variant.[155,156]

Another way of linking triple-octahedral units is realized in γ-$CsAlF_4$ (Figure 34), the structure of which can be deduced from the pyrochlore-type (Figure 31).

Complex bimetallic quinary compounds $Ba_2CaM^{II}M^{III}F_{14}$ and $Ba_7M^{II}M^{III}F_{34}$ with structures built from interconnected rings of four or eight octahedra, respectively, attracted interest because of their low-dimensional magnetic properties when appropriately substituted by transition metal ions (see recent survey in Refs. 157 and 158). The basic chain elements derived from the minerals usovite and jarlite are shown in Figure 35.

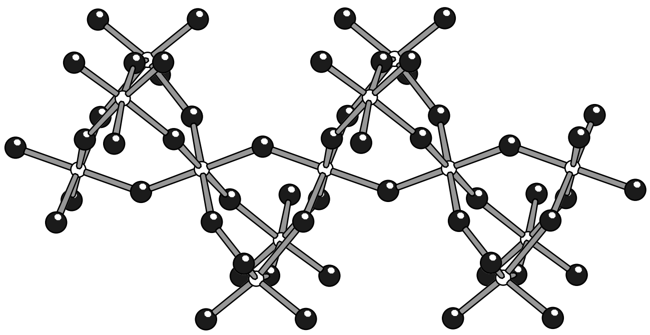

Figure 34 Chain of γ-$CsAlF_4$

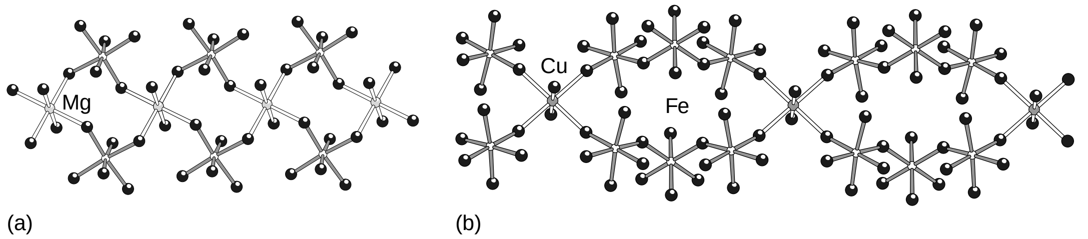

Figure 35 Chain sections of an usovite-type (a) and jarlite-type (b) structure

3.2.11 *Structures with [MF_6] Octahedra Sharing Common Edges*

The structure element of edge-sharing octahedra, encountered already in the rutile-type structure (Section 3.1, Figure 1(a)) and in AuF_5 (Figure 14(e)) is mainly found in some compounds $M^{II}M^{III}F_5$ and in a huge variety of Ba compounds. Structures $M^{II}M^{III}F_5$ have been mentioned already in Section 3.2.6 because the M^{III} cations are located in infinite *vertex-sharing* trans-chains. The M^{II} ions can also have octahedral coordination, and form infinite chains of *edge-sharing* octahedra alternatingly linked by common vertices to the M^{III} chains ($MnAlF_5$-type).

Quasi-isolated dimers [M_2F_{10}] of edge-sharing octahedra are aligned along the *c*−axis in the tetragonal compounds $BaTiF_5$,[159] $Sr_5Cr_3F_{19}$,[110] and an $SrAlF_5$ phase.[108] NH_4MnFeF_7[160] and $BaZnFeF_7$[161] are two different examples of 3D structures built from corner-sharing dimers (Figure 36).

In $BaMnFeF_7$, [Mn_2F_{10}] dimers are linked with [FeF_6] octahedra through vertices to form a dense 3D network. A typical structural unit is shown in Figure 37(a). A rich structural chemistry is reported for Ba-Cu^{II} and Ba-Zn^{II} compounds where the Ba:metal ratio can be varied in a large range. Here, edge-sharing octahedra are mostly condensed to linear trans-chains or kinked chains (or oligomeric chain sections) where alternatingly *trans*- and *skew*-edges are involved. An example for the latter mode is $Ba_2Cu_5F_{14}$ (Figure 37(b)) while pure quasi-isolated trans-chains are found in Na_2CuF_4 and Na_2CrF_4. Here, the Jahn−Teller effect leads to strongly asymmetrical bridges (Figure 37(c)).

3.2.12 *Structures with Oligonuclear Units*

Dimeric octahedral units sharing corners were reported for $CsBa_2Cr_2F_{11}$[123] and cyclamH_4[$Mn_2F_9(H_2O)_2$]-[$MnF_4(H_2O)_2$],[18] edge-sharing dimers for AuF_5,[62] $BaTiF_5$,[159] $SrAlF_5$,[108] and $Sr_5Cr_3F_{19}$,[110] as already mentioned. Four-membered rings of vertex-sharing octahedra are known from binary fluorides of NbF_5- or RuF_5-type (Section 3.1, Figure 14). In ternary compounds, corresponding units have been found in $Ba_3Al_2F_{12}$,[162] $Pb_3Al_2F_{12}$,[163] and $Pb_3Fe_2F_{12}$.[164] Tetrahedral 4-membered units [Al_4F_{18}] are formed with the dabcoH_2 cation (dabco = diaminobicyclooctane) in (dabcoH_2)$_2$(H_3O)[Al_4F_{18}] ·$3H_2O$.[18] Even pentameric units of five vertex-sharing octahedra have been reported: a planar ‘cross’ in $Na_3Sr_4Al_5F_{26}$[165] (Figure 38(a)) and a tetrahedron-like unit in $Na_3Sr_4Cr_5F_{26}$[166] (Figure 38(b)). The central octahedron has in the first case the two terminal fluorine ligands in *trans*-, in the second in *cis*-positions: Using the voluminous guanidinium (guaH_2) dication, recently a heptameric anion was obtained[167] in which two tetrahedral four-octahedra units are

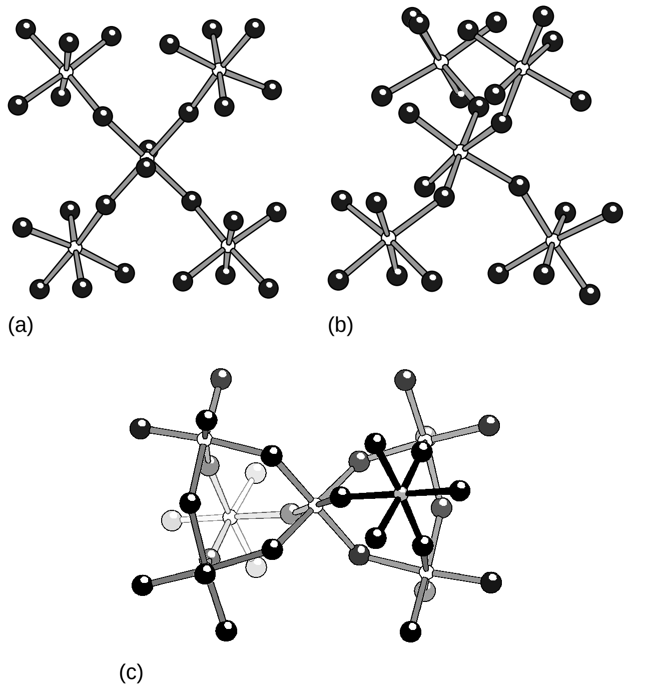

Figure 38 Pentameric units in (a) $Na_3Sr_4Al_5F_{26}$ and (b) $Na_3Sr_4Cr_5F_{26}$; (c) Heptameric anion in $[guaH_2][H_3O][Al_7F_{30}]$

condensed in the way of the pyrochlore-type structures (Figure 38(c)).

3.2.13 Structures with Unusual Coordination Numbers

Tetrahedral Coordination. Tetrahedral fluorine coordination is observed only for a few small cations, including some Li compounds as mentioned in Section 3.1 already: The only fluoride spinel Li_2NiF_4 has the inverse structure with half of the Li in octahedral and half in tetrahedral coordination.[168] In fluoride garnets $Li_3Na_3M_2F_{12}$ (M = Al, Ga, In, Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Rh), Li has tetrahedral coordination, M octahedral, and Na CN 8 (see Ref. 33). In compounds $LiBaMF_6$[33] (M = Al, Ga, Ti, V, Cr, Fe, Co), $[LiF_4]$ tetrahedra are linked to a framework with $[MF_6]$ octahedra, and in β-$Li_3M^{III}F_6$[81,82] phases (see Section 3.2.3) the Li cations are located in edge-sharing double-tetrahedra. In compounds $LiMF_4$ with M = Tl, Bi or a rare-earth metal, the scheelite-type ($CaWO_4$) structure is observed with tetrahedral coordination for Li and CN 8 for M. However, there are also scheelites $CaZnF_4$ and $SrZnF_4$ with Zn in CN 4.[33]

There are many compounds with $BeF_4{}^{2-}$, $Be_2F_7{}^{3-}$, and $BF_4{}^-$ anions, the structural chemistry of which is less surprising. However, there are some analogies to more complex silicate structures in fluoroberyllates: In $CsBeF_3$[169] 'zweier single chains' (nomenclature after Liebau[170]) are observed, in the cyclotrifluoroberyllate $KZnBe_3F_9$[171] a benitoite-like 'dreier single ring', and in the phyllofluoroberyllate $RbBe_2F_5$[172] a layer structure built from 6-membered rings ('zweier single layer'). These examples illustrate how fluoroberyllates may be used successfully as (lower melting) models for silicate chemistry, as already proposed by Goldschmidt in the 1920s.

The occurrence of a tetrahedral $[AlF_4]^-$ anion in solid $[(CH_3)_4N]AlF_4$ was deduced early from infrared spectra.[173] However, it was confirmed by single-crystal X-ray analysis only in 1993 for this compound[174] and analogs with cations 1,8-bis(dimethylaminonaphthalene)H or collidineH[175] and, recently, $[(C_6H_5)_4P]^+$.[176] Interestingly, in $[(CH_3)_4N][(i\text{-}Bu)_2AlF_2]$ even a mixed organic/fluoride coordination was found[176] with remarkable elongation of the Al–F bond by 0.06 Å. The biological activity of 'tetrafluoroaluminates' and their significance for catalytic purposes have been reviewed recently.[177]

Square-planar and Fivefold Coordination. In most fluoro compounds of the d^9-ion Cu^{2+}, elongated octahedral coordination is observed. However, in a few cases, the coordination geometry is square planar or square pyramidal (*see also Square Pyramidal*). All three coordination types are realized in the structure of $CsCu_2F_5$.[178] Planar CN 4 is frequently found in fluorides of Pd^{II} (d^8) as mentioned, for example, in Section 3.1. Other examples are fluorides of Cr^{II}, Ag^{II}, Ag^{III}, and Au^{III}. Several compounds AMF_4, such as $CaCuF_4$ or $KAuF_4$, crystallize in the $KBrF_4$-type structure (see Ref. 33). The structural chemistry of fluorides of the noble metals, especially in higher oxidation states at which this coordination type is frequently found, is reviewed in Refs. 179–181.

7- and 8-Coordination. While all bi- and tervalent first-row transition metals have octahedral coordination, exceptional pentagonal bipyramidal CN is observed for Mn^{II} in $MnCrF_5$.[182] Partial 8-coordination for Mn^{II} is even found in $BaMnGaF_7$.[183] While in many compounds $A^I_3M^{IV}F_7$ and $A^{II}_2M^{III}F_7$, M has CN 6 and 'independent' fluoride ions are present bound only to the A ions, CN 7 is actually observed in some cases, for example, in K_2NbF_7.[33,184] Examples of edge-sharing chains of $[ZrF_7]$ and $[ZrF_8]$ polyhedra are reported for fluorozirconates with amino-guanidinium(1+)[185] and (2+)[186] cations, respectively. Coordination numbers of 7–9 are normal for some other fluorozirconates and – hafnates and for the numerous rare-earth fluoro compounds known at the present time.

3.2.14 Hybrid and Mixed-ligand Compounds

Though the term 'hybrid' is not sharply defined and is a matter of taste, it is used here to summarize compounds containing besides an inorganic part – here a fluoride species – an organic component. This may be an organic cation, a template molecule, or an organic ligand. As there is

a large region of overlap between both classes of compounds, *mixed-ligand compounds* are mentioned here at the same time, even if no organic part is included.

Compounds with Organic Cations. As mentioned in Sections 3.2.12 and 3.2.13, unusual structural units like oligomeric anions could be obtained by using organic counter cations, normally protonated amines, which can vary widely in size and shape. The most frequently used cations are tma (tetramethylammonium), enH_2 (ethylenediammonium(2+)), and protonated higher diamines $H_3N\text{-}(CH_2)_n\text{-}NH_3$, pyH (pyridinium), $pipzH_2$ (piperazinium(2+)), $dabcoH_2$ (1,4-diazabicyclo[2.2.2]octane), $cyclamH_4$ (1,4,8,11-tetraaza cyclotetradecane), guaH (guanidinium), and derivatives of it. The preparation is performed in aqueous HF, often under hydrothermal conditions (cf. Section 2.4). The result is strongly dependent on the conditions, that is, concentrations, pH, temperature and pressure.

In systems containing no anion other than fluoride, mixed aqua-fluorometalates mainly with $[MF_5(H_2O)]^{2-}$ and $[MF_4(H_2O)_2]^{-}$ are frequently formed. Therefore the possibility of H-bond formation plays an important role (*see* ***Hydrogen Bonding & Dihydrogen Bonding***). The most investigated systems contain Al^{III}, Fe^{III}, Mn^{III} (surveys in Refs. 18, 113), and Zr^{IV}.[185,186] Aluminium compounds are of interest as possible precursors for the generation of catalytically active forms of AlF_3 (cf. Section 3.1) by thermal decomposition. Iron and manganese compounds are of interest because of their low-dimensional magnetic properties (see Section 4.1).

Mixed-Ligand Systems

Fluoride Phosphates (see ***Phosphates: Solid-state Chemistry****).* Simple metal fluoride phosphates like $M_2(PO_4)F$ (M = Mn, Fe, Cu) and alkali fluoride phosphates like $KFe(PO_4)F$ have been known since a long time. A modern development in the structural chemistry of fluoride phosphates (and phosphates) is the use of (mostly protonated) organic amines as templates to construct new structural architectures. As an example for the construction of microporous frameworks (*see* ***Porous Inorganic Materials***), the Ga compound $(C_6H_{14}N)_{1.5}(H_3O)_{0.5}[Ga_4F_2(PO_4)_4]\cdot 0.5H_2O$ ('ULM-16') is shown in Figure 39. The framework is built by Ga polyhedra of CN 6, 5, and 4 and orthophosphate anions. The large channels containing the cyclohexylammonium groups have a diameter of 10 × 10 Å. A survey on related fluoride phosphate microporous systems is given in Refs. 19, 187.

Several new fluoride phosphates with chain or layer structures have been reported for the Jahn–Teller ion Mn^{3+}.[113]

Other Mixed-Ligand Systems. From the smaller number of *sulfato-fluorometalates*, two recent examples are given. Compounds $A^{I}_2MnF_3(SO_4)$ have chain structures with antiferrodistortive Jahn–Teller ordering.[188] The mixed-valence iron compound $[HN(CH_2)_6\ NH][H_3O][Fe^{III}Fe^{II}_2F_6(SO_4)_2]$[189] exhibits a perfect $[FeF_3]$-Kagomé-net structure (similar to Figure 28) with 3-membered rings capped by sulfate units. With imidazole cations, *oxalato-fluoro* compounds of Mn^{III} and Fe^{III} could be prepared. While the manganese compound[113] has isolated $[MnF_2ox(H_2O)_2]^{-}$ anions, the iron compound $(imidH)_2[Fe_2oxF_6]$[190] has a ladder structure with low-dimensional magnetic properties (Section 4.1). *Fluoride carbonates* are generally built from alternating planar carbonate layers and fluoride containing layers (see structure-systematical survey in Ref. 191).

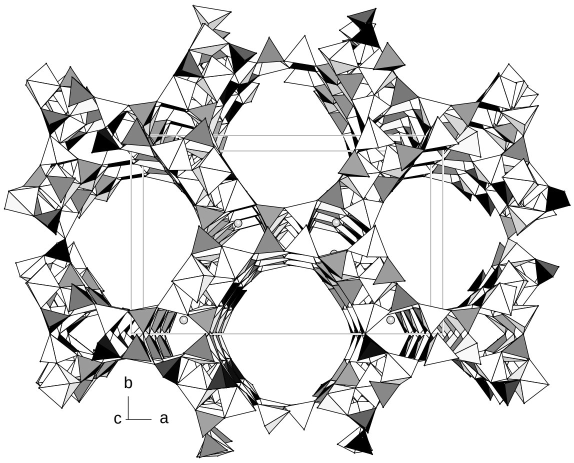

Figure 39 Open framework structure of the gallium fluoride phosphate ULM-16 (Ga polyhedra bright, PO_4 dark, amine molecules in the channels omitted)

In most fluorides with organic nitrogen bases, these are protonated and enter the structure as counter cations. However, the example of 4,4′-bipyMnF_3 (bipy = bipyridine) shows that it is also possible to construct hybrid coordination polymers with the amine and fluoride as bridging ligands (Figure 40). The structure is modulated at low temperature and has 1D magnetic properties.[16]

Alternating pyridine and fluorine ligands are found in the chain structure $[\text{-}Cu(py)_4\text{-}F\text{-}TiF_4\text{-}F\text{-}]\cdot 3H_2O$[192] as

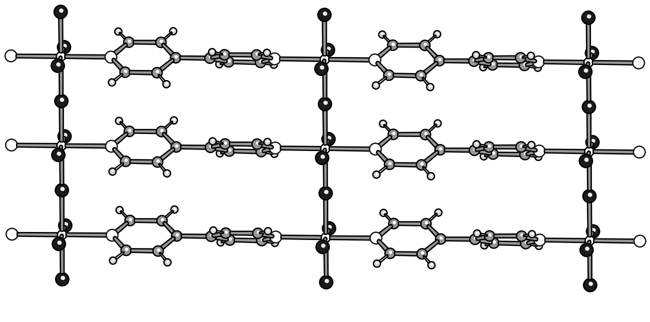

Figure 40 Section of the layer structure of 4,4′-bipyMnF_3

well as in similar Zr, Nb, and Ta compounds. In mixed-ligand oligomers like the tetramer $[Zr_4F_{12}Cp^*_4]$[193] or finally the In/Mg cluster with mesityl and fluorine ligands $[(mes)InF_{10}MgF_2]\cdot$5toluene,[194] the seamless transition from inorganic solids toward organometallics is completed (*see* ***Polynuclear Organometallic Cluster Complexes***).

4 PHYSICAL PROPERTIES

The physical properties of fluorides are determined mainly by the high ionicity of the metal–fluorine bond and the low polarizability of the fluoride ion (*see* ***Dielectric Polarizabilities of Oxides & Fluorides***). Therefore, magnetism based on superexchange interactions and high optical transparency in a wide spectral range are the most interesting properties. They define, together with the anionic conductivity in fluorite-like compounds, the main area of possible applications of fluorides in material science or industry.

4.1 Magnetic Properties

Exchange interactions between magnetic ions over bridging ligands (here over p orbitals of fluorine) are described by the superexchange mechanism following the rules of Anderson, Goodenough, and Kanamori[195] (*see* ***Magnetism of Extended Arrays in Inorganic Solids***; ***Magnetism of Transition Metal Ions***). In systems with localized electrons, the sign (positive for ferromagnetic, negative for antiferromagnetic coupling) and the strength of the exchange energy J depends on the state of the involved d orbitals at the metal centers (filled, half-filled, empty) and the bridge angle M–F–M (called β). In the common case of 'symmetrical' exchange (same metal, same orbital occupation), at $\beta = 180°$ *antiferromagnetic* properties are expected, at $\beta = 90°$ (in edge- or face-sharing octahedra) *ferromagnetic* coupling is expected.

1D Magnetic Systems. The experimental determination of exchange energies J can be done by fitting a theoretical model to the experimental data, namely, the temperature-dependent magnetic susceptibilities. The theoretical approach can be best applied to 1D systems. Fluorides with chain structures, where the chain geometry and the magnetic metal ion can be varied over a wide range, are textbook examples therefore for the confirmation of theoretical concepts. $CsNiF_3$ with a chain of face-sharing octahedra (Section 3.2.4) is a classical example for a 1D ferromagnet.[196] Antiferromagnetic fluoromanganates(III) A_2MnF_5 with trans-chain structures of varying bridge angles β (Section 3.2.6) provide the best experimental proof that the exchange energy J follows the orbital overlap:[114,197] Their values fit equation (13) very well.

$$\frac{J}{k} = 18\cos^2\beta[K] \qquad (k = \text{Boltzmann constant}) \qquad (13)$$

In addition, in these and related systems, nonlinear magnetic excitations (solitons) have been observed.[198,199]

Special 1D systems, chains made of rings, are fluorides with jarlite or usovite structures (Section 3.2.10). Homometallic or bimetallic chains with various combinations of spins (or nonmagnetic metals) allow the study of 1D antiferromagnets, 1D ferrimagnets, or linear trimers.[157,158]

2D Magnetic Systems. Fluorides with $TlAlF_4$-related layer structures (Section 3.2.5) normally have antiferromagnetic properties, when the exchange interactions along the M–F–M bridges are 'symmetrical', for example, e_g^1–e_g^1 in compounds $AFe^{III}F_4$. The only exception in homometallic compounds are Jahn–Teller systems like $A^I_2Cu^{II}F_4$, $A^I_2Ag^{II}F_4$, and $A^IMn^{III}F_4$ with antiferrodistortive ordering where 'asymmetrical' exchange e_g^2–e_g^1 or e_g^1–e_g^0, respectively, becomes possible. If the bridge angle β within the layers is higher than about 150°, *ferromagnetic* behavior is observed.[197,200,201]

3D Systems. Similar 'asymmetrical' ferromagnetic exchange conditions can be realized in ordered bimetallic systems, for example in compounds $M^{II}M^{IV}F_6$, by choosing appropriate cations. In most other cases, antiferromagnetic properties are observed or ferrimagnetism when two antiferromagnetically coupled sublattices do not compensate their moments. The sequence of strengths and sign of interaction can be understood when looking at the charge and the electron configurations of the involved magnetic ions and the dimensionality of the interaction.[202]

Systems with Triangular Units. In structures with layers of Kagomé- (HTB-) or TTB-type like pyrochlores or weberites (Sections 3.2.8–9) or chain structures with triple-octahedral units (Section 3.2.10), the magnetic exchange interactions within a triangular unit can be 'frustrated', that is, not all interactions can be satisfied at the same time in a 3D order (surveys in Refs. 203, 204). Different types of ordering of the magnetic moments can be encountered: a) a 'star' structure (120° angle between three moments or 109.5° angle in a tetrahedral spin array); b) orthogonal sublattices; c) colinear spin arrangement under breaking of one interaction; d) colinear array of 2/3 of the spins, one remaining disordered ('spin fou'); e) spin glass behavior.

4.2 Optical Properties

The main reasons for the interest in fluorides as optical materials are a) the high *transparency* especially in the infrared

region, b) the *wide band gap* allowing for special luminescence properties (*see* ***Luminescence***), especially emission from high-energy levels, c) special *ligand-field properties* in rare-earth fluorides with high CN, and d) *low phonon energy* allowing for laser applications in the infrared.

Several fluoride systems have therefore found technical applications. Thus, large single crystals of CaF_2 are used, for instance, for optics in lithographic processes of the semiconductor industry. Crystals of $LiYF_4$ doped with rare earths like Nd, Dy, Er, Ho are used as laser sources or amplifiers. Tunable laser emissions were obtained in V^{2+} doped MgF_2 or $KMgF_3$.[205] For applications in glass fiber optics, fluoride glasses (*see* ***Noncrystalline Solids***) are used, mainly based on ZrF_4, BaF_2, InF_3, GaF_3, AlF_3, ZnF_2, and CdF_2.[206] Their refractive index n_D is between 1.5 and 1.65, and the transmission starts at about 250 nm in the UV and reaches up to 10 µm in the IR. They find applications as passive optical devices, as glass fibers, glass fiber lasers, glass channel waveguides, and so on.

Photostimulable phosphors based on Eu^{2+} doped BaBrF are used in area detector systems in X-ray crystallography and medicine.[205]

4.3 Electrical Conductivity

Electronic Conductivity. Fluorides usually are good insulators owing to the wide band gap of more than 6 eV in most compounds. In some cases it is possible, however, to obtain n-type semiconducting properties by doping, for example, in $CdF_2(Y)$.[207] Exceptional metallic conductivity is observed in the metal-rich compound Ag_2F,[208] even superconductivity in $Hg_{3-\delta}AsF_6$[209] – despite the presence of fluoride. Mixed-valence silver fluorides have been recently discussed as possible candidates for superconductivity.[210]

Ionic Conductivity (see ***Ionic Conductors****).* Fluoride anionic conductivity is observed mainly in derivatives of fluorite (CaF_2) and tysonite (LaF_3). If CaF_2 is doped by a tervalent rare-earth metal ion, the additional fluoride ions are positioned in interstitials where they become mobile by a hopping mechanism.

1 INTRODUCTION

Fluorine displays a unique reactivity among the elements in that it forms compounds with all naturally occurring elements except He and Ne. The first compound of argon, HArF, was only recently isolated in a solid argon matrix and characterized by infrared (IR).[1] Fluorspar and other fluorides were used for several hundred years as fluxes in metallurgy, but the elemental nature of fluorine was not recognized until the nineteenth century.[2,3] After Davy recognized the elementary nature of chlorine in 1810, Ampère proposed that the acid formed from fluorspar and sulfuric acid was like hydrochloric acid. For the next 70 years, numerous chemists attempted to isolate elemental fluorine. The high reactivity of fluorine thwarted all efforts at isolation until H. Moissan succeeded in 1886 to generate fluorine gas by the electrolysis of hydrogen fluoride and potassium fluoride.

Fluorine is widely distributed in Nature, representing about 0.065% of the earth's crust, making it the 13th most abundant element.[4,5] It is more abundant than chlorine and much more abundant than common metals such as zinc and copper. Fluorine occurs in many minerals in which fluoride ion replaces hydroxide. The conversion of hydroxyapatite to fluoroapatite strengthens tooth enamel.[6] However, this would result in an increased brittleness in bones. An untested theory is that the widespread use of fluoride in drinking water, which had remarkable benefits in preventing dental caries in the 1960s, may be the cause of the rise in osteoporosis in the elderly population.

The three most important fluorine-containing minerals are fluorspar (CaF_2), cryolite (Na_3AlF_6), and fluorapatites containing variable amounts of fluorine. Fluorspar is the main source of hydrogen fluoride from which essentially all fluorine compounds are derived either directly or indirectly. Hydrogen fluoride is the primary industrial source of fluorochemicals as well as the source of elemental fluorine, which gives it a position of great importance in the chemistry of fluorine-containing compounds.

The exceptional stability of fluorinated compounds, however, can have deleterious environmental impacts. Recently, for example, it has become apparent that fluorinated compounds such as perfluorooctanesulfonate are widespread in nature[7] and in living systems.[8]

1.1 Hydrogen Fluoride

Hydrogen fluoride is produced worldwide in $\approx 10^6\,\mathrm{t\,a^{-1}}$ by reaction of fluorspar with sulfuric acid (equation 1). The reaction is endothermic ($\Delta H_{298} = 59\,\mathrm{kJ\,mol^{-1}}$) and is carried out in rotary furnaces that produce up to $45\,\mathrm{t\,d^{-1}}$. The crude HF is scrubbed by H_2SO_4 and purified further by distillation as required. Silicon tetrafluoride is a by-product from silicate impurities (equation 2) and is recovered as H_2SiF_6 (equation 3). Another by-product, $CaSO_4$, is used in cement production and other applications.[5]

$$CaF_2 + H_2SO_4 \xrightarrow{200-350\,^\circ C} 2HF(g) + CaSO_4 \quad (1)$$

$$CaF_2 + SiO_2 + 2H_2SO_4 \longrightarrow SiF_4 + 2CaSO_4 + 2H_2O \quad (2)$$

$$SiF_4 + 2HF \xrightarrow{H_2O} H_2SiF_6 \quad (3)$$

Hydrogen fluoride is an excellent solvent for many organic and inorganic compounds and has a wide liquid range.[9] Its properties are summarized in Table 1.

Commercial HF cylinders will contain H_2 owing to the slow reaction of HF with iron and varying amounts of H_2O. Very dry HF can be obtained in the laboratory by adding SbF_5 to HF and removing the HF from the mixture at $-40\,^\circ C$ in a suitable vacuum system (equation 4).[10]

$$HF + SbF_5 + H_2O \longrightarrow H_3O^+ + SbF_6^- \quad (4)$$

Hydrogen fluoride is very corrosive to many metals, glass, and other materials. Many plastics are resistant to HF and fluorinated polymers such as Kel-F, Teflon, Teflon-PFA, and others are inert to HF. A variety of useful equipment for handling and studying HF can be easily prepared from commercially available fluoropolymers and fluoropolymer components. Copper, Monel, and nickel are excellent metals for handling HF at higher temperatures. Stainless steels are satisfactory at lower temperatures.

Hydrogen fluoride causes severe burns to the skin and mucus membranes. Handling of HF should only be attempted

Table 1 Physical properties of hydrogen fluoride

Freezing point	$-83.55\,°C$
Cryoscopic constant	$1.55 \pm 0.05\,°C\,mol^{-1}$
Boiling point	$19.51\,°C$
Vapor pressure (25 °C)	921.4 mmHg
Density (0 °C)	$1.002\,g\,L^{-1}$
(25 °C)	$0.995\,g\,L^{-1}$
Dielectric constant (0 °C)	83.6
Specific conductance (0 °C)	$1 \times 10^6\,\Omega^{-1}\,cm^{-1}$

with proper protection and after consulting appropriate safety information.[11]

1.2 Fluorine

Elemental fluorine is produced commercially by the electrolysis of KF·2HF (mp 72 °C) using carbon anodes and steel cathodes.[5,9,12] The voltage of the cells is 8–12 V (standard electrode potential for $F_2 = 2.85$ V) and current is as high as 15 kA, depending on cell size. The cathode and anode are separated by skirts to prevent mixing of F_2 with H_2 formed at the cathode. The western world production of fluorine is ca. $2–3 \times 10^3\,t\,a^{-1}$, of which about 55% is used for production of UF_6 and 40% is for SF_6. Other uses include production of CF_4, NF_3, and fluorinated graphite for batteries.

The physical properties of F_2 are given in Table 2. Fluorine is an orange-yellow liquid at −196 °C, and the gas at 1 atm in a 2 L glass bulb has a pale yellow-green color. Fluorine has an almost pleasant, sweet smell, and is easily detected by humans at the 1 ppm level in the air. It is highly toxic and can be very dangerous to handle in high concentrations unless proper precautions and equipment are employed.[13] Fluorine reacts exothermically with all elements at high concentrations except O_2, N_2, He, Ne, Ar, and Kr. Many metals form a protective fluoride coating on contact with fluorine at low concentrations and can be passivated towards further reaction at higher concentrations. Many fluoropolymers such as Teflon and Teflon-PFA are resistant to fluorine near room temperature but will burn at higher temperatures and high concentrations of fluorine. Fluorine can be handled under various conditions in properly cleaned and passivated metal apparatus of copper, brass, steel, stainless steel, Monel, and nickel. At high temperatures, Monel and nickel must be employed.

Table 2 Physical properties of fluorine

Melting point	53.54 K
Boiling point	85.02 K
Vapor pressure (77.17 K)	280.4 mmHg
(89.40 K)	1219.9 mmHg
Critical temperature and pressure	144 K and 55 atm
Density (liquid) (77.22 K)	$1.562\,g\,cm^{-3}$

2 METHODS FOR THE FORMATION OF ELEMENT–FLUORINE BONDS

Fluorine forms bonds to all elements except He, Ne, and Ar and the bond strengths are generally high except with other very electronegative elements. The methods used for forming bonds with fluorine in main group compounds are diverse but can be broadly grouped into four classes based on hydrogen fluoride, elemental fluorine, metal fluorides, and nonmetal fluorides. Laboratory preparations favor the use of metal fluorides and nonmetal fluorides, which avoid the use of the more experimentally difficult reagents HF and F_2. Regardless of the method, the origin of the fluorine in every reagent can be traced back to HF. Naturally occurring CaF_2 (fluorspar) is perhaps the only exception, but CaF_2 is rarely used directly as a fluorinating reagent.

2.1 Hydrogen Fluoride

Hydrogen fluoride is most often employed to prepare metal fluorides by reaction of oxides, hydroxides, carbonates, and chlorides with either pure HF or concentrated aqueous solutions. Obviously water-sensitive fluorides require pure HF and conditions that will not result in a mixture of fluorides and oxides. Hydrogen fluoride reacts with all metals below hydrogen in the electromotive series and numerous metal fluorides can be prepared at high temperatures by reaction of the powdered metal with HF(g). Authoritative reviews on metal fluorides can be consulted for details.[2,9,14]

Many nonmetal fluorides can be prepared by reaction of readily available chlorides and bromides with HF, particularly groups 14, 15, and 16, excluding nitrogen and oxygen.[15,16] For example both SbF_3 and SbF_5 can be prepared from the respective chlorides (equations 5 and 6). In many reactions, much more rapid conversion of halides to the fluorides in HF is achieved by adding a Lewis acid catalyst such as SbF_5 or SbF_3/Cl_2 (SbF_3Cl_2). The pentahalide becomes the fluorination reagent and the resulting Sb–Cl bonds are converted to Sb–F bonds by the HF.

$$SbCl_3 + 3HF \longrightarrow SbF_3 + 3HCl \quad (5)$$

$$SbCl_5 + 5HF \longrightarrow SbF_5 + 5HCl \quad (6)$$

The reaction of HF with chlorocarbons in the presence of Lewis acid catalysts is the basis of much of the commercial production of aliphatic organofluorine compounds.[17,18] The important chlorofluorocarbons (CFCs) are produced on a large scale by this method as well as environmentally more friendly hydrofluorocarbons (HFCs) and hydrochlorofluorocarbons (HCFCs), which are replacing CFCs such as CF_2Cl_2, $CFCl_3$, and $CF_2ClCFCl_2$. As an indication of the importance of this method industrially, two important perfluoroalkene intermediates can be illustrated (equations 7 and 8). Both C_2F_4 and C_3F_6 are important monomers for a variety of fluoropolymers

and other fluorochemicals having a broad spectrum of utility in modern technology. Recently, carbon–hydrogen bond hydrogenolysis involving the heterolytic activation of H_2 has been employed to prepare HFC-134a.[19]

$$CHCl_3 + 2HF \xrightarrow{\text{catalyst}} CHF_2Cl + 2HCl \tag{7}$$

$$CHF_2Cl \xrightarrow{\text{heat}} CF_2{=}CF_2 + CF_3CF{=}CF_2 + HCl + \text{Others} \tag{8}$$

Another aspect of HF fluorinations involves the process of electrochemical fluorination (ECF) (Simons process) carried out in anhydrous HF.[20] The Simons process is applied mainly to the synthesis of organofluorine compounds, but more inorganic compounds (e.g. CF_3SF_5 from CS_2 and CF_3SO_2F from $MeSO_2F$, Cl) are prepared in very high yield by this method. In ECF the fluorination takes place at a nickel or Cu/Ni anode in HF using a voltage below that required to produce elemental fluorine (5–6 V) and a current of a few to several hundred amps depending on cell size and electrode details. Fluorination is believed to take place via high-valent nickel fluorides formed on the surface of the anode, but after more than 50 years of use the process is still not well understood. Hydrogen gas is produced at the cathode and the consumed HF is replenished continuously to maintain an appropriate volume in the ECF cell. Products are removed as gases or liquids and the entire process can be operated continuously. To be effective, the compound to be fluorinated must be soluble in HF. Compounds containing oxygen, sulfur, and nitrogen are particularly useful because the heteroatoms are protonated in the HF medium, providing solubility and conductivity. Yields decrease with molecular complexity owing to cleavage reactions, incomplete fluorination, and other complications. The utility of the Simons ECF process is illustrated by two commercial fluorocarbon derivatives prepared in this way, $C_8F_{17}SO_2F$ from $C_8H_{17}SO_2F$ and $(n\text{-}C_4F_9)_3N$ from $(n\text{-}C_4H_9)_3N$. More recently the first example of the direct ECF of a thiazole ring was reported.[21]

2.2 Elemental Fluorine

In principle, all binary fluorides of main group elements could be prepared by direct combination with fluorine. In practice this is impossible since fluorine is a powerful oxidizer and favors high oxidation states of the elements. Nevertheless, F_2 is essential in the preparation of many compounds in both low and high oxidation states, particularly compounds of nitrogen, oxygen, sulfur, higher halogens, krypton, and xenon.[15,16] Increasingly, fluorine is also used in the preparation of fluorocarbons, especially complex fluorocarbon ethers.[22] For many metals, high oxidation state fluorides and oxyfluorides can only be obtained via F_2 or fluorine atom sources such as KrF_2 and O_2F_2.

The use of elemental fluorine in the preparation of main group fluorides is carried out in batch and flow systems depending on the activation required and the exothermicity of the reaction. Clearly it can be exceedingly dangerous and foolhardy to combine substantial amounts of fluorine with an easily oxidized element or compound in a batch reaction. As an illustration, SF_6 is prepared commercially by passing pure fluorine gas over lump sulfur, resulting in ignition and complete consumption of the fluorine ($\Delta H = -262$ kcal g mol^{-1}). If pure fluorine were condensed on to sulfur at −196 °C in a closed vessel without ignition and then warmed, an explosive reaction would ensue at the moment the temperature reached a point where the fluorine began to react with the sulfur. On the other hand, ClF is safely prepared on a 0.2 mol scale by cocondensing equimolar amounts of F_2 and Cl_2 into a 150 mL Monel reactor at −196 °C, warming to 22 °C and then heating at 250 °C. The latter reaction proceeds first to ClF_3 ($\Delta H = 26$ kcal mol^{-1}) and the ClF_3 reacts with Cl_2 at 250 °C to give ClF.

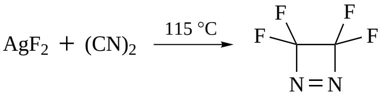
Many reactions of nitrogen and oxygen compounds involving elemental fluorine require catalysts. Two of the most useful catalysts are AgF_2 and CsF. The catalysts function in different ways, as illustrated by equations (9) and (10).[23] Without the catalyst there is no reaction between F_2 and COF_2 up to 200 °C. The catalytic intermediate with AgF_2 may be an Ag^{II} derivative and with CsF the CF_3O^- anion is strongly suspected.

$$COF_2 + F_2 \xrightarrow[180-200\,^\circ C]{AgF_2} CF_3OF + CF_3OOCF_3 \tag{9}$$

$$COF_2 + F_2 \xrightarrow[-78\,^\circ C]{CsF} CF_3OF \text{ (no peroxide)} \tag{10}$$

2.3 Metal Fluorides

Because of the ready availability of chlorides and bromides of the main group elements, simple metathesis reactions provide an excellent route to many fluorinated compounds. Many metal fluorides have been employed in fluorinations of main group halides including groups 1 and 2 metal fluorides, ZnF_2, AgF, AgF_2, HgF_2, PbF_2, CoF_3, SbF_3, SbF_5, and SbF_3Cl_2. The high oxidation state fluoride AgF_2 is used in oxidative fluorinations and often in conjunction with F_2, for example, equations (11) and (12).



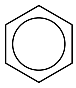
(11)

$$SO_3 + AgF_2 \xrightarrow[160\,^\circ C]{F_2} (FSO_2O)_2 \tag{12}$$

Cobalt trifluoride is used almost exclusively to replace hydrogen on carbon and in oxidative fluorination of hydrocarbons,[24] for example, equations (13) and (14). Zinc fluoride, SbF_3, and PbF_2 are mild fluorinating reagents that can often be used to give partially fluorinated

compounds depending on conditions and stoichiometry (equations 15–17).[15,16]

$$n\text{-}C_5H_{12} \xrightarrow[300\,^\circ C]{CoF_3} n\text{-}C_5F_{12} \quad (13)$$



$$\xrightarrow[250\text{–}300\,^\circ C]{CoF_3} \text{cyclo-}C_6F_{12} \quad (14)$$

$$PCl_3 + SbF_3 \xrightarrow{40\,^\circ C} SbClF_2 + PFCl_2 \quad (15)$$

$$OPCl_3 + ZnF_2 \xrightarrow{40\,^\circ C} OPClF_2 + ZnCl_2 \quad (16)$$

$$OPCl_3 + SbF_3 \xrightarrow{150\,^\circ C} OPF_3 + SbCl_3 \quad (17)$$

Zinc fluoride can often be used in a polar solvent to effect fluorinations that are difficult with other reagents (equation 18). The addition of Cl_2 or $SbCl_5$ to SbF_3 as a catalyst greatly increases the utility of SbF_3 in fluorinations (equations 19–22).

$$CH_2(SO_2Cl)_2 \xrightarrow[Et_2O]{ZnF_2} CH_2(SO_2F)_2 \quad (18)$$

$$SO_2Cl_2 \xrightarrow[300\,^\circ C]{SbF_3/SbCl_5} SO_2ClF \quad (19)$$

$$COCl_2 \xrightarrow[130\,^\circ C]{SbF_3/Cl_2} COF_2 \quad (20)$$

$$SO_2Cl_2 \xrightarrow[200\,^\circ C]{SbF_3} \text{No reaction} \quad (21)$$

$$COCl_2 \xrightarrow[300\,^\circ C]{SbF_3} COF_2 + OCFCl \quad (22)$$

The recognition that polar solvents such as MeCN, tetramethylene sulfone, benzonitrile, and others greatly increase the activity of the alkali metal fluorides NaF and KF has led to their widespread use in metathesis reactions.[25] Potassium fluoride is more active than NaF but the latter is easily dried and does not readily absorb H_2O. Many fluorinations are readily accomplished by refluxing the halide with excess NaF in the solvent in standard glass apparatus or by heating under autogenous pressure in an autoclave. Some examples of useful fluorinations are shown in equations (23–28). It was recently found that the reactivity of KF is enhanced when used in ionic liquids.[26]

$$SO_2Cl_2 \xrightarrow[MeCN]{NaF,\ 80\,^\circ C} SO_2FCl \quad (23)$$

$$SO_2Cl_2 \xrightarrow[\text{sulfolane}]{NaF,\ 150\,^\circ C} SO_2F_2 \quad (24)$$

$$SPCl_3 \xrightarrow[140-170\,^\circ C]{NaF,\ \text{sulfolane}} SPF_3 \quad (25)$$

$$COCl_2 \xrightarrow[MeCN]{NaF,\ 40\,^\circ C} COF_2 \quad (26)$$

$$(CNCl)_3 \xrightarrow[\text{reflux}]{NaF,\ \text{sulfolane}} (CNF)_3 \quad (27)$$

$$C_4F_9SO_2Cl \xrightarrow[\text{sulfolane}]{KF,\ 35\,^\circ C} C_4F_9SO_2F \quad (28)$$

2.4 Nonmetal Fluorides

Many nonmetal fluorides have been employed for the preparation of other main group fluorides. These fluorination reagents fall into two general classes: strong oxidative fluorination reagents such as ClF, ClF_3, BrF_3, and IF_5, and weak oxidizing reagents such as SF_4, SeF_4, and AsF_3. The major utilization of these reagents has been in fluorocarbon derivatives and as selective fluorination reagents in organic chemistry, for which numerous authoritative reviews are available.[27–29] Sulfur tetrafluoride and halogen fluorides have been used extensively in the preparation of metal fluorides.[9,14]

The halogen fluorides react very vigorously with oxidizable substrates with the reactivity decreasing from chlorine to iodine. Often, halofluorination is a desired outcome of these reactions. While the number of reactions that have been examined with main group compounds is large, the number of useful preparative reactions is limited. Some examples of useful reactions involving the formation of element–fluorine bonds are given in equations (29–35).[16,30]

$$PF_3 + ClF \xrightarrow{-196 \text{ to } 22\,^\circ C} F_4PCl \quad (29)$$

$$4SOCl_2 + IF_5 \xrightarrow{22\,^\circ C} 3SOClF + SOF_2 + ICl_3 + Cl_2 \quad (30)$$

$$SO_2 + BrF(BrF_3/Br_2) \xrightarrow{22\,^\circ C} SO_2BrF \quad (31)$$

$$ClF + SO_3 \xrightarrow{22\,^\circ C} FSO_2OCl \quad (32)$$

$$6ClF + BrCN \xrightarrow{-196 \text{ to } 22\,^\circ C} CF_3NCl_2 + BrF_3 + 2Cl_2 \quad (33)$$

$$N{\equiv}SF_3 + 2ClF \xrightarrow{-196 \text{ to } 22\,^\circ C} SF_5NCl_2 \quad (34)$$

$$KBrO_3 + BrF_5 \xrightarrow{22\,^\circ C} KBrO_2F_2 + BrO_2F \quad (35)$$

Weak oxidizing fluorides such as SF_4 and SeF_4 are useful as fluorination reagents in selected cases to replace oxygen or hydroxide by fluorine and as mild oxidative fluorination reagents. Some useful examples are shown in equations (36–39).

$$SeO_2 + 2SF_4 \xrightarrow{200\,^\circ C} SeF_4 + 2SOF_2 \quad (36)$$

$$2Ph_3P + SF_4 \xrightarrow{150\,^\circ C} 2Ph_3PF_2 + S \quad (37)$$

$$2PhAsO_3H_2 + 3SF_4 \xrightarrow{70\,^\circ C} 2PhAsF_4 + 3SOF_2 + 2HF \quad (38)$$

$$4Me_3SiCl + SF_4 \xrightarrow{20\,^\circ C} 4Me_3SiF + SCl_2 + Cl_2 \quad (39)$$

Arsenic trifluoride is a particularly useful reagent for the fluorination of chlorides. Its physical properties (bp 63 °C)

often make it more useful than SbF_3. Examples of useful fluorinations with AsF_3 include those in equations (40) and (41).

$$3PCl_5 + 5AsF_3 \xrightarrow{22\,^{\circ}C} 3PF_5 + 5AsCl_3 \quad (40)$$

$$3HN(SO_2Cl)_2 + 2AsF_3 \xrightarrow{\text{reflux}} 3HN(SO_2F)_2 + 2AsCl_3 \quad (41)$$

3 BONDING AND STRUCTURE

3.1 Bond Energies

Fluorine is unique in forming the largest number of examples of element–element bonds. It is also unique in forming chemical bonds ranging from one of the strongest single bonds known (BF_3) to some of the weakest bonds in compounds isolable under ordinary laboratory conditions (KrF_2). Table 3 lists the mean thermochemical bond energies for some main group fluorides.[9,31]

Two regular trends are evident in the decrease in bond energies across a row from left to right and a decrease in bond energies with increasing oxidation state. Clearly the often stated generalization that bond energies decrease in going down a group does not apply in general to nonmetal fluorides.

The very low dissociation energy of fluorine ($155\,kJ\,mol^{-1}$), its small atomic size ($r = 0.5741$ Å), high electronegativity (3.98, Pauling), and high electron affinity ($338.9\,kJ\,mol^{-1}$) all contribute to the ability of fluorine to form a wide variety of stable fluorides and oxyfluorides of nonmetals. It has been pointed out, however, that many fluorides are not as stable as might be expected, based on comparisons with other halogens. This has been attributed to the fact that addition of an electron into the outer shell of the fluorine atom, as in the formation of a covalent bond, is energetically less favorable by a ca. $109\,kJ\,mol^{-1}$ than would be expected by extrapolation from the other halogens. This anomaly is primarily due to the small size of the fluorine atom and is suggested as an explanation for the unusually small dissociation energy of difluorine. Based on the other halogens, an extrapolation of $1/R_e$ versus D_e would give $D_e \sim 381\,kJ\,mol^{-1}$ for F_2, which is $2 \times 109\,kJ\,mol^{-1}$ larger than the observed value. Similarly, based on an extrapolation of the ionization potential of the halogens versus electron affinity, fluorine would be expected to have an atomic electron affinity of $443\,kJ\,mol^{-1}$, which is approximately $109\,kJ\,mol^{-1}$ greater than the observed value.

Fluorine is generally able to produce the highest oxidation states in nonmetals, but in many cases this state can only be observed in an oxyfluoride of the nonmetal. These exceptions occur with nitrogen, chlorine, bromine, and xenon. Thus NF_5, ClF_7, BrF_7, and XeF_8 are unknown but NOF_3, ClO_2F_3, BrO_3F, ClO_3F, and XeO_3F_2 are well known.[30] However, for all the aforementioned elements except xenon, the maximum oxidation state for each has been achieved with fluorine in cationic derivatives of the unknown parent fluoride in NF_4^+, ClF_6^+, and BrF_6^+ salts. The X-ray structures of $[XF_6][Sb_2F_{11}]$ (X = Cl, Br, I) have recently been reported.[32] Numerous related examples of the inability of fluorine alone to form the highest oxidation state of an element are also observed among several transition metals.[33]

3.2 Molecular Structures

The structures of nonmetal fluorides and oxyfluorides are remarkably well predicted on the basis of VSEPR considerations (*see Valence Shell Electron Pair Repulsion Model*). In fact, nonmetal fluoride and oxyfluoride structures are the most often used examples of the success of VSEPR predictions of molecular shape. The small size of fluorine and its high electronegativity give rise to smaller bond angles in an analogous series of halogen compounds in cases where nonbonding electron pairs are present in the valence shell. In PX_3 the XPX bond angle increases from 96° in PF_3 to 102° in PI_3. Other examples include OF_2 (103°), OCl_2 (111°), and OSF_2 (93°), $OSCl_2$ (96°), and $OSBr_2$ (97°).

[a]All in pm.

Element–fluorine bond distances in neutral binary fluorides vary over a considerable range from BF_3 (1.31 pm) to XeF_2 (1.98 pm)[34] Table 4 shows the small variation in bond distances as a function of increasing oxidation state for a related series of compounds and the relatively small variation in bond distances across a given row in the periodic table, in spite of a more than fivefold decrease in the average thermochemical bond energies from KrF_2 to GeF_2.

4 SPECTROSCOPY

Nonmetal fluorides and oxyfluorides have been studied by nearly every available modern spectroscopic and diffraction technique. This is due in part to the strong practical and theoretical interest in the structure and reactivity of simple molecules of this type, the diversity of compounds that can be obtained, and their amenability to study by many different techniques. Many structures of simple fluorides and oxyfluorides have been determined by electron diffraction, microwave spectroscopy, X-ray diffraction, and vibrational analysis. For many chemists interested in the synthesis and reactivity of main group fluorides and derivatives, ^{19}F NMR, IR, and Raman spectroscopy, and mass spectrometry are the indispensable routine tools of analysis.

4.1 Fluorine NMR

Fluorine has 100% natural abundance of ^{19}F ($I = 1/2$) and ^{19}F NMR is arguably one of the most useful techniques for structural information, rivaling that provided by ^{1}H and ^{13}C NMR.[35,36] The relative sensitivity of ^{19}F is 0.83 compared to ^{1}H and the range of observed fluorine chemical shifts in diamagnetic compounds covers more than 1000 ppm. The accepted standard for ^{19}F NMR chemical shifts is $CFCl_3$ and since the late 1960s this reference has been used almost exclusively. Earlier chemical shifts are often reported relative to other standards and some care must be exercised in using earlier literature values if the reference standard is not given. Also, up to the early 1980s the sign convention for chemical shifts was not always uniform. At present, chemical shift values at lower frequency than $CFCl_3$ are assigned a negative value and vice versa. Again, care must be exercised in using literature values prior to the early 1980s in that the sign convention used was usually opposite to the presently accepted convention.

The range of ^{19}F chemical shifts for fluorine bonded to a given element can be very large, for example, +479 (FNO) versus −127 ($CF_3NH\underline{F}$) and −448 (ClF) versus 247 ($FClO_3$). In spite of the large dispersion observed in ^{19}F chemical shifts, chemical shift values can be used effectively as a diagnostic tool. With modern high-field NMR spectrometers, spectra of complex molecules are often easily interpreted. Line broadening for fluorine attached to quadrupolar nuclei is typically of the same magnitude as that observed with hydrogen bonded to the same nucleus. The effects of solvent on chemical shift values varies but, at the low concentrations needed for FT-NMR spectrometers, different noncomplexing solvents do not give large variations in chemical shifts. The difference in solvents such as $CDCl_3$ and CD_3CN is usually less than 0.1–0.2 ppm. Some representative ^{19}F NMR chemical shift values for a variety of nonmetal fluorides and oxyfluorides are given in Table 5.[35–38]

Fluorine undergoes strong spin–spin coupling with many other nuclei and with other magnetically nonequivalent fluorines, providing further structural information in many compounds. The magnitude of these J couplings is difficult to predict and long-range fluorine–fluorine couplings are dominated by through space interactions.[39] Long-range multiband $^nJ_{FF}$ couplings are often observed in fluorine compounds if the magnetically nonequivalent fluorine atoms are close through space owing to the molecular structure or conformation. The latter is most often of consequence in organofluorine compounds such as in 4,5-difluorophenanthrene ($^5J_{FF} = 174$ Hz), but it is clearly evident in many nonmetal fluorine derivatives. For example, in SF_4=NF the two axial sulfur–fluorine bonds and S=N–F lie in a plane. The $^3J_{FF}$ *cis*-NF–SF_{ax} is 227 Hz compared to only 93 Hz for the *trans*-NF–SF_{ax}.[40]

Table 6 gives some possible values for spin–spin coupling constants as a function of the number of intervening bonds. Long-range ^nJ values can be observed in many cases, especially for F–F couplings. Values of ^2J and ^3J strongly depend on the element to which the fluorine is bonded (e.g. $^2J_{FF} = 422$ Hz in ClF_3, whereas $^2J_{FF} = 128$ in $ClCF_2NClF$) and ^3J values are strongly dependent on structure type ($^3J_{FF}$ CF_3OF, 34 Hz; FC(O)OF, 141 Hz).

In recent years, solid-state magic angle spinning NMR has become a direct and sensitive method for distinguishing different fluorine species in various solid-state materials. For

example this technique can be used to demonstrate that at low fluoride loadings the basic hydroxyl groups on γ-alumina are replaced by fluoride.[41]

4.2 Vibrational Spectroscopy

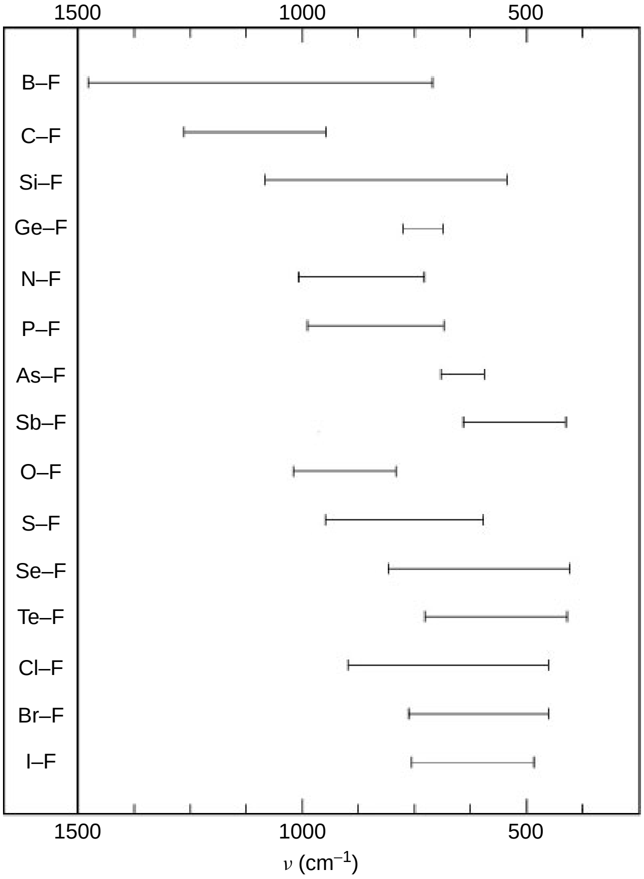
As for other inorganic compounds, vibrational spectroscopy provides useful information on the identity and structure of main group fluorides and oxyfluorides.[42,43] Characteristic M–F stretching frequencies can be identified for all nonmetal fluorides and simple molecules have very characteristic fingerprints in the IR.[44] Sampling problems for highly oxidizing fluorides are challenging and Raman spectra are often more easily obtained. Many common IR window materials are attacked by reactive fluorides and silver chloride is one of the most useful window materials in this respect for liquid, solid, and gas-phase spectra. On the other hand, Raman spectra of liquids and solids can be obtained in glass or transparent fluoropolymer containers and low-temperature spectra are more easily obtained on highly reactive or unstable compounds. Gas-phase Raman spectra are generally difficult to obtain because of the high pressures required and spectra of compounds having boiling points well below 22 °C are generally obtained on condensed liquids or solids at low temperatures. Numerous excellent reviews and books can be consulted for details of instrumentation, sampling, and summaries of vibrational spectra of fluorides and oxyfluorides.[42,43] Some typical group frequencies for M–F stretching are shown in Table 7.

4.3 Mass Spectrometry

Modern mass spectrometers provide a powerful tool for the indentification and study of nonmetal fluorides and their derivatives.[45] Many compounds are sufficiently volatile to make sampling relatively easy. In highly fluorinated compounds, the 100% natural abundance of ^{19}F simplifies interpretation of many spectra and high-resolution spectra are often not required for unambiguous interpretation of mass spectra. Numerous nonmetal fluorides and derivatives were first identified by mass spectrometry and subsequently obtained in sufficient amounts to characterize by other methods. Modern quadropole mass spectrometers are particularly useful in the analysis of fluorine compounds and their open architecture facilitates the analysis of highly reactive fluorine compounds and compounds of low thermal stability.

Both positive and negative ion mass spectrometry are useful for fluorine compounds and often are complimentary. Fluorocarbons rarely show an M^+ peak in positive ion EI spectra but often exhibit intense M^- in negative ion spectra. Chemical ionization techniques routinely offered in inexpensive mass spectrometer systems greatly enhance the ability to observe molecular ions in both positive and negative ion spectra. Most mass spectral data on simple main group

Table 7 Main group element–fluorine stretching frequencies



fluorides and oxyfluorides were obtained before the routine availability of CI.

Highly fluorinated nonmetal compounds in both positive and negative EI readily lose fluorine atoms on ionization. For example, the 70 eV EI spectrum of NF_3 gives M^+ (26%), M–F^+ (100%), and M–$2F^+$ (26%), and ONF_3 gives M^+ (0.2%), M–F^+ (78%), M–$2F^+$ (1.6%), and NO^+ (100%), as well as weak NF_2^+ and NF^+ ions. For SeF_6, the 70 eV EI spectra consist of SeF_5^+ and SeF_4^+ but no M^+. At 20 eV the negative ion spectra consist of SeF_5^- (50%), SeF_4^- (7%), SeF_3^- (5%), Se^- (1%), and F^- (100%). Using SF_6 as a CI gas and below 10 eV, SeF_6^- can be observed in appreciable amounts.

For very sensitive molecules like $\overline{O\text{–}CF_2\text{–}O}$, obtaining a molecular ion in the mass spectrum is difficult. However, by selective ion monitoring, M^+ at $m/z = 82$ was easily observed at 20 eV in EI.

Often soft ionization techniques such as fast-atom bombardment (FAB)[46] and matrix-assisted laser desorption (MALDI)[47] greatly increase the utility of mass spectrometry in the analysis of fluorinated compounds. Using a commercial matrix-assisted laser desorption time-of-flight mass spectrometer, molecular ions of a polyelectrolyte, $[–SO_2NNaSO_2(CF_2)_4SO_2–]_n$ could be observed. Future applications of these techniques are very promising.

5 NONMETAL FLUORIDES AND OXYFLUORIDES

The number of inorganic fluorine-containing compounds of metals and nonmetals is very large and many organofluorine compounds are borderline between the traditional boundaries of organic and inorganic chemistry. The following sections focus on the binary fluorides and tertiary oxyfluorides of main group nonmetals as representative examples of the extensive and interesting chemistry of fluorine-containing inorganic compounds. The cited literature and cross references provide easy access to compounds not covered.

5.1 Boron Fluorides

Boron forms strong bonds to fluorine (644 kJ mol^{-1}), usually combining with three or four fluorides in its compounds or salts. Several binary fluorides of boron are known including boron trifluoride, BF_3, a stable gas of great industrial importance as a Lewis acid. Boron trifluoride is synthesized industrially by reaction of hydrofluoric acid with borates or boric oxides (equation 42).[48]

$$Na_2B_4O_7 + 12HF \xrightarrow{-6H_2O} [Na_2O(BF_3)_4] \xrightarrow{2H_2SO_4} 4BF_3(g) + H_2O + 2NaHSO_4 \quad (42)$$

Boron trifluoride forms addition compounds that incorporate an sp^3 hybridized boron into a tetravalent structure.[49] Salts of BF_4^- are readily formed with BF_3 and a suitable fluoride donor. Halogen fluorides such as chlorine trifluoride react with BF_3 to generate interhalogen cations such as $[ClF_2]^+[BF_4]^-$.[50] Some further examples are shown in equations (43) and (44). In an organic application, the Schiemann reaction provides an entry into fluorinated aromatics by thermal decomposition of a diazonium tetrafluoroborate (equation 45).

$$NO_2 + BF_3 + \tfrac{1}{2}F_2 \longrightarrow [NO_2]^+[BF_4]^- \quad (43)$$

$$[ClF_6]^+[AsF_6]^- + CsBF_4 \longrightarrow [ClF_6]^+[BF_4]^- + CsAsF_6 \quad (44)$$

$$PhNH_2 \xrightarrow[2.\ HBF_4]{1.\ NaNO_2,\ H^+} [PhN_2]^+[BF_4]^- \xrightarrow{heat} PhF \quad (45)$$

Reaction of BF_3 with B at 1850 °C generates the reactive intermediate species boron monofluoride, BF, which cannot be isolated. Cocondensation of BF with BF_3 yields B_2F_4, a metastable lower fluoride of boron, and BF_2–B(F)–BF_2, which is unstable and disproportionates according to equation (46).[51] Mixtures of boron trihalides undergo exchange reactions, presumably via a four-centered

transition state, to yield the two boron chloride fluorides, for example, as shown in equation (47).

$4(BF_2)_2BF \longrightarrow 2B_2F_4 +$  (46)

$$BCl_3 + BF_3 \rightleftharpoons BFCl_2 + BF_2Cl \quad (47)$$

Heavier halogens such as chlorine and bromine provide their boron trihalides with better complexing ability than BF_3, but their facile hydrolysis makes BF_3 the more effective Lewis acid choice.

5.2 Carbon, Silicon, and Germanium Fluorides and Oxyfluorides

5.2.1 Carbon Fluorides and Oxyfluorides

As a result of the differences in polarity between the carbon–fluorine and the carbon–hydrogen bond, fluorocarbon chemistry is wrought with more differences than similarities to hydrocarbon chemistry despite their similarities in van der Waal's radii (1.20 vs. 1.35 Å). A great body of chemistry for the functionalized fluorocarbons has been developed in the areas of perfluoroalkenes, halofluoroalkanes, ethers, epoxides, peroxides, ketones, acids, and esters.

Fluorocarbons. Fluorocarbons represent a large class of compounds, which could in principle encompass the known variety of hydrocarbon derivatives. For the extensive literature in this area a number of comprehensive works can be consulted.[52–55] The focus of much fluorocarbon chemistry is technically organic chemistry and will not be covered here. The more inorganic aspects of carbon–fluorine chemistry such as the chemistry of simple fluorocarbons, oxyfluorides, and their derivatives will be covered. Trends in reactivity can often be generalized from small molecules to compounds with longer fluoroalkyl chains.

The simplest fluorocarbon, carbon tetrafluoride, CF_4, is an inert gas, bp −128 °C, which is made commercially by direct fluorination of carbon. Carbon tetrafluoride is used in the electronics industry for the purpose of dry etching of silicon.[56]

Among the simple transient species of carbon and fluorine are included: trifluoromethyl cation, CF_3^+, which has a very transient existence; trifluoromethyl anion, CF_3^-, which is stable at low temperature and can be generated from CF_3TMS (trimethylsilyltrifluoromethane); $CF_3\cdot$, a free radical available from irradiation of CF_3I; and difluorocarbene, CF_2:, which exists as a ground-state singlet.

Difluorocarbene can be generated by high-temperature reaction of chlorodifluoromethane in the production of tetrafluoroethylene (TFE) (equation 48). Another method of in situ generation of the carbene is thermal decomposition of hexafluoropropylene oxide (HFPO) (equation 49).

$$CHClF_2 \xrightarrow[0.5\ \text{atm}]{650\,°C} [CF_2] \longrightarrow CF_2{=}CF_2 \quad (48)$$

 $\xrightarrow{160\ °C} CF_3C(O)F + [CF_2]$ (49)

Finally, the trifluoromethyl anion decomposes on warming to give fluoride ion and difluorocarbene if it is not captured by a suitable electrophile.

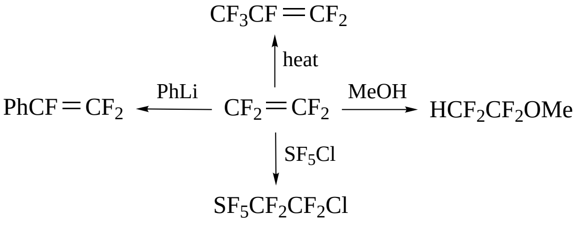
Perfluorination techniques have been developed for the conversion of many hydrocarbons to their perfluorinated counterparts.[57,58] Fluorocarbons are chemically inert because of their kinetically unreactive carbon skeletons and have been considered as blood substitutes because of their high oxygen solubility. The thermal stability and low secondary bond forces of fluorocarbons have contributed to their use as greases, lubricants, and vapor-phase heat transfer reagents.

Perfluoroalkenes are significant industrial starting materials, of which the simplest and most important is TFE. This reactive alkene can be reacted, mainly under free radical or anionic conditions, to yield a variety of saturated addition products (Scheme 1). TFE displays versatile polymerization and copolymerization applications.[59]

Polytetrafluoroethylene (PTFE), better known as Teflon, is the preeminent member of the class of saturated fluoropolymers. Commercial uses span from nonstick cooking appliances to inert surfaces for high-energy oxidizing reactions and compressible, durable vacuum-tight gaskets and fittings. Teflon exhibits high stability and inertness and remains the material of choice for many industrial processes despite somewhat high costs.[60]

Despite the great strength of the C–F bonds, methods have been found for their cleavage. For example, a C–F bond may be protonated and cleaved with iridium compounds[61,62] and vinylic and allylic C–F bonds may be activated by $Cp^*{}_2ZrH_2$.[63]

Graphite Fluorides. Graphite fluorides, made by direct fluorination of graphite at different temperatures, have been characterized for the stoichiometries, $(CF)_n$ and $(C_2F)_n$. For the $(CF)_n$ variety (gray-white) temperatures from 300 to 600 °C are required while the $(C_2F)_n$ variety (black)



Scheme 1 Some reactions of tetrafluoroethylene

requires 350–400 °C. The bonds in these compounds are covalent, making them electrical insulators. The high density of repulsive fluorine lone pairs provides for good lubricating properties. Graphite fluoride and highly reducing lithium are coupled in Li/$(CF)_n$ batteries, where the $(CF)_n$ serves as the cathode in the electrochemical cell.

In a like manner fluorinated carbon nanotubes and fibers can be formed.[64,65] These materials are the subject of a great deal of interest, owing in part to their variable electronic properties.[66]

Fluorohalocarbons. Volatile CFCs like trichlorofluoromethane, $CFCl_3$, and dichlorodifluoromethane, CF_2Cl_2, developed as refrigerants, solvents, and blowing agents, are now being phased out because of deleterious effects to the ozone layer. The problem of ozone depletion has restricted the production of CFCs and turned attention to chlorine-free fluorinated hydrocarbons and ethers as alternative refrigerants. Some halofluorocarbons such as halothane, $CF_3CHClBr$, have found usage as anesthetics. Other halofluorocarbons are manufactured industrially as flame retardants (CF_2ClBr, CF_2BrCF_2Br).

Trifluoroiodomethane (CF_3I) is a critical starting point for synthetic fluorine chemistry. Many trifluoromethyl–element bonds can be achieved from the relatively reactive carbon–iodine bond. Scheme 2 shows some of the range of CF_3I chemistry. The industrial synthesis of CF_3I is based on the Hunsdiecker reaction of the silver salt of trifluoroacetic acid with iodine. Homologous perfluoroalkyl iodides, sources of longer chain perfluoroacid derivatives, can be made by free radical reaction of CF_3I with TFE.

Oxyfluorides of Carbon. The literature on compounds containing only carbon, oxygen, and fluorine is extensive, numerous reviews are available, and many compounds are of industrial importance.[67] Functional groups included under this classification are ketones, acid fluorides, ethers, epoxides, peroxides, and hypofluorites. Only very simple molecules are mentioned here as representatives of this large class of compounds.

The smallest carbon oxyfluoride, carbonyl difluoride, COF_2, can be synthesized from phosgene by metathesis with sodium fluoride or by the direct reaction of carbon monoxide and fluorine in the gas phase. Carbonyl difluoride boils at −83 °C. It reacts readily with nucleophiles with loss of one or two units of fluoride to yield acid fluorides, amides, and esters. A typical fluorinated nucleophile, $(CF_3)_2N^-$, is implicated as an intermediate in the reaction of the perfluoroimine depicted in equation (50).

$$CF_3N{=}CF_2 + COF_2 \xrightarrow{KF} (CF_3)_2N{-}C(O)F \quad (50)$$

The electrophilic nature of COF_2 is beneficial in the reaction of carbonyl difluoride with CsF, which produces trifluoromethyl hypofluorite (CF_3OF) with fluorine and trifluoromethyl hypochlorite (CF_3OCl) with chlorine monofluoride. Both reactions imply the presence of the trifluoromethoxide anion as an intermediate.

A crystal structure of a stable salt of the trifluoromethoxide anion has been made.[68] The preparation involved the use of the stabilizing tris(dimethylamino)sulfonium cation, TAS, as the counterion for CF_3O^-. The reaction is shown in equation (51).

$$COF_2 + [(Me_2N)_3S]^+[SiMe_3F_2]^- \longrightarrow [(Me_2N)_3S]^+[CF_3O]^- + Me_3SiF \quad (51)$$

Perfluoroalkoxide ions are postulated as intermediates in the mechanism leading to the hypohalites from acid fluorides. Generally, organic hypofluorites can be prepared from acid fluorides by the action of metal fluorides and elemental fluorine (equation 52).[69]

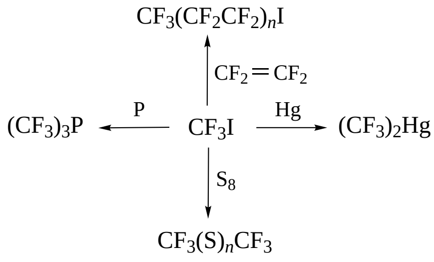
$$R_fCOF + MF \xrightarrow{F_2} R_fCF_2OF \quad (52)$$
$$M = Cs, K$$

Trifluoromethyl hypofluorite, CF_3OF, the first organic hypofluorite, reacts as if the O–F bond is homolyzed to the trifluoromethoxy radical and a fluorine radical in many reactions, but it has been used effectively as a selective electrophilic fluorination reagent in organic chemistry.[70] It has limited selectivity as a fluorination reagent in inorganic chemistry but it can be oxidatively added to numerous compounds.

Trifluoromethyl hypofluorite can be reacted with carbonyl difluoride to yield bis(trifluoromethyl) peroxide, CF_3OOCF_3, a colorless gas, bp −37 °C, which is quite stable up to 220 °C and chemically relatively inert (equation 53). At high temperatures the peroxide appears to be in equilibrium with COF_2 and CF_3OF. The peroxide is best prepared by reaction of CO and F_2 over AgF_2 at ≈220 °C (equation 54).

$$COF_2 + CF_3OF \underset{}{\overset{>220\,^\circ C}{\rightleftharpoons}} CF_3OOCF_3 \quad (53)$$

$$2CO + 3F_2 \xrightarrow[220\,^\circ C]{AgF_2} CF_3OOCF_3 \quad (54)$$



Scheme 2 Some reactions of trifluoromethyl iodide

The reaction of CsF and fluorine with carbon dioxide generates the stable bis-hypofluorite $CF_2(OF)_2$. This remarkable, energetic compound is presumably formed via the intermediacy of the smallest acyl hypofluorite, FC(O)OF, which can itself be prepared by the photochemical fluorination of difluoroformyl peroxide, FC(O)OOC(O)F.

Bis(fluoroxy)difluoromethane reacts with carbonyl difluoride over CsF to yield a bis(trifluoromethyl) trioxide, CF_3OOOCF_3, bp −19 °C, or the peroxy acyl fluoride, $CF_3OOC(O)F$, depending on conditions (equation 55). At low temperature, the trioxide is favored.

$$F_2C(OF)_2 + 2COF_2 \xrightarrow{CsF} CF_3OOOCF_3 + CF_3OOC(O)F + CF_3OF \quad (55)$$

Fluorine and trifluoromethyl groups appear to stabilize oxygen catenation. The trioxide can be approached alternatively by the reaction of oxygen difluoride and carbonyl difluoride over a metal fluoride catalyst.[71] Depending on conditions, the trioxide will be the major product (equations 56 and 57).

$$OF_2 + COF_2 \xrightarrow{CsF} CF_3OOF \quad (56)$$

$$CF_3OOF + COF_2 \xrightarrow{CsF} CF_3OOOCF_3 \quad (57)$$

The trioxide is thermally stable to 70 °C, where it slowly decomposes to CF_3OOCF_3 and oxygen. Many interesting reactions are known for the trioxide involving oxidative additions of both CF_3O and CF_3OO moieties to various substrates.[72]
